Abstracts

33rd Annual Meeting of the
European Society of
Human Reproduction and Embryology,
Geneva, Switzerland
2 to 5 July 2017

The abstracts are available on-line to all Human Reproduction/Update/Molecular Human Reproduction subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals. org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference.

The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers.

Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results.

The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers, but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

ESHRE COMMITTEES

Executive Committee (2015–2017)
Chair
Kersti Lundin (Göteborg, Sweden)

Chair-elect
Roy Farquharson (Liverpool, United Kingdom)

Study question: Could cell therapy using autologous peripheral blood CD133+ bone marrow-derived stem cells (BMDSCs) offer a safe and efficient therapeutic approach for patients with refractory Asherman's syndrome (AS) and/or endometrial atrophy (EA) and a wish to conceive?

Summary answer: In the first 3 months, autologous cell therapy, using CD133+ BMDSCs in conjunction with hormonal replacement therapy, increased the volume and duration of menses as well as the thickness and angiogenesis processes of the endometrium while decreasing intrauterine adhesion scores.

What is known already: Asherman's syndrome (AS) is characterized by the presence of intrauterine adhesions and endometrial atrophy (EA) prevents the endometrium from growing thicker than 5 mm, resulting in menstruation disorders and infertility. Many therapies have been attempted for these conditions, but none have proved effective.

Study design, size, duration: This was a prospective, experimental, non-controlled study. There were 18 patients aged 30–45 years with refractory AS or EA recruited, and 16 of these completed the study. Medical history, physical examination, endometrial thickness, intrauterine adhesion score and neoangiogenesis were assessed before and 3 and 6 months after cell therapy.

Participants/materials, setting, methods: After the initial hysteroscopic diagnosis, BMDSC mobilization was performed by granulocyte-CSF injection, then CD133+ cells were isolated through peripheral blood aphaeresis to obtain a mean of 124.39 million cells (range 42–236),which were immediately delivered into the spiral arterioles by catheterization. Subsequently, endometrial

treatment after stem cell therapy was assessed in terms of restoration of menses, endometrial thickness (by vaginal ultrasound), adhesion score (by hysteroscopy), neoangiogenesis and ongoing pregnancy rate. The study was conducted at Hospital Clinico Universitario of Valencia and IVI Valencia (Spain).

Main results and the role of chance: All 11 AS patients exhibited an improved uterine cavity 2 months after stem cell therapy. Endometrial thickness increased from an average of 4.3 mm (range 2.7–5) to 6.7 mm (range 3.1–12) (P = 0.004). Similarly, four of the five EA patients experienced an improved endometrial cavity, and endometrial thickness increased from 4.2 mm (range 2.7–5) to 5.7 mm (range 5–12)(P = 0.03). The beneficial effects of the cell therapy increased the mature vessel density and the duration and intensity of menses in the first 3 months, with a return to the initial levels 6 months after the treatment. Three patients became pregnant spontaneously, resulting in two babies born, and a miscarriage. Furthermore, seven pregnancies were obtained after fourteen embryo transfers, resulting in three biochemical pregnancies, one miscarriage, one ectopic pregnancy, and two babies born.

Limitations, reasons for caution: Limitations of this pilot study include the small sample size and the lack of control group. It is consider as a phase I study for this advance cell therapy

Wider implications of the findings: This novel autologous cell therapy is a promising therapeutic option for patients with these incurable pathologies and a wish to conceive

Study funding/competing interest(s): This study was funded by the Spanish Ministry of Science and Innovation (SAF 2012–31017, Principal Investigator C.S.), Spanish Ministry of Health (EC11-299, Principal Investigator C.S.) and Regional Valencian Ministry of Education (PROMETEOII/2013/018, Principal Investigator C.S.). Four authors (X.S., I.C., A.P. and C.S.) are co-inventors of the patent resulting from this work (Application number: 62/013,121). S.C., C.A., F.R., J.F., J.P. and J.R. have in relation to this work.

Trial registration number: This study was approved by the Ethical Committee at the Hospital Clinico Universitario, Valencia, Spain and was registered with ClinicalTrials.gov (NCT02144987).

O-002   Non-invasive prenatal testing (NIPT) - state of the art

Y.M.D. Lo[1]

[1]The Chinese University of Hong Kong, Li Ka Shing Institute of Health Sciences Prince of Wales Hospital, Shatin- New Territories, Hong Kong

Abstract text

We explored the limit of noninvasive prenatal testing (NIPT) by sequencing the plasma DNA of a pregnant woman to 270X haploid genome coverage. This sequencing depth represents the deepest that any case has been sequenced to date. By using such a depth of sequencing and a custom-built bioinformatics pipeline, we were able to detect fetal de novo mutations on a genomewide level at a sensitivity of 85% and a positive predictive value of 74%. These results indicate that we have solved a hitherto unsolved challenge in NIPT. Furthermore, we have shown that at such a depth of sequencing, we were also able to elucidate the maternal inheritance of the fetus without using haplotype-based approaches. This development has allowed us to increase the resolution of determining the maternal inheritance of the fetus by 90-fold. Furthermore, we have observed that there are recurrent DNA sites that plasma DNA molecules tend to preferentially end on. We called such positions "preferred DNA ends". Interestingly, circulating DNA fragments derived from the fetus and

those derived from the pregnant woman have sets of different preferred ends. This development allows one to predict the likelihood that a plasma DNA fragment is of fetal or maternal origin without using DNA polymorphisms. This approach also allows one to estimate the fetal DNA fraction without using DNA polymorphisms or size analysis. We believe that such 'second generation noninvasive fetal genomics' would have many exciting diagnostic applications and may facilitate an increased understanding of the biology of circulating DNA.

O-003   Influence of opening the incubator on morphokinetics in mouse embryos

Q. Nguyen[1], S. Sommer[1], C. Wrenzycki[2], U. Wagner[3], V. Ziller[1]

[1]University Hospital Giessen and Marburg, Department of Gyn. Endocrinology and Reproductive Medicine, Marburg, Germany
[2]Justus-Liebig-University, Clinic for Veterinary Obstetrics- Gynecology and Andrology- Chair for Molecular Reproductive Medicine, Giessen, Germany
[3]Unversity Hospital Giessen and Marburg, Department of Gyn. Endocrinology and Reproductive Medicine, Marburg, Germany

Study question: Does the twice daily opening of the incubator door for 10 seconds affect mouse embryo development, cleavage, blastocyst formation and morphokinetic analysis of cell division compared to undisturbed culture?

Summary answer: This study underlines the importance of culture conditions as small and brief changes through simple door openings lead to significant changes in morphokinetics.

What is known already: It has been well established that using time lapse systems lead to increases in pregnancy rates. It remains yet an open question whether this is due to improved selection or to stable and undisturbed culture conditions. In standard laboratory practices incubators are opened and embryos removed from the incubator to assess cleavage and morphology once a day. During embryo manipulation and monitoring, both temperature and pH of the medium change slightly. Stress is thereby not only exposed sequentially to the removed embryos, it also affects the embryos cultured in the same incubator.

Study design, size, duration: To mimic laboratory practice and to evaluate minimal changes in culture conditions we designed a randomized parallel group study employing mouse embryos. 176 zygotes were arranged randomly in control and intervention group. The control group was cultured in an incubator that was completely closed for 5 days, while the intervention group was interfered by two door openings of 10 seconds per day. Environmental factors and morphokinetic analysis of cell division were recorded via a Primovision-System.

Participants/materials, setting, methods: Hybrid Bl6/CBAca mouse embryo assay (MEA) was used to identify morphokinetic cleavage parameters derived from time-lapse imaging. Female mice were sacrificed and zygotes were isolated 20 hours post-insemination. Zygotes were cultured in Primovision micro well group culture dishes with GTL Medium (Vitrolife). Zygotes were observed in the Primovision time lapse system that integrates a digital inverted microscope into a standard Memmert IVF incubator. Pictures of embryos were taken at 10 minute intervals for 5 days.

Main results and the role of chance: Zygotes did not significantly differ in baseline characteristics as age of parents, number of cells derived per mouse, procedures or media.

There was no significant difference in blastocyst rate (86,7% and 88,2%) and blastocyst size (104 and 103 mm) between control and intervention Group. The embryos in the intervention group showed significantly quicker development. They reached 3-cells stage at 1898 versus 2025 minutes, p = 0.002; 5-cells stage at 2637 versus 2833 minutes, p = 0.002; morula stage at 3247 versus 3557 minutes, p = 0.001, blastocyst stage at 4464 versus 4692 minutes, p < 0.001 and hatching at 4960 versus 5250 minutes, p < 0.001 comparing to control group.

Limitations, reasons for caution: The present study used surrogate parameters as morphokinectics and blastocyst rates. No data on pregnancy or birth rates can be provided as blastocysts were not transferred. The results may differ in different laboratory settings as type of incubator and laboratory procedures may also have significant impact on embryo development.

Wider implications of the findings: The findings underline the importance of further evaluation of culture conditions in IVF. As even small and short environmental changes can significantly impact the characteristics of development, the evaluation of time lapse parameters as morphokinetics in this context may further improve our understanding of these factors.

Trial registration number: N/A.

O-004   Image analysis of human embryos grown in vitro as a new non-invasive tool to determine embryo health

A. Leida Mölder[1], G. Hartshorne[2], S. Czanner[1], N. Costen[1], S. Drury[3]

[1]Manchester Metropolitan University, School of Computing- Mathematics and Digital Technology, Manchester, United Kingdom
[2]University Hospitals Coventry and Warwickshire NHS Trust, Centre for Reproductive Medicine, Coventry, United Kingdom
[3]Centre for Reproductive Medicine, University Hospitals Coventry and Warwickshire NHS Trust, Coventry, United Kingdom

Study question: Which embryo criteria have the most potential for automatic monitoring and embryo quality assessment using images captured during embryo growth in vitro?

Summary answer: Detection of syngami, timing of mitosis, blastocyst formation and blastomere number are quantifiable attributes. Embryo activity and fragmentation are also detectable but not quantifiable.

What is known already: Non-invasive imaging has recently made it possible to monitor embryos continuously without any known consequences to their health. It has been shown that the timing of key occurrences within the embryo can vary greatly between embryos that have similar morphological appearance at the conclusion of the recording period and that embryo morphology can change in a matter of hours, emphasizing the fact that dynamic monitoring is preferred over intermittent monitoring of embryos. Dynamic monitoring of embryos requires computerized analysis but few studies have systematically attempted to map automatically extracted embryo imaging criteria to manual detection of the same.

Study design, size, duration: Time lapse image series of human embryos fertilized *in vitro* were acquired as anonymized sequences donated to research with ethical approval. Images were analysed for a number of embryo trait known to correlate with embryo health. Results from computerised analysis were compared to manual detection of the same trait. The study consisted of seven studies performed on the same imaging material over a course of three years.

Participants/materials, setting, methods: Embryos were cultured in 25 μl culture media (Origio, Redhill, UK) under mineral oil for up to 6 days, incubated at 37°C in an atmosphere of 5%CO_2, 5%O_2 and 90%N_2. The images were captured using the Embryoscope® time-lapse system (Vitrolife, Gothenburg, Sweden), with 9 focal depth planes, 15–25 μm apart, recorded at 20 minute intervals using a HMC optical set up and a 635 nm LED as light source. Images were analyzed using Matlab® 7.12.0.635 (R2011a).

Main results and the role of chance: Detection accuracy of of syngami was 83%, timing of mitosis 80.8% (1–6 cells), blastocyst formation 71.8% and blastomere number 80.8% (1–6 cells). Using the timing information, it was possible to measure the time elapsed between divisions to 10.27 h (2–3 cells), and 1.11 h (3–4 cells), respectively. Detection accuracy for mitosis reduced by cell number. 100% of divisions from 1 to 2 cells were detected, 73% from 2 to 3 (or 4) cells, 30% from 3 to 4 cells, and 59% from 4 to 5 (or 6) cells. Using the timing of blastocyst and morula formation, we calculated the duration of the morula stage to 1/7 of the duration of the cleavage stage, with some patient variability. Embryo activity and fragmentation were detectable in images but the accuracy not quantifiable, due to the lack of a standardized way to measure these traits manually. The automatic counting of blastomere number was semiautomatic and required manual selection of typical images prior to analysis. The

counting was tested up to the 8 cell stage, in which case the accuracy was 74.9%. The accuracy was less than for other imaging techniques, e.g. using fluorescent markers.

Limitations, reasons for caution: Images were obtained from a range of microscopy settings using different protocols for embryo cultivation and different lighting conditions in the microscopy. However, the study cohort was small (38 embryos from 7 patients from 3 laboratory settings at the largest).

Wider implications of the findings: Continuous imaging of human embryos growing in vitro is being routinely generated as part of IVF cultivation. The material poses a method to study dynamic properties of embryos without having to result to experimentation on human tissue and has the possibility to provide new methods to improve IVF success rates.

Trial registration number: Ethical approval by Coventry Research Ethics Committee (04/Q2802/26) and the Human Fertilisation and Embryology Authority (R0155).

O-005   Study of embryo surface variation and contraction pattern as potential predictors of embryo chromosomal content

X. Viñals[1], X. Mania[1], A. Doshi[1], K. Loutradi[1], V. Seshadri[2], P. Serhal[2]

[1]The Centre For Reproductive and Genetic Health, Embryology, London, United Kingdom
[2]The Centre For Reproductive and Genetic Health, Clinical, London, United Kingdom

Study question: Do embryo contraction behaviour and surface variation have a predictive value on embryo chromosomal content?

Summary answer: Blastocyst contraction pattern shows to be related to embryo chromosomal content.

What is known already: Time-Lapse monitoring (TLM) together with next-generation sequencing (NGS) are considered to be two main techniques for selecting the embryos with the potential to result in a healthy pregnancy. Together with morphology based criteria, many selection parameters for embryonic competence based on TLM have emerged to refine this selection process. First reported by Lewis and Gregory in 1929, blastocyst contractions during blastulation were first related to the ability for an embryo to hatch. Other studies reported a reduced implantation and live birth rates in embryos presenting contractions. The physiological role and the cause for this phenomenon remains to be fully understood.

Study design, size, duration: 141 good quality blastocysts generated after ICSI or IMSI between January 2016 to January 2017, derived from 46 patients (mean age 38.6 (SD 2.3) years), were included in the study. Two different outcomes were considered after the NGS testing (Normal and Abnormal) in this retrospective study of TLM embryos after day 5/6 blastocyst biopsy.

Participants/materials, setting, methods: Different morphokinetic parameters were assessed together with some contraction pattern variables in the different groups. Embryo contraction was defined as the event during blastulation where the perivitelline space is observed by retraction of trophectoderm cells. Surface variation was determined with EmbryoViewer software measuring tools. Univariable and Multivariable Analysis of the data was performed using STATA software, considering that one or more embryos belonged to the same patient (random effect analysis).

Main results and the role of chance: A total of 104/141 (73.8%) blastocysts were proven to be chromosomally abnormal (not mosaic) while 37/141 were chromosomally normal embryos (29.2%). A total of 77 blastocysts presented contractions (54.6%), of these 26 presented more than one contraction during development (18.4%). Data analysis shows no statistical significance on the total number of contractions between both groups. Univariable logistic regression analyses showed significance in time of first contraction (Tc1), surface loss in first contraction (loss1) and Surface Gain after Blastulation (Gain) at the 5% level between both groups. Followed by a multivariable logistic regression analysis only tc1 and loss1 showed significance at the 5% level. Our data suggests that a unit increase of time of Tc1 and loss1 reduces the odds of a Normal genetic result by about 16% and 31%, respectively after adjusting for the other variables in the model.

Limitations, reasons for caution: Larger studies with an increased number of embryos are needed to confirm our findings.

Wider implications of the findings: According to our results we could suggest that blastocyst contraction pattern could possible be used as a potential predictor of embryo chromosomal content. Surface measurements during blastulation could be an extra check-point on embryo quality.

Trial registration number: N/A.

O-006   Oliana Strings: Perivitelline threads that originate from corona radiata cells and cause fragmentation in human embryos

O. Oliana Membrado[1], R. Derrick[2], C. Hickman[3], T. Wilkinson[1], D. Gwinnett[1], R. Fawthrop[1], A. Carby[4], S. Lavery[5]

[1]Boston Place Clinic, Embryology, London, United Kingdom
[2]Imperial College London, Medicine, London, United Kingdom
[3]Boston Place Clinic- Imperial College London, Embryology, London, United Kingdom
[4]Boston Place Clinic, Clinical, London, United Kingdom
[5]The Fertility Partnership, Clinical, London, United Kingdom

Study question: Where do Oliana Strings (OS) originate from? What is their function? Do OS affect ploidy or implantation potential?

Summary answer: OS are observed in most embryos, originate from corona-radiata, are mostly visible at 2-cell stage, significantly correlate with fragmentation but not with ploidy or implantation.

What is known already: Embryoscope Plus optics has improved the visibility of certain embryonic structures. OS are amongst the structures which have become more clearly visible with this type of incubator. OS are defined as thin filaments that extend across the perivitelline space connecting the zona pellucida with the oogenic. OS were first described by our group at Fertility 2017 conference in Edinburgh. This abstract presents further work conducted by our group to clarify the origin and role of OS in early embryo development.

Study design, size, duration: Retrospective assessment of time-lapse imagery from 525 human embryos cultured for clinical IVF treatment. The assessor was blinded to ploidy and implantation potential.

Participants/materials, setting, methods: Time-lapse videos were reviewed for the presence of OS, the cell stage when OS were first observed, association with fragmentation, ploidy or implantation potential. ICSI videos were also reviewed to determine the origin of OS.

Main results and the role of chance: OS were observed in the majority (77%,404/525) of embryos. There was no difference in incidence of OS in embryos that were euploid (78%,61/78) versus aneuploid (83%,91/109); or those that implanted (73%,64/88) versus those that did not (75%,195/261). In the embryos where OS were observed, 98%(396/404) were first observed at the two-cell stage. OS were observed to directly pull fragments from the embryo in most embryos (95%, 384/404). Fragmentation occurred significantly less frequently in embryos without OS (67%,81/121;p < 0.001). ICSI videos demonstrated string-like structures extending from corona cells, through the zona, interacting with the oolemma through perivitelline debris.

Limitations, reasons for caution: It is expected that the true incidence of OS be higher than observed given that embryos could not be rotated within the time-lapse incubator and OS may have occurred outside the view of the seven focal planes, or may have been smaller than detectable by the resolution of the images.

Wider implications of the findings: This data suggests that OS may be a cause of fragmentation, although the high incidence of fragmentation in string-free embryos suggests OS are not essential for fragmentation to occur. OS may be useful in differentiating between fragments and cells.

Trial registration number: not applicable.

O-007   Does the extent of blastocyst hatching at time of trophectoderm biopsy affect PGD clinical outcome?

Y. Dajani, M. Elshahidy, T. El-Toukhy, Y. Khalaf, V. Bolton

Guy's and St. Thomas' hospital, Assisted Conception Unit, London, United Kingdom

Study question: Does the extent of blastocyst hatching at time of trophectoderm biopsy (TB) affect PGD clinical outcome?

Summary answer: Implantation of fully hatched blastocysts is significantly reduced compared to hatching blastocysts following TB and vitrification for PGD.

What is known already: High rates of survival and implantation have been reported after blastocyst biopsy and vitrification for PGD (Galn et al. 2003; Van Landuyt et al. 2010). The effect of TB for PGD at different degrees of blastocyst hatching followed by vitrification on blastocyst implantation potential has not been adequately explored. Data investigating the fate of vitrified blastocysts at different stages of hatching are limited (Zech et al. 2005).

Study design, size, duration: Retrospective analysis was undertaken for all PGD cycles that took place between January 2014 and June 2016. Following zona ablation on day 3, trophectoderm cells were biopsied from hatching and fully hatched blastocysts on day 5/6; biopsied blastocysts were vitrified. Genetically suitable embryos were warmed and transferred individually. Implantation rates were compared for blastocysts biopsied at different stages of hatching (Group A: < 50% hatched; Group B: ≥50% hatched; Group C: fully hatched).

Participants/materials, setting, methods: Following ICSI, pronucleate stage embryos were cultured in single-step medium (SAGE; Origio, USA) and incubated in Embryoscope incubators (Unisense-FertiliTech, Denmark) in $5\%O_2:6\%CO_2:89\%N_2$. After laser-assisted zona ablation on day 3, 5–10 trophectoderm cells were biopsied on day 5/6 followed by vitrification (Cryotop/Kitazato; Dibimed, Japan); genetically suitable embryos were warmed and transferred individually. Retrospective scoring of herniation/hatching prior to biopsy was carried out by a single, independent operator using time-lapse images.

Main results and the role of chance: The mean age of participants, number of PGD cycles, eggs collected and fertilised normally, and type of genetic test (aCGH or PGH) were not significantly different between the three groups (p > 0.05). From 407 egg collection/PGD cycles, 614 embryos were warmed for 340 patients, resulting in 542 single embryo transfers (overall survival rate 88% [542/614]). Survival and implantation rates (SR, IR) per embryo were not statistically different between Groups A and B (90% [393/438] vs 88% [127/145]; p = 0.54, and 41% [179/438] vs 32% [47/145]; p = 0.08 respectively), but were significantly lower in Group C compared to both Group A (71% [22/31]; p = 0.005 vs 19% [6/31]; p = 0.02 respectively). The clinical pregnancy rates (CPR) per transfer for Groups A, B and C were 42% [164/393], 35% [45/127] and 18% [4/22] respectively. There was no significant difference between Groups A and B; p = 0.21, but CPR was significantly reduced in Group C compared to Group A; p = 0.04. The mean interval between the time of ICSI and the time of TB, as evaluated from time-lapse images, was 123.7hrs (Group A; n = 438), 128.7hrs (Group B; n = 145) and 136.5hrs (Group C; n = 31).

Limitations, reasons for caution: This is retrospective study; the number of embryos in Group C is relatively small; the impact of additional morphological and morphokinetic differences between embryos have not been evaluated.

Wider implications of the findings: In order to maximise implantation and clinical pregnancy rates, TB for PGD/PGS should be carried out before the blastocyst hatches fully. This finding has important implications for the management and scheduling of egg collection, ICSI and TB procedures for PGD/PGS cases.

Trial registration number: N.A.

O-008   Complete zona pellucida removal facilitates embryo attachment and outgrowth by upregulating the integrin α5 and β1 expression in human blastocysts: in vitro outgrowth model

K. Ezoe[1], S. Ueno[2], A. Yabuuchi[1], K. Uchiyama[2], T. Okimura[2], T. Kobayashi[3], K. Kato[3]

[1]Kato Ladies Clinic, R&D Division, Tokyo, Japan
[2]Kato Ladies Clinic, Embryology Laboratory, Tokyo, Japan
[3]Kato Ladies Clinic, Department of Gynecology, Tokyo, Japan

Study question: Does complete removal of the zona pellucida (ZP) as a method of assisted hatching improve the adhesion and outgrowth of vitrified-warmed human blastocysts?

Summary answer: Complete ZP removal increases the chance of blastocyst adhesion and promotes subsequent outgrowth by upregulating the integrin α5 and β1 expression after the vitrification-warming procedure.

What is known already: Laser-assisted hatching (LAH) has become the primary assisted hatching method used in many IVF laboratories. Generally, in LAH method, ZP is partially removed using laser system. However, in some cases, low-viability blastocysts cannot hatch even after partial ZP removal. Furthermore, escaping through the assisted hatching holes still requires a considerable energy-consuming effort from blastocysts and cause a marked distortion of their shape. Binding of cells to fibronectin is mediated through fibronectin receptor, Integrin heterodimer α5β1. In addition, human blastocysts express integrin α5 and β1 mRNA during the process of implantation.

Study design, size, duration: A total of 217 discarded cryopreserved human blastocysts donated for research by consenting couples (Woman's age: 35.4 ± 0.3 years, Blastocyst morphology: 3CC or greater) were warmed and subjected to assisted hatching to remove the ZP partially (n = 79) or completely (n = 79), or did not undergo assisted hatching (ZP intact controls, n = 59). Blastocyst adhesion rate, outgrowth speed and mRNA expression level of integrin α5β1 after plating on fibronectin coated dish were compared among the groups.

Participants/materials, setting, methods: Human blastocysts were warmed using the Cryotop[R] method. Laser drilling was performed to remove 30–40% of ZP of blastocysts (Partial ZP removal). Subsequently, the blastocyst was gently denuded of ZP by pipetting (Complete ZP removal). These blastocysts were plated on fibronectin-coated dish and cultured for 96 hours in time-lapse incubator to monitor hatching, adhesion and outgrowth. qRT-PCR assay was performed to measure mRNA expression of integrin α5 and β1 in blastocysts during in vitro outgrowth.

Main results and the role of chance: Blastocyst hatching rate was improved by partial ZP removal group (64%, 32/50) compared with ZP intact group (10%, 3/30), still, 34% (18/50) blastocysts in the partial ZP removal group failed to hatch despite assisted hatching treatment. The blastocyst adhesion was initiated earlier in complete ZP removal group compared with the other groups. The blastocyst adhesion rate at 96 hours after the culture was significantly higher in complete ZP removal group (80.0%, 40/50) than in partial ZP removal (60%, 30/50) and ZP intact group (10%, 3/30). The outgrowth speed of the ZP intact, partial removal and complete removal groups were 2.4×10^3 µm²/h, 4.7×10^3 µm²/h and 5.8×10^3 µm²/h, respectively and complete removal group tended to show faster outgrowth. The expression levels of integrin α5 and β1 at 24 hours after plating in complete ZP removal group were significantly higher than ZP intact and partial ZP removal groups (complete ZP removal: 1.9 ± 0.3 and 3.1 ± 0.4, ZP intact:1.0 ± 0.2 and 1.0 ± 0.2 and partial ZP removal: 1.1 ± 0.5 and 1.5 ± 0.4).

Limitations, reasons for caution: The use of the in vitro blastocyst outgrowth assay was a weakness in this study since hatching process may vary between in-vitro and in-vivo conditions. Therefore, further clinical studies are required to explore the clinical efficacy of the complete ZP removal.

Wider implications of the findings: The complete ZP removal as an assisted hatching method prevents hatching failure and is advantageous for blastocyst adhesion and its outgrowth as assessed in an in-vitro model. Therefore, when a blastocyst is chosen for vitrified-warmed blastocyst transfer, complete ZP removal may help to increase the chance of blastocyst attachment.

O-009   Ovarian stimulation in IUI cycles in couples with unexplained subfertility: follicle stimulating hormone (FSH) or clomiphene citrate (CC)?

ABSTRACT UNDER PRESS EMBARGO

What is known already: There are only two published randomised controlled trials (RCT) of IUI with and without stimulation compared with no treatment. In one trial the IUI did not include ovarian stimulation. In the other trial the IUI included gonadotropin stimulation and patients had a favourable probability of natural pregnancy in the next 12 months between 30 and 40%. Neither trial suggested benefit. In 2013 NICE Fertility guidelines recommended that intrauterine insemination should not be routinely offered, with or without ovarian stimulation for couples with unexplained infertility. In spite of this recommendation many UK clinics still offer IUI. 100/95

Study design, size, duration: A RCT of three cycles of IUI-C compared with three cycles of EM in couples with unexplained infertility. Computer generated randomized numbers in sequentially numbered opaque sealed envelopes were opened by a third party study coordinator after consent signed. We needed to include 90 women in each arm to demonstrate an increase from the predicted 8% to 22% in LBR (80% power, 5% level).

Participants/materials, setting, methods: From March 2013 - May 2016, 201 couples with unexplained infertility were recruited from two fertility clinics. Inclusion criteria were ovulatory women with patent tubes, partners with normal semen analysis (>15 mil/l, motility > 32%) and probability of natural pregnancy in the next 12 months <30%. 101 couples were allocated to three cycles of IUI-C and 100 couples were allocated to three cycles of expectant management. The couples with expectant management completed a diary recording sexual activity.

Main results and the role of chance: IUI: 31 live births includes 3 LB who were pregnant at study entry and 5 LB that occurred prior to or between IUI cycles

EM: 9 LB including 1 who was pregnant from IUI at study entry and 1 from IVF.

Two ectopic pregnancies and two multiple pregnancies were reported in the IUI group and one stillbirth at 20 weeks gestation was reported in the EM group.

Using an intention to treat analysis for live births (LB):

IUI-C was associated with an increase in CLBR compared to EM group (31 of 101 [31%] vs. 9 of 100 [9%], $P = 0.0003$; risk ratio (RR) for cumulative live birth, 3.41; 95% confidence interval (CI), 1.71 to 6.79)). There were two sets of twins, both in the IUI-CC group (one from a cancelled cycle for overresponse).

Using a per protocol analysis for LB: excluding treatment protocol violations, the cumulative live birth rate was 22/85 (25.6%) with IUI-C and 6/88 (6.8%) with EM and the RR was 3.80, 95% CI, 1.62 to 8.90) ($P = 0.005$).

Number needed to treat: Five women (95% CI, 3–12) would need to undergo 3 cycles of IUI-C for one additional live birth.

Limitations, reasons for caution: Protocol breaches included 5 women who conceived before and between IUI-C cycles, 5 women in the EM group who had IUI or IVF (two conceived), and 8 women in each group who had prediction scores > 30% and in both groups 2 conceived. In addition, three women conceived on CC without undergoing insemination.

Wider implications of the findings: Intrauterine insemination is associated with a three-fold increase in live birth rate when compared to EM. IUI-C may be offered to couples with unexplained infertility as a safe and effective treatment.

Trial registration number: U1111-1134–9722 24/09/2012.

O-011   Intrauterine insemination: does timing matter? A multicenter randomised controlled trial

Study question: Does the ongoing pregnancy rate differ between intrauterine insemination (IUI) at the moment of ovulation triggering ('immediate IUI") and IUI performed 32–36 hours after that ('traditional IUI")?

O-010   A randomized controlled trial of intrauterine insemination with clomiphene citrate stimulation compared with expectant management for women with unexplained infertility (The TUI study)

[1]University of Auckland, Auckland, New Zealand
[2]Fertility Plus, Auckland, New Zealand

Study question: Does 3 cycles of IUI with clomiphene (IUI-C) increase cumulative livebirth rates (CLBR) versus 3 cycles of expectant management (EM) in couples with unexplained infertility.

Summary answer: LBR was increased following 3 cycles of IUI-C compared with three cycles of EM in couples with unexplained infertility with low probability of natural pregnancy in next 12 months.

Summary answer: Immediate IUI, at the moment of human chorionic gonadotropin (hCG), results in an ongoing pregnancy rate that is not significantly different from traditional IUI.

What is known already: IUI is a widely used treatment for couples with unexplained and mild male factor subfertility. Although IUI is a common treatment, its timing is poorly investigated and is usually performed 32–36 hours after hCG. The largest probability of pregnancy in natural cycles, however, occurs with intercourse one day before ovulation, with chances rapidly decreasing thereafter. Järvelä et al (2010), showed significantly higher pregnancy rates when IUI was performed immediately after hCG (19.6%) in comparison to 24–36 hours after hCG (10.9%). Aydin et al (2013) however did not show any difference in clinical pregnancy rates between the two groups

Study design, size, duration: Between February 2013 en July 2016 we conducted an open-label randomized controlled trial in seven Dutch fertility clinics. We included 165 couples for immediate IUI and 207 couples for traditional IUI.

Participants/materials, setting, methods: Ovarian Stimulation (OS) was performed by subcutaneous FSH (according to local protocol and in a personalized dosage), starting between cycle day three and five. The 'Immediate IUI" group had IUI the day after the largest follicle had reached 16–18 mm, immediately followed by administration of hCG for triggering ovulation. The"Traditional IUI" group received care as usual, namely hCG for triggering ovulation when the largest follicle reached 16–18 mm, followed by IUI 32–36 hours later.

Main results and the role of chance: After randomisation six couples did not start with IUI-OS treatment (five because of spontaneous pregnancy before the start of IUI-OS and one started with another fertility treatment). In total 163 couples (immediate IUI) and 205 couples (traditional IUI) started IUI-OS treatment. We did not receive information about three couples (one in the immediate IUI group and two in the traditional IUI group).

The groups did not show any difference in BMI, age, type of subfertility (primary versus secondary subfertility (respectively 69.3% versus 30.6 % in the immediate IUI group and 64.4% versus 35,6% in the traditional IUI group), indications for IUI, semen analysis outcome or number of follicles (average 1,34 in the immediate IUI group and 1,31 in the traditional IUI group).

After one cycle, there was no difference in ongoing pregnancy rate: 6.79% (11/162) in the immediate IUI group and 7.88% (16/203) in the traditional IUI group yielding a relative risk of 0.86 (95% confidence interval 0.41–1.80).

Limitations, reasons for caution: This study compared two timing strategies for IUI: IUI immediately followed by hCG-triggering versus traditional timing, 32–36 hours after hCG triggering. We cannot say anything about the chances of ongoing pregnancy with other timing strategies.

Wider implications of the findings: We did not find any difference in ongoing pregnancy rate between the two different timing strategies. Our findings imply that scheduling IUI relatively to the hCG trigger in everyday practice can be more flexible.

Trial registration number: Portal ToetsingOnline Kenmerk: NL39738.068.12, approval October 31st 2012.

O-012   Anovulatory women not conceiving after six ovulatory cycles with clomiphene citrate – should we switch to gonadotrophins and/or add IUI? A 2 by2 factorial RCT

[10]The Robinson Institute- University of Adelaide, School of Paediatrics and Reproductive Health, Adelaide, Australia

Study question: What is the effectiveness of extended treatment with clomiphene (CC) compared with FSH and what is the additional value of IUI in women who had six ovulatory cycles after CC?

Summary answer: Extended ovulation induction with CC resulted in less ongoing pregnancies compared to FSH, while addition of IUI had no impact on ongoing pregnancy chances

What is known already: CC is a first line treatment in women with World Health Organization (WHO) type II anovulation and polycystic ovary syndrome (PCOS). If women ovulate but do not conceive after several cycles CC, medication is usually switched to FSH with or without IUI. At present, it is unclear whether such a switch to ovulation induction with gonadotropins with or without IUI is effective

Study design, size, duration: We performed a 2 by 2 factorial multicenter RCT in the Netherlands from November 2008 until November 2015. The study aimed to compare CC and FSH and IUI with no IUI in a superiority design. The data safety monitoring board reviewed the data after inclusion of 320 women and advised to include at least 600 women

Participants/materials, setting, methods: We included women with WHO type II anovulation who had been ovulatory for six cycles CC without conception. Women were randomly allocated in a factorial design to receive ovulation induction with CC or FSH with IUI or intercourse for six cycles. Women were treated for six cycles or until an ongoing pregnancy occurred. Primary outcome was live birth rate at 12 weeks gestation within eight months after randomisation. Primary analysis was by intention to treat

Main results and the role of chance: We randomised 666 women to CC (N = 173), CC plus IUI (N = 162), FSH (N = 165), or FSH plus IUI (N = 166). Included women were on average 29 years old with a BMI of 25. At the moment of writing this abstract, the ongoing pregnancy data for 95% of the couples was known. For the comparison of CC with FSH the ongoing pregnancy rates were 42% for CC and 53% for FSH (relative risk (RR) of 0.79 (95%CI: 0.68–0.92)). For the comparison IUI to no IUI the ongoing pregnancy rates were 49% for IUI and 45% for no IUI (RR 1.08 (95%CI: 0.93–1.26)). There were 7 multiple pregnancies following CC and 7 multiple pregnancies following FSH. There were 9 multiple pregnancies following IUI and 5 multiple pregnancies following no IUI. Average time leading to an ongoing pregnancy was 4.6 months following CC and 4.2 months following FSH. Average time leading to an ongoing pregnancy was 4.3 months with IUI and 4.5 months without IUI

Limitations, reasons for caution: These results are based on 95% of the data, while data on live birth are currently being collected.

Reason for caution is that a cost-effectiveness has not been done as of yet. This will decide the ultimate interpretation of the data

Wider implications of the findings: These preliminary results suggest that in type II anovulatory women with CC failure, a switch to FSH slightly increases ongoing pregnancy chances over a 42% with CC alone. Addition of IUI is not useful in these women.

[3]Faculty of Health- Aarhus University and Faculty of Health- University of Southern Denmark, The Fertility Clinic- Skive Regional Hospital, Aarhus, Denmark

Study question: Does administration of corifollitropin alfa followed by hp-HMG result in higher ongoing pregnancy rates compared with daily recombinant FSH in young Bologna poor responders?

Summary answer: Corifollitropin alfa followed by hp-HMG does not increase ongoing pregnancy rates compared with rFSH in young poor responders. However, more supernumerary cryopreserved embryos are obtained.

What is known already: Poor ovarian response (POR) remains one of the main therapeutic challenges in women undergoing ovarian stimulation, given that very low live birth rates of 6% have been reported in this special group of infertile patients. Nevertheless, concerns have been raised that a degree of heterogeneity remains, as the prognostic effect of individual factors is still unclear, particularly for the young poor responder group. The rationale for conducting the current randomized trial lies to a previous pilot study demonstrating promising results with the administration of hp-HMG following corifollitropin alpha in women less than 40 years of age, fulfilling the "Bologna" criteria.

Study design, size, duration: This is a multicenter, phase III superiority randomized trial using a parallel two –arm design. The study included 152 patients <40 years old, fulfilling the "Bologna" criteria for POR from 1 tertiary referral center in Europe and 1 tertiary referral center in Asia, who underwent ovarian stimulation for ICSI from March 2013 to May 2016. Randomization sequence was performed using a computer generated randomization list, stratified by center, using 1:1 allocation.

Participants/materials, setting, methods: Eligible patients were randomized to either administration of 150 μg corifollitropin alfa followed by 300 IU hp-HMG (Group A) or to 300 IU of daily recombinant FSH (Group B) in a fixed GnRH antagonist protocol. The primary outcome was ongoing pregnancy rates (defined as presence of intrauterine gestational sac with an embryo with cardiac activity at 9-10 weeks of gestation). Secondary outcomes included clinical /biochemical pregnancy rates and number of oocytes retrieved cryopreservation rates.

Main results and the role of chance: Overall, 152 poor ovarian responders defined by the "Bologna" criteria were included in the study. Using an intention-to treat analysis the ongoing pregnancy rates did not differ significantly between Group A 11/77 (14.3%) and Group B 11/75 (14.7%), OR = 1.03 (0.4–2.5). Biochemical/clinical pregnancy rates and the number of oocytes retrieved were also comparable between the two groups. Nevertheless, more patients in the corifollitropin alfa group had cryopreserved embryos compared to recombinant FSH [14 (31.1%) versus 6 (15.8%), OR = 2.4 (1.04–5.5)]. Furthermore, Asian poor responders had significantly lower cancellation rates compared to European poor responders [2/64 (3.1%) versus 17/83 (20.4%), OR = 0.12 (0.03–0.5)]. This discrepancy could be explained by the fact that Asian women were of better prognosis than European patients, with significantly lower FSH [9.8(5.3) versus 11.5(5.4), p = 0.017] and significantly higher AMH [1.1(0.9) versus 0.4(0.3), p value <0.001].

Limitations, reasons for caution: Although we failed to identify differences between the two randomized arms, we cannot exclude that smaller differences might exist, which our study was underpowered to detect.

Wider implications of the findings: POR represents a challenge and although specific protocols may increase the number of cryopreserved embryos, no difference is observed in ongoing pregnancy rates. Our study, being one of the largest RCTs in Bologna poorresponders, highlights that baseline characteristics may play a crucial role in the clinical prognosis of this population.

Trial registration number: The EUDRACT number of the trial was 2013-000583-29 and the study was registered to clinicaltrials.gov (NCT01816321).

O-014   Letrozole step-up protocol: the effect of a novel superovualtion induction protocol to enhance pregnancy rate in a couple with unexplained infertility undergoing intrauterine insemination

A. Galal[1]

[1]Alexandria, Egypt,

Study question: investigate success of novel step-up protocol of letrozole as an attempt to achieve multifollicular development and to assess its effect on outcome of IUI cycles in couples with unexplained infertility.

Summary answer: letrozole step up protocol is potentially valid novel induction protocol, has privilege of similar pregnancy rate to standard HMG ovulation induction with lower cost

What is known already: Objective Empiric ovarian stimulation with clomiphene citrate, aromatase inhibitors (Letrozole) or exogenous gonadotropin is commonly combined with IUI in the treatment of couples with unexplained infertility. The successful use of the aromatase inhibitor,letrozole, for ovarian stimulation was documented when administered as a single dailydose or multiple daily fixed dose. To our knowledge,achieving consistent multifollicular development with letrozole, without the addition of FSH, has not been reported except in a retrospective trial.

Study design, size, duration: Design a prospective randomized controlled study.

Materials and Methods 100 couples with unexplained infertility undergoing IUI were randomized by computer number system into two groups.The sample size was calculated using Epi-Info 2002 software. Using a power of 80% to detect a significant difference at conception rate after IUI between the two groups = 19% with 5% precision and alpha error = 0.05, the sample size was 50 couples per group.

Participants/materials, setting, methods: ovulation stimulation by letrozole step up protocol from day 2, 3 of menstrual cycle starting by dose 2.5 mg increased daily by 2.5 mg for next 3 days.Group B, HMG ampoules 75 iu, tailred according to response,HCG when leading follicle 17 mm, IUI done 36 hours later.luteal support by vaginal progesterone, serum B HCG was measured after 14 days, clinical pregnancy by fetal heart pulsation 6–8 weeks

Main results and the role of chance: The step-up letrozole protocol was associated with multifollicular ovarian development with a mean of 1.5 ± 0.7 that was less than this detected with HMG 3.1 ± 1.0 however this did not affect so much clinical pregnancy rate that was statistically insignificant (16% in letrozole group versus 18% in HMG group) that may reflect the good quality of oocyte in addition to the good receptivity suggested by non significant difference in endometrial thickness. The cost of letrozole cycles was significantly lower than HMG group.

Limitations, reasons for caution: small scale

Wider implications of the findings: can be applied on a large number of patients

Trial registration number: ACTRN12614000024640

O-015   Blood-testis barrier organization in a prepubertal and peripubertal boys' cohort: correlation with Sertoli cell maturation, clinical puberty and testicular anatomopathology

F. De Michele[1], M.G. Giudice[2], J. Poels[3], F. De Smedt[4], J. Ambroise[5], C. Wyns[1]

[1]Cliniques universitaires st Luc- Institut de Recherche Expérimentale et Clinique IREC-Université Catholique de Louvain, Gynecology - Andrology, Brussels, Belgium
[2]Cliniques universitaires st Luc, Gynecology - Andrology, Brussels, Belgium
[3]Cliniques universitaires st Luc- Institut de Recherche Expérimentale et Clinique IREC-Université Catholique de Louvain, Andrology, Brussels, Belgium
[4]Cliniques universitaires st Luc, Gynecology, Brussels, Belgium
[5]Institut de Recherche Expérimentale et Clinique IREC, Centre de Technologies Moléculaires Appliquées CTMA, Brussels, Belgium

Study question: How do blood-testis barrier (BTB) proteins correlate with Sertoli cell maturation, testicular histopathological and clinical characteristics during transition from prepubertal to pubertal stages?

Summary answer: We observed that BTB proteins expression and organization were correlated to Sertoli cell maturation and to increasing age, in association with histopathological and clinical puberty

What is known already: The BTB consists of tight and gap junctions, which preserve paracrine interactions between Sertoli and germ cells as well as the

migration of differentiating germ cells towards the seminiferous lumen. Claudin 11 and connexin 43 are main proteins of tight and gap junctions, respectively. In connexin 43 knockout mice, Sertoli cells do not fully differentiate, implying thus that the BTB is essential for their maturation. In humans knowledge on the BTB is limited to adult tissue, where abnormal BTB formation was associated with impaired spermatogenesis. However, before puberty and during the pubertal transition, BTB establishment has not yet been described.

Study design, size, duration: The study was designed to assess the dynamic evolution of the BTB in a cohort of pre- and peripubertal boys. 49 patients, aged 0–15 years, who underwent a testicular biopsy to preserve their fertility before gonadotoxic treatment and had no previous history involving risks for infertility were selected. Correlations between the presence of BTB proteins, patient's age and Sertoli cell maturation were analyzed.

Participants/materials, setting, methods: Connexin 43 and claudin 11 immunostaining was performed to evaluate the BTB. A scoring system was used to assess their absence or disorganized-organized presence. Sertoli cell maturation was evidenced by Anti Mullerian hormone (AMH) immunohistochemistry. Tanner stages and the histological presence of haploid cells were recorded. AMH evolution, association between age and BTB, and correlation between AMH and BTB proteins were analyzed with linear regression, Fischer's test and Spearman correlation, respectively.

Main results and the role of chance: Connexin 43 and claudin 11 expressions increased significantly with age (p = 0.04 and p ≤ 0.01, respectively). Connexin 43 was expressed in a disorganized state from the first year of age and its organized expression was only observed after 12 years of age, simultaneously with the onset of claudin 11 expression, the presence of haploid germ cells and the progression towards more advanced Tanner stages. AMH staining decreased significantly with age (p ≤ 0.01), showing a progressive maturation of Sertoli cells. Moreover, we observed an inverse correlation between the expression of AMH and both connexin 43 (p = 0.05) and Claudin 11 (p < 0.01), indicating that Sertoli cell maturation is linked to the organization of the BTB. We showed for the first time, in a cohort of pre- and peripubertal boys, that the progression through puberty, demonstrated by Tanner stages and by testicular histological analysis, was simultaneous to the establishment of an organized BTB and Sertoli cell maturation. Further studies on the association between BTB components and onset of spermarche during the pubertal transition period are required to increase knowledge on differentiation of prepubertal testicular tissue and achieve in vitro maturation of immature testicular tissue.

Limitations, reasons for caution: Assessment of more BTB proteins may help to fully understand its establishment. The size of the population of peripubertal boys should be increased to study the correlation between germ cells at all stages of differentiation and the BTB and understand how alterations of the formation of BTB can affect spermatogenesis.

Wider implications of the findings: Since the knowledge on the human BTB in a pre-peripubertal cohort was lacking, our data provide a control population which can serve to assess in vitro maturation protocols for prepubertal testicular tissue. Furthermore, it may also be useful for in vivo applications as male contraception.

Trial registration number: not applicable.

O-016 Gradient system for testicular organoids generation – a novel system to model germ to somatic cell association in vitro

J.P. Alves Lopes, O. Söder, J.B. Stukenborg

Karolinska Institutet, Women's and Children's Health, Stockholm, Sweden

Study question: Can germ and somatic testicular cells reorganize in vitro in a close to in vivo association if co-cultured in a three dimensional gradient system (3DGS)?

Summary answer: Germ and Sertoli rat cells reorganized in seminiferous-like structures when co-cultured in the 3DGS allowing the study of germ-to-somatic cell interactions in vitro.

What is known already: Germ cell proliferation and differentiation are delicate and complex processes governed by a broad network of factors and somatic cells. These signaling pathways and cell-to-cell interactions have been exhaustively studied, but a lot still remain unknown. Different approaches such as organ culture or *de novo* formation of seminiferous-like structures from

primary testicular cells have been applied to investigate the mechanisms that govern germ cell fate decision into proliferation or differentiation. However, a more efficient and controlled model which recapitulate the germ-to-somatic cell associations is still need to study the germ cell niche *in vitro*.

Study design, size, duration: Primary testicular cells from 20 *dpp* rat were culture for 10 and 21 days using the 3DGS in basic culture condition. The effect of the treatment for 10 days with retinoic acid (RA) IL-1α, TNFα and RA inhibitors in germ cell maintenance and BTB organization was compared to the control culture conditions for the same period of time.

Participants/materials, setting, methods: For the gradient system setting, 3 concentric drops of Corning® Matrigel® diluted 1:1 with culture medium were sequentially applied on the bottom membrane surface of a hanging cell insert. The middle drop had a final cell concentration of 44 million cells/mL. DMEM-α supplemented with 1% pen/strep and 10% KnockOut serum replacement was used as basic culture medium. Evaluation of the results was done by bright-field microscopy and by confocal microscopy after whole-mount staining.

Main results and the role of chance: Sertoli and germ cells reassembled in spherical-tubular structures (STSs) showing similarities to seminiferous tubules organization. The characterization of STSs revealed that they are mainly formed by epithelized Sertoli cells. Moreover, the formation of a blood-testis barrier (BTB) *in vitro* was demonstrated by the detection of Zo-1 and occluding proteins between Sertoli cells and by the impermeability of the spherical-tubular structures to Evans Blue, a small molecule that cannot cross healthy BTB *in vivo*. Additionally, germ cells could be maintained for 21 days on the STSs. Furthermore, undifferentiated germ cells were observed to proliferate and formed cellular chains in a similar way as observed *in vivo*.

In order to validate the 3DGS to investigate signaling pathways and cell-to-cell interactions in the germ cell niche, we verify the role of retinoic acid (RA), IL-1α, TNFα and RA inhibitors in germ cell maintenance and BTB organization in vitro. RA treatment had a positive effect in germ cell maintenance compared with control conditions. Furthermore, IL-1α and TNFα were observed to impair the formation of testicular organoids and germ cell maintenance. Thus, we demonstrated our 3DGS to be a new model to explore germ cell niche *in vitro*.

Limitations, reasons for caution: The testicular organoids do not completely mimic testicular physiology yet. More specifically, progression in spermatogenesis was not observed in the basic culture conditions utilized mainly due to the lack of knowledge regarding the factors involved in germ cell differentiation.

Wider implications of the findings: The 3DGS constitutes a new method to generate testicular organoids representing a unique model of germ-to-somatic cell association in vitro with possible application to search for factors involved in the germ cell niche regulation. Moreover, the model might be applied to generate organoids and study organogenesis in other scientific fields.

Trial registration number: Not applicable.

O-017 In vitro re-assembly of human primary testicular cells into seminiferous cord-like structures

M. Mincheva[1], R. Sandhowe-Klaverkamp[1], J.B. Stukenborg[2], J. Wistuba[1], S. Schlatt[1]

[1]*University Hospital of Münster, Centre of Reproductive Medicine and Andrology, Münster, Germany*
[2]*Karolinska Institutet and University Hospital, Pediatric Endocrinology Unit-Department of Women's and Children's Health- NORDFERTIL research lab Stockholm, Stockholm, Sweden*

Study question: Can enzymatically dispersed testicular cells from adult men re-organize into seminiferous cords *in vitro*?

Summary answer: Adult human testicular somatic cells re-assembled into testicular cord-like structures consisting of Sertoli and peritubular cells showing dynamic interactions.

What is known already: Attempts to induce spermatogenesis *in vitro* have a long lasting history with no success in human so far. Current evidence from animal studies suggests that an intact testicular somatic microenvironment is required to support germ cells. The capacity of testicular cell suspensions from adult prostate cancer patients to self-organize in spheroid testis-like units, albeit

not displaying typical testicular architecture, has been recently shown. Our study aims at describing in more detail the cellular and molecular mechanisms involved in human testicular tubulogenesis.

Study design, size, duration: Testes from 15 adult gender dysphoria patients (mean age 35 ± 9.3, SD) of varying spermatogenic status (spermatogonia arrest to complete spermatogenesis), were used for this study after sex reassignment surgery. *In vitro* primary testicular somatic cell cultures were generated to investigate the self-organizing ability of testicular cells to form cord-like structures over a three-week period. Morphological appearance, marker expression by immunohistochemistry, phenotype and dynamics of cell re-organization were analyzed.

Participants/materials, setting, methods: Cell suspensions obtained by two-step enzymatic digestion which were plated onto glass inserts in 24-well plates for two days. To enrich for adherent somatic cells, the supernatant was discarded and the culture of the attached cell population was continued. Re-assembly into cord-like structures was analyzed daily by microscopic observations. Endpoints were qualitative changes in morphology. Cell types were characterized by phase-contrast and immunohistochemistry. Dynamics of cord formation were recorded by time lapse microscopy.

Main results and the role of chance: Primary human testicular cells underwent a stepwise cascade of re-assembly into distinctive morphological patterns, resulting in cord-like structures after two weeks. Already at day two testicular somatic cells had aggregated into irregular- and spherically-shaped structures. Between days 3 and 6 adjacent aggregates connected with each other by ´bridges' of elongated spindle-shaped cells. Then, aggregates fused to form multi-layered spherical or elongated cord-like structures between days 7 and 14. Time-lapse imaging between days 3 and 6 confirmed the dynamics of cord formation. Processes observed were cell migration, compaction and fusion via contraction of spindle-shaped cells. Immunohistochemical analysis revealed that both SOX9-positive Sertoli and α-SMA-positive peritubular myoid cells interacted and contributed to cord-like structure formation. By day 14, peritubular cells had aligned in single layer, acquired flattened appearance, surrounding the cord-like structures.

Limitations, reasons for caution: Due to scarcity of normal human testicular tissue, testes from gender dysphoria patients were used in the study, which tissue might differ from the normal one. Despite sharing morphological features with *in vivo* testicular cords, further refinement of this *in vitro* model is required.

Wider implications of the findings: The proposed *in vitro* culture system can be developed further into a tool for the examination of testicular cell interactions during testis organogenesis under controlled experimental conditions.

Trial registration number: Not applicable.

O-018 Oxidation reduction potential: a valuable tool for male fertility evaluation

S. Al Said[1], A. Majzoub[1], M. Arafa[1], H. El Bardisi[1], A. Agarwal[2], K. Al Rumaihi[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar
[2]American Center for Reproductive Medicine- Cleveland Clinic Foundation, Urology, Cleveland, U.S.A.

Study question: Is there a significant correlation between seminal oxidation reduction potential (ORP) and total motile sperm count (TMSC)?

Summary answer: Seminal ORP measures have a significant positive correlation with TMSC.

What is known already: Oxidative stress results from imbalance between oxidants and reductants. Its detrimental effects on sperm production proposed its use a biomarker for overall semen quality. While previous attempts assessing OS in semen samples measured single features of the redox system, ORP can be considered a better measure of OS as it determines the balance between oxidants and reductants. TMSC is considered to be the single most important parameter of the semen analysis result that can predict the severity of male infertility. Examining the correlation between ORP and TMSC should provide solid information on the usefulness of ORP in male fertility evaluation.

Study design, size, duration: This is a cross sectional study of 1162 patients presenting to the male infertility unit of a tertiary medical center over a period of 12 months. After the collection of demographic and clinical data, patients were asked to provide a semen sample for analysis after >=2 days of sexual abstinence.

Participants/materials, setting, methods: Semen samples were analyzed according to the 5th Edition WHO manual. TMSC was calculated using the formula = volume (ml) x sperm concentration (million/ml) x total motility (%)/100. Seminal ORP levels were assessed using the MiOXSYS system. Pearson's correlation was used to assess the relationship between ORP and TMSC. Using a TMSC threshold of 20 million, receiver operator characteristic (ROC) analysis was utilized to determine the ORP cutoff associated with highest predictive values.

Main results and the role of chance: The patients mean age ± standard error of mean was $35.9 ± 0.2$ years. Infertility was primary in 69.6% and secondary in 30.4% of patients. After a mean abstinence time of $3.7 ± 0.04$ days, semen analysis results revealed a sperm concentration of $32.7 ± 0.78$ million/ml, total motility of $50.1 ± 0.57\%$ and normal morphology of $5.7 ± 0.22\%$. The mean calculated TMCS was $55.5 ± 1.7$ million. A significant negative correlation exists between TMSC and the ORP result (r -0.36, CI -0.12 - -0.42, p < 0.001). Using a TMSC threshold of 20 million, ROC curve analysis determined a ORP cutoff value of $2.34 \, mV/10^6$ sperm/mL to be associated with a sensitivity of 83.5%, specificity of 82.5%, negative predictive value of 81.4%, positive predictive value of 82.9% and overall accuracy of 79.9% (area under the curve 0.9).

Limitations, reasons for caution: Results were obtained from semen samples of patients presenting with primary or secondary infertility and hence were not compared with a control group or with men of proven fertility.

Wider implications of the findings: Using a single drop of semen (30ul) applied to a sensor, ORP measurement with the MiOXSYS system is a simple, quick and user friendly method that can reliably measure OS in biologic samples. The significant correlation between ORP and TMSC allows its use as a predictor of fertility potential.

Trial registration number: Not applicable.

O-019 High prevalence of PLCζ mutations among cases of failed oocyte activation, but not anomalous fertilization, after IVF/ICSI

M. Barragan, M. Torra, D. Cornet, A. Ferrer-Vaquer, A. Rodríguez, R. Vassena

Clínica EUGIN, EUGIN, Barcelona, Spain

Study question: Is oocyte activation failure (OAF) associated with PLCz mutations in sperm?

Summary answer: Mutations in PLCz sequence are associated with OAF and could explain cases of fertilization failure.

What is known already: Total fertilization failure (FF) occurs in 1–3% of ICSI cycles, often due to oocyte activation failure (OAF). PLCz, a soluble factor responsible for oocyte activation, possess X and Y catalytic domains, an X-Y linker region, and a C2 domain at the C-terminus. PLCz hydrolyzes PIP2 in the oocyte, leading to intracellular calcium release and oocyte activation. So far, 4 PLCz point mutations have been reported (H233L, H398P, I489F and S500L), all linked to cases of fertilization failure and associated to a decrease of either PLCz levels or activity. Nevertheless, the impact of PLCz mutations on OAF cases specifically is unknown.

Study design, size, duration: All consecutive cases (n = 34) of low (<20%) to complete FF in cycles with donor oocytes between 2014 and 2016 were included in the study; of these, 14 cases presented OAF (undetected pronuclei), while 20 presented anomalous fertilization (AF, 1PN or 3PN). As control group, 13 sperm donors with fertilization rate >75% were analyzed. The percentage of mutated cases within groups was assayed by Bernouilli binomial test (P < 0.05).

Participants/materials, setting, methods: Sperm genomic DNA was isolated; the exonic regions of PLCζ were amplified by PCR and sequenced, and compared to the published sequence of the genomic PLCζ locus (Homo sapiens 12 BAC RP11-361I14) by BLAST analysis. To characterize PLCζ mutations in silico, 3D protein structure modelling (SWISS-MODEL) was performed. To analyze PLCζ protein in sperm, protein expression and localization was analyzed through Western blot and immunofluorescence.

Main results and the role of chance: 8 of the 14 (57.14%) OAF patients carried at least one PLCz mutation, versus 1 out of 20 in AF group (5%; p < 0.05)

and none of the 13 sperm donors (0%; p < 0.05). In total, 5 mutations were identified. Four were single nucleotide missense mutations; previously unreported R197H and L223P, with H233L, were located in the X catalytic domain; S500L was located in the C2 N-terminal domain. One OAF patient presented 2 mutations (S500L and R197H), while single S500L mutations were found in 4 patients with OAF and 1 with AF. All patients presented mutations in heterozygosis, except 1 from OAF group (S500L, in homozygosis) and no relationship was found between PLCζ mutations and protein expression levels or subcellular localization. 3D protein structure modelling did not predict significant changes in the overall structure or the ligand recognition motif in any of the single missense mutations. The fifth mutation, an unreported frameshift, was found in one patient with complete OAF (fertilization rate: 0/5), leading to a truncated protein at the X-Y linker region, resulting in the loss of the Y- and C2-domains. This patient underwent assisted oocyte activation (fertilization rate: 6/9), and a healthy baby was born.

Limitations, reasons for caution: This study reports a clear association between OAF and PLCz mutations; although further functional studies are needed to test mutant PLCz activity. Donor oocytes were used in all IVF cycles included, significantly decreasing the chances of a concurrent oocyte factor.

Wider implications of the findings: Almost 60% of patients presenting OAF carried at least one mutation in PLCz. We reported 3 new and 2 previously described PLCz mutations, and suggest that PLCz gene sequencing might be used as a tool for counseling and treatment of couples presenting OAF.

Trial registration number: NA.

O-020 Klinefelter syndrome and fertility – impact of X-chromosomal inheritance on spermatogenesis

S. Franik[1], D. Smeets[2], G. Van de Zande[2], I. Gomes[2], K. D'Hauwers[3], D. Braat[1], K. Fleischwer[1], L. Ramos[1]

[1]Radboudumc, Obstetrics and Gynaecology, Nijmegen, The Netherlands
[2]Radboudumc, Human Genetics, Nijmegen, The Netherlands
[3]Radboudumc, Urology, Nijmegen, The Netherlands

Study question: This study investigates if paternal or maternal inheritance of the additional X-chromosome determines the absence or presence of spermatogenesis in males with Klinefelter syndrome.

Summary answer: The maternal or paternal origin of the additional X-chromosome in men with KS cannot predict the presence or absence of spermatogenesis.

What is known already: Klinefelter syndrome (KS) is one of the most common chromosomal disorders leading to azoospermia in men. However, with the use of intracytoplasmic sperm injection (ICSI) in combination with testicular sperm extraction (TESE), in about 50% of men diagnosed with KS spermatogenesis is present in the testicular biopsies and they can potentially still father their own children. The reason for absence or presence of spermatozoa in half of men with KS remains unknown.

Study design, size, duration: For this retrospective study, all men with Klinefelter sydrome who have had a TESE in the Radboud University Medical Center from 2010 to present were eligible for inclusion in this study. From 9 participants and their parents, buccal swabs were taken in order to be able to compare X-chromosomal markers to determine the parental origin of both X-chromosomes in the males with KS.

Participants/materials, setting, methods: The testicular biopsies were obtained by our standard procedure. Biopsies were prepared and evaluated at the fertility laboratory for presence or absence of spermatozoa (wet –prep). The presence of at least one spermatozoon was considered a positive sperm retrieval (TESE+). Histopathological analysis of the spermatogenesis and cytology evaluation by scoring the ratios between spermatozoa, pachytene spermatocytes and Sertoli cells was also performed on the TESE samples.

Main results and the role of chance: The results of our analysis show that in 8 of 35 (23%) patients spermatozoa were retrieved by single or double TESE. Different levels of spermatogenesis appeared to be present in 16 of 35 (46%) participants by combining the results of spermatozoa retrieval, and cytological as well as histological analysis of the retrieved testicular tissue, meaning that spermatogonia are present but not always can mature up to spermatozoa. From the 9 KS-trios that were further genetically analyzed for inheritance origin,

no evidence of a correlation between the maternal or paternal origin of the extra X-chromosome and the presence of spermatogenesis was found. The hormonal levels (testosterone, LH and FSH) measured prior to the TESE did not differ between the TESE positive and negative subgroups. A combination of high serum testosterone levels > 7.5 nmol/l and low serum LH <17.5U/l was a weak positive predictive marker for presence of spermatogenesis in our study group.

Limitations, reasons for caution: Based on the small number of participants in this study, a larger study is needed to confirm our findings that a combination of high serum testosterone and low luteinizing hormone is a positive predictive marker for the presence of spermatozoa upon TESE.

Wider implications of the findings: Unfortunately, determining the origin of the extra X-chromosome in men with Klinefelter Syndrome cannot predict the presence or absence of spermatogenesis. Although of weak predicting value, a combination of high serum testosterone and low serum LH levels have been identified as prognostic markers for the presence or absence of spermatogenesis.

Trial registration number: No Clinical Trial.

O-021 Endometrial function in women with diabetes: role of the hexosamine biosynthetic pathway (HBP)

J. Muter[1], P. Ruane[2], D. Brison[2], J. Aplin[2], M. Westwood[2], J. Brosens[1]

[1]University of Warwick, Division of Biomedical Sciences, Warwick, United Kingdom
[2]University of Manchester, Faculty of Medical and Human Sciences, Manchester, United Kingdom

Study question: Does action of the HBP, and subsequent modification of proteins with O-linked β-N-acetylglucosamine (O-GlcNAcylation), act to link glucose metabolism with early pregnancy success/failure?

Summary answer: Expression of the O-GlcNAc transferase EOGT is negatively correlated with BMI. Knockdown of EOGT impedes expansion of endometrial stem-cells, leading to reduced regenerative capacity.

What is known already: Animal studies suggest that high glucose levels are detrimental to endometrial function; however, the molecular mechanisms that translate abnormal glucose availability into altered endometrial function are unknown. In glucose-sensing tissues, the HBP is a nutrient driven regulator of cellular function. HBP activation results in the synthesis of uridine diphosphate N-acteyl glucosamine (UDP-GlcNAc), which is used to glycosylate proteins post-translationally. O-GlcNAcylation is catalysed either by O-GlcNAc transferase (OGT), or EGF-domain specific-OGT (EOGT). EOGT targets include Notch ligands and receptors which are known to regulate the endometrial perivascular stem cell niche, which is critical for endometrial function and successful implantation.

Study design, size, duration: Primary cultures were derived from endometrial biopsies obtained from consenting women recruited from the Implantation Clinic, a dedicated research clinic at University Hospitals Coventry and Warwickshire NHS Trust. A total of 45 fresh endometrial biopsies were processed for human endometrial stromal cell (HESC) primary cultures. The average age (± SD) of the participants was 33 ± 1.8 years. Data were obtained from at least 3 independent cultures for all experiments.

Participants/materials, setting, methods: HESCs were isolated from endometrial biopsies and expanded in vitro. Treatment with 8-bromo-cAMP and medroxyprogesterone was used to induce a decidual phenotype. HESCs were transfected using a jetPRIME Polyplus kit with either EOGT siGENOME or non-targeting (NT) small interfering RNA. Gene and protein expression were assayed by real-time quantitative (qRT)-PCR and Western blots, respectively. Clonal ability was assessed by seeding cells at low density and maintaining in culture for 10 days before staining with hematoxylin.

Main results and the role of chance: Decidualization of HESCs, an obligatory process for embryo implantation, is associated with altered expression of key HBP enzymes, including down-regulation of OGT and up-regulation of O-GlcNAcase (OGA). The most striking observation, however, is the marked induction of EOGT in decidualizing HESCs. Small interfering RNA-mediated knockdown of EOGT in primary HESC cultures did not affect the induction of decidual marker genes, including PRL, IGFBP1 and HSD11B1. However, EOGT knockdown enhanced NOTCH signalling by stabilising NOTCH1 and NOTCH3, which in turn blunted activation of endometrial mesenchymal stem cells in colony-forming assays (P < 0.01). Furthermore, loss of EOGT enhanced the pro-inflammatory cytokine profile in decidualizing HESCs. Analysis of 80 mid-luteal endometrial biopsies revealed an inverse correlation between EOGT mRNA levels and body mass index (Spearman rank test, $\rho = -0.3260$; $P = 0.049$), which was confirmed at protein level by Western blot analysis of whole endometrial tissues from 48 women (Spearman rank test, $\rho = -0.335$, $P = 0.020$). Taken together, these observations suggest that endometrial EOGT deficiency associated with obesity reduces the regenerative capacity of the endometrium and prolongs the pro-inflammatory endometrial environment at implantation.

Limitations, reasons for caution: In vitro assays are associated with inherent limitations as there are difficulties in extrapolating perturbed pathways in vitro to effects in vivo. Further studies are required to characterise interactions between different cell types in the endometrium upon O-GlcNAc cycling and responses to varying glucose conditions.

Wider implications of the findings: These observations link increased BMI to impaired endometrial function. This will increase our understanding of the impact of diabetes on reproductive function and underpin the development of (i) biomarkers to identify women at high risk of early pregnancy problems and (ii) interventions to optimise endometrial function in these women.

Trial registration number: N/A.

O-022 Improving the pre-conceptual uterine natural killer (uNK) cell test to predict pregnancy outcome in recurrent miscarriage

M. Lokman[1,2], K. Fishwick[2], V. Kandavel[1], J. Brosens[2], S. Quenby[2]

[1]University Hospital of Coventry and Warwickshire, Obstetrics and Gynaecology, Coventry, United Kingdom
[2]University of Warwick, Biomedical Research Unit in Reproductive Health, Coventry, United Kingdom

Study question: Can we improve the pre-conceptual endometrial uNK cell test, in its ability to predict subsequent pregnancy outcome in women with recurrent miscarriage?

Summary answer: A pre-conceptual endometrial test that measures synchronicity of stromal and glandular decidualisation can improve prediction of pregnancy outcome in recurrent miscarriage.

What is known already: Decidualisation of the endometrium is crucial in creating a micro-environment suitable for embryo selection, implantation and sustaining pregnancies. Impaired decidualisation is strongly associated with recurrent miscarriage (RM). Our endometrial uNK cell test correlated with in-vitro decidualisation but has limited ability to predict pregnancy outcome. Our recent research, found that impaired decidualisation in RM was characterised by accelerated senescence and a lack of endometrial mesenchymal stem cells (eMSC).

Study design, size, duration: This was a cohort study of women with RM who had a mid-luteal phase endometrial biopsy and a pregnancy event of ongoing/livebirth or first trimester miscarriage within one year of biopsy (2012–16). An exploratory study used immunohistochemistry (IHC) to identify senescence and proliferation markers that differentiated women who had a miscarriage from those who had a successful pregnancy (n = 20). A further 89 patients were used to confirm or refute findings from the exploratory phase.

Participants/materials, setting, methods: This study was performed in a specialist tertiary referral, Implantation Clinic, where mid-luteal endometrial biopsies are taken for uNK cell assessment. Biopsies from women with known pregnancy outcome were retrieved from our tissue bank for serial sectioning then immunohistochemistry (IHC) staining with antibodies to detect uNK cells-CD56, proliferation-Ki67 and senescence-HMGB2 and p16. The density and

localisation of each marker was measured with colour de-convolution and thresholding using Panoramic Viewer and Image J software.

Main results and the role of chance: As cells senesce HMGB2 density is lost and p16 expression is increased. HMGB2 facilitates DNA flexibility and repair, and P16 is a tumour suppressor protein that decelerates cell progression from G1 to S phase.

uNK and p16 density measurements were normalised to the day of cycle using centile reference ranges developed in our laboratory (n = 1,800). uNK centiles did not differentiate miscarriage from pregnancy success. However, glandular p16 centile was significantly higher in those with a subsequent live birth than those who miscarried (p = 0.005).

The best differentiation of those who had a further miscarriage from those who had a successful pregnancy was the difference between uNK cell and p16 (glandular) centile 'uNK-p16'. The larger positive values appear to be related to subsequent pregnancy loss (p = 0.0163).

The validity of 'uNK-p16' was assessed by receiver operative characteristics curve. It improves prediction of subsequent miscarriage compared to uNK alone but is still not robust enough for clinical application.

However, our data does suggest that synchronicity in stromal and glandular decidualisation are important for pregnancy success.

Limitations, reasons for caution: Any prediction of pregnancy outcomes in RM is limited by the fact that losses of both normal and abnormal pregnancies occur. We have yet to determine whether endometrial defects account for both or one of these. Another confounding factor is that the endometrial biopsy itself could alter pregnancy outcomes.

Wider implications of the findings: The findings support the concept that co-ordinated decidualisation in stromal and glandular compartments is needed for successful pregnancy outcome. It may be not be possible to predict pregnancy outcome with a pre-conceptual endometrial test however an endometrial test could select women who would benefit from pre-pregnancy therapeutic interventions.

Trial registration number: not applicable.

O-023 Acetylsalicylic acid for prevention of pregnancy loss: a randomized trial

L. Blomqvist, M. Hellgren, A. Strandell

Institution for Clinical Research- Sahlgrenska Academy- University of Gothenburg, Obstetrics & Gynecology, Gothenburg, Sweden

Study question: Does low dose acetylsalicylic acid (ASA) prevent miscarriage in subsequent pregnancy in women with at least three consecutive miscarriages without a known etiology?

Summary answer: In women with at least three consecutive miscarriages, treatment with ASA from early gestation compared with placebo, does not increase live birth.

What is known already: One percent of fertile couples suffer from recurrent pregnancy loss. Immunologic factors, chromosomal aberrations, disturbed placental circulation and anomalies of the uterus are suggested risk factors, although the condition is of unknown etiology in the vast majority of couples. Without proper evidence for an effect, treatments like ASA, low molecular weight heparin, immunoglobulin, progesterone and immunization have been used when no etiological factor has been detected. In couples with at least three consecutive miscarriages, ASA is sparsely investigated in randomized controlled trials and has been included only together with other drugs.

Study design, size, duration: The study is randomized, double-blind, placebo-controlled, stratified for age and conducted at a single center between 2008 and 2015. Recurrent pregnancy loss was defined as at least three consecutive miscarriages within the couple. Randomization was through a third party, who manufactured and delivered the study drugs. Group allocation was concealed until all study patients had a pregnancy outcome registered. Primary outcome was live birth.

Participants/materials, setting, methods: Couples were referred to one center. Women <40 years old with a BMI <35 were eligible if the work-up was negative. They were randomized after 42 gestational days when fetal heartbeat was detected by transvaginal ultrasound. Active treatment arm received 75 mg ASA and controls received placebo pills with identical appearance. Patients

were seen by the same gynecologist at gestational weeks 9, 13, 30 and 36. The study drug was discontinued at the last check-up.

Main results and the role of chance: Of 594 screened patients, 505 were eligible and 200 were randomized to each group. The study group was in mean 32.3 years (SD 4.3) old, had a mean BMI of 23.9 (SD 3.8), and had experienced three (median) miscarriages (range 3–7). Primary recurrent pregnancy loss within the couple was present in 52%, secondary being present i 48%. Thirty (7.5%) women were smokers. Women were randomized at gestational age 45.5 (SD 4.6) days. Conception was spontaneous in 356 (89.0%), through IVF in 31 (7.8%) and as a result of ovarian stimulation in 13 (3.2%) women. All demographic variables were evenly distributed between randomization groups. Live birth rates were 83.0% and 86.0% in patients having received ASA and placebo, respectively (p = 0.24). Ninety-eight percent of deliveries were singletons, the remaining being duplex. Premature birth before 37 gestational weeks occurred in 3.0% and 7.6% having received ASA and placebo, respectively (p = 0.08). There were no differences between randomization groups in pregnancy loss during first and second trimesters.

Limitations, reasons for caution: New miscarriage during current pregnancy was not studied by histological/pathological or chromosomal examination. Uterine evacuation would have been a prerequisite, but was not a part of the study protocol. Such a procedure is not included in the routine management and would have implied an additional invasive procedure for the patient.

Wider implications of the findings: Treatment with ASA, starting at detection of fetal heart beat, did not prevent recurrent miscarriage in women with at least three consecutive miscarriages in the same relationship. The fertility prognosis is very good, the live birth rate being more then 80 percent with or without ASA.

Trial registration number: Clinicaltrials.gov NCT02823743.

O-024   A placebo-controlled, randomized, double-blind study of pregnancy and live birth rates after single oral administration of a novel oxytocin antagonist, nolasiban, prior to embryo transfer

H. Tournaye[1], A. Humberstone[2], V. Lecomte[2], P. Terrill[3], P. Pierzynski[4], E. Loumaye[5]

[1]UZ Brussel, Center for Reproductive Medicine, Brussels, Belgium
[2]ObsEva SA, Clinical Operations, Geneva, Switzerland
[3]CROS NT, Statistics, Maidenhead, United Kingdom
[4]Medical University of Bialystok, Reproduction Endocrinology and Gynecology, Bialystok, Poland
[5]ObsEva SA, Medical, Geneva, Switzerland

Study question: Does the oral administration of the novel oxytocin antagonist, nolasiban, prior to Day 3 (D3) fresh embryo transfer (ET) improve pregnancy and live birth rates?

Summary answer: Overall live birth rate was 40% after administration of different oral doses of nolasiban compared to 29% in the placebo group.

What is known already: Infusion of atosiban at the time of ET has been reported to improve pregnancy rates in several clinical studies. These studies have included D3 and D5 fresh transfers and frozen ET. It has been hypothesized that antagonism of oxytocin and/or vasopressin V1a receptors expressed in uterus at the time of ET could enhance uterine receptivity and improve pregnancy rates possibly by decreasing uterine contractions and by improving endometrial receptivity and perfusion. Good endometrial blood flow on the day of embryo transfer was associated with higher pregnancy success after in vitro fertilization (IVF).

Study design, size, duration: Multinational, prospective, double-blind, dose-finding, randomized, parallel group, placebo-controlled study assessing a single oral dose of nolasiban (100, 300 or 900 mg) or placebo, administered 4 hours before ET following IVF or intracytoplasmic sperm injection (ICSI). 247 subjects (≥60/arm) were recruited from 26 fertility clinics in Europe from Jan–Jul 2015. Following ET, pregnancy status was assessed at 2, 6 and 10 weeks. Pregnancies were followed until birth and neonatal/infant outcomes at 1 and 6 months.

Participants/materials, setting, methods: Eligibility criteria included age ≤ 36 years, ≤ 1 failed ART cycle, use of a gonadotropin releasing hormone antagonist cycle, luteal support with vaginal micronized progesterone (P4), and

> 1.5 uterine contractions/min assessed by time-lapse ultrasound before ET. One or two embryos (at least one of good quality) were transferred. The primary analysis was performed on the full data set and an additional post-hoc sub-set analysis was performed excluding subjects in the top P4 quartile.

Main results and the role of chance: The pregnancy rates at week 10 in the placebo, 100, 300 and 900 mg groups were 29%, 44%, 35%, 45% (trend test: p = 0.15) and the live birth rates were 29%, 40%, 35%, 43% (p = 0.17). When all of the active treatment groups were pooled the live birth rate was 40% compared to 29% for placebo (p = 0.18). Demographics were generally comparable between treatment groups (e.g. mean age 31; oocytes retrieved 11; good quality embryo 3.5; single ET: 60%; double ET: 40%). However, more oocytes and higher pre-treatment serum P4 were recorded in the 300 mg group, and P4 level negatively predicted pregnancy (p < 0.05, as covariate in logistic regression model). In a post-hoc analysis excluding subjects in the top P4 quartile, live birth rates were 31%, 38%, 49% and 51% (trend test: p = 0.025). There was a slight reduction in uterine contractions after treatment compared to placebo, which was highest in the 900 mg group (median change: -13%, p = 0.051). However, overall there was no correlation between pregnancy outcome and uterine contraction rate. Single dose administration of nolasiban at doses up to 900 mg appeared to be well tolerated in this study and did not result in increased occurrence of adverse events or neonatal outcomes.

Limitations, reasons for caution: This study investigated D3 fresh transfers in relatively young women without repeat implantation failure. It was a relatively small study with about 60 patients per group and there was some imbalance in baseline characteristics including serum P4 which appeared to have a confounding effect on pregnancy outcomes.

Wider implications of the findings: The results indicate a potential 10–20% absolute increase in pregnancy and live birth rates compared to placebo after administration of a single oral dose of nolasiban before ET. If confirmed in larger prospective trials this finding has important potential for improving live birth rates following IVF/ICSI.

Trial registration number: ClinicalTrials.gov: NCT02310802.

O-025   High-quality human preimplantation embryos actively influence endometrial stromal cell migration

R.P. Berkhout[1], C.B. Lambalk[2], J. Huirne[2], V. Mijatovic[2], S. Repping[1], G. Hamer[1], S. Mastenbroek[1]

[1]Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands
[2]VU University Medical Center, Obstetrics and Gynecology, Amsterdam, The Netherlands

Study question: Do human preimplantation embryos regulate endometrial stromal cell (hESC) migration?

Summary answer: High-quality embryos stimulate migration of decidualized hESCs and suppress migration of non-decidualized hESCs, irrespective of embryonic developmental stage.

What is known already: Most embryos fail to implant in IVF/ICSI. Little is known about the interaction between the embryo transferred to the uterus and the endometrium. From the embryo point-of-view it is clear that not every embryo has similar chances of implantation. To estimate the developmental potential of each embryo, morphological assessment is most commonly used to rank and select embryos for transfer. Transferring higher ranked embryos results in higher live birth rates. However, whether higher ranked embryos achieve these improved live birth rates by actively interacting with the endometrium has not been elucidated.

Study design, size, duration: An In vitro study using primary hESCs from fertile patients undergoing hysterectomy for benign conditions (uterine scar niche n = 3, dysmenorrhea n = 2; no hormonal treatment) subjected to embryo conditioned medium (ECM). Per assay ECM was pooled from 5 individually cultured embryos with similar developmental stage and morphological quality. Per developmental stage, high-quality embryos were defined by <20% fragmentation and low-quality embryos were defined by >20% fragmentation. ECM was collected at day 4 after fertilization.

Participants/materials, setting, methods: Primary hESCs were decidualized with cAMP and medroxyprogesterone acetate (MPA) for 5 consecutive

days. Migration assays were performed by culturing hESCs in the presence of ECM from high-quality embryos (n = 34), low-quality embryos (n = 23) or in an equal volume of non-conditioned medium (control, n = 21). To quantify the migration response of hESCs, the surface area of cells entering the migration zone was measured.

Main results and the role of chance: ECM from high-quality embryos, i.e. with low fragmentation, actively stimulated decidualized hESCs migration (p < 0.0001). This effect was consistent throughout embryonic development from cleavage stage embryos with 2–7 cells (high-quality vs. control; p = 0.030), 8–18 cells (high-quality vs. control; p < 0.0001) to morulae (high-quality vs. control; p = 0.002). Additionally, linear regression analysis showed that hESCs migration was influenced by embryo quality (fragmentation: β -0.299; p = 0.025) and not developmental stage (cell number: β 0.177; p = 0.176) or maternal age (β -0.036; p = 0.78). Opposite to decidualized hESCs, the migration response of non-decidualized hESCs was inhibited by ECM from high-quality embryos (p = 0.019). ECM from low-quality embryos, i.e. with high fragmentation, did not cause an altered migration response in decidualized hESCs (p = 0.860) or non-decidualized hESCs (p = 0.986). Furthermore, ECM of both high- and low-quality human embryos did not influence proliferation of both decidualized and non-decidualized hESCs (p = 0.375).

Limitations, reasons for caution: Limitations of this study include the *in vitro* design and pooling of five individual embryo conditioned media.

Wider implications of the findings: This study reveals a mechanism by which the high-quality human preimplantation embryo interacts actively with its surroundings to increase its chances of successful implantation. Our study contributes to the further understanding of human embryo implantation, with the ultimate aim to develop more effective treatment strategies in IVF/ICSI.

Trial registration number: not applicable.

O-026 Evidence base for investigation and management for unexplained Recurrent Implantation Failure (RIF): A systematic review and meta-analysis

E. Wade[1], L. Polanski[2], N. Menon[3], W. Maalouf[4], K. Jayaprakasan[5]

[1]Bourn Hall Fertility Clinic, Embryology, Wymondham, United Kingdom
[2]Peterborough and Stamford Hospitals NHS Foundation Trust, Obstetrics & Gynaecology, Peterborough, United Kingdom
[3]School of Medicine- The University of Nottingham, Medicine, Nottingham, United Kingdom
[4]School of Medicine- The University of Nottingham, Obstetrics and Gynaecology, Nottingham, United Kingdom
[5]Derby Fertility Unit- Royal Derby Hospital- Derby, Fertility Unit, Derby, United Kingdom

Study question: To compare the prevalence of immunological conditions between women with RIF and controls (non-RIF) and evaluate the effect of empirical treatments for unexplained RIF.

Summary answer: Prevalence of certain immunological conditions were higher in RIF, but evidence to support most of the currently practised investigations and treatments for RIF is limited.

What is known already: RIF poses a complex medical challenge for clinicians and scientists alike; its devastating consequences affect approximately 10% of all women undergoing IVF treatment worldwide. The explorative manner in which medical investigations and treatments are often prescribed for RIF is a consequence of its ill-understood aetiology and it bears a significant economic burden to both the public and private sector along with significant emotional burden for the couple.

Study design, size, duration: Design – Systematic Review & Meta-analysis.

We identified 30 studies, comprising 5146 women, that compared the prevalences of positive immunological test outcomes between women with RIF and non-sufferers. A further 17 studies, comprising 2247 women, were identified that compared IVF outcome between women with RIF who received empirical treatment/s before IVF and those with the condition that had received a placebo or no empirical treatment. Medline and The Cochrane Library were searched; commencement to June 2016.

Participants/materials, setting, methods: Our case group comprised women with RIF; we used RIF criteria as described by the authors of individual studies. The review included two control groups; For the prevalence study, the

control group comprised both fertile and subfertile women with out a history of RIF whereas for the treatment study, it comprised women with RIF who were either administered a placebo or no empirical treatment during IVF.

Main results and the role of chance: The prevalence of positive antiphospholipid antibody test outcomes was significantly higher in women with RIF than in controls (OR = 3.35; 95%CI 2.05–6.05, p < 0.001); more specifically lupus anticoagulant (OR = 5.03; 95%CI 1.81–13.99, p = 0.002). Similar results were seen for inherited thrombophilias; more specifically Factor V Leiden (OR = 2.69; 95%CI 1.28–5.63, p = 0.009). While meta-analyses for the prevalences of high NK cells and Th1:Th2 ratio were not possible, there was no difference in the prevalence of anti-thyroid antibodies. Endometrial injury performed in the previous menstrual cycle was shown to benefit clinical pregnancy rate in women with RIF (OR = 3.38; 95%CI 2.26–5.06, p < 0.001). Similar results were seen for peripheral blood mononuclear cell administration to the uterus (OR = 3.68; 95%CI 2.01–6.64, p < 0.001) and intravenous immunoglobulin therapy on live birth rate (OR = 10.51; 95%CI 1.52–76.66, p = 0.02), although the data need to be interpreted with caution due to small sample sizes and low quality evidence. There was no significant benefit of empirical low molecular weight heparin on pregnancy rate or live birth rate for unexplained RIF.

Limitations, reasons for caution: The presence of heterogeneity; our exclusion criteria were not conservative leading to the inclusion of a highly heterogeneous group of women. The meta-analyses specific to objective one were limited by the control groups comprising both fertile and subfertile women with no history of RIF introducing confounding to our results.

Wider implications of the findings: Our results support considering testing for congenital and acquired thrombophila but evidence for testing various other immunological factors is limited in cases of RIF. Empirical treatments for unexplained RIF require robust randomised controlled trials to establish appropriate recommendations.

O-027 Spent Blastocyst Media and Blastocoel Fluid are not reliable DNA sources for preimplantation genetic diagnosis of aneuploidies and monogenic disorders

V. Romanelli[1], L. Girardi[1], D. Cimadomo[2], C. Patassini[1], C. Scarica[2], M. Albricci[2], M. Stoppa[2], A. Cecchele[1], M. Poli[3], F.M. Ubaldi[2], L.F. Rienzi[2], A. Capalbo[1]

[1]Genetyx, Molecular Biology Laboratory, Marostica, Italy
[2]Clinica Valle Giulia, Genera reproductive medicine center, Rome, Italy
[3]Reproomics, Molecular Biology, Amsterdam, The Netherlands

Study question: Is DNA from Spent Blastocyst Media (SBM) and Blastocoel Fluid (BF) a reliable template for preimplantation aneuploidy testing (PGD-A) and/or PGD for monogenic disorders (PGD-M)?

Summary answer: PGD-A/PGD-M analysis using BF and SBM-derived DNA is unreliable due to high diagnostic failure rate and inconsistency with results derived from trophectoderm biopsy.

What is known already: BF has been suggested as a reliable source of embryonic DNA (eDNA) for the assessment of blastocyst chromosomal constitution. BF aspiration entails a smaller degree of invasiveness compared to trophectoderm (TE) biopsy. The literature on the use of BF as source of eDNA for PGD/PGA reports extremely conflicting results and recommendations. Recently, attempts to use eDNA collected in SBM as a template for PGD have been made with poor results. To add further data on both these novel applications, we performed a prospective study investigating the reliability of BF and SBM for clinical diagnostics in PGD cycles.

Study design, size, duration: Prospective cohort blinded study performed between December 2015 and December 2016. Three groups of samples were

analyzed: BF (n = 80), SBM (n = 42) and TE (n = 84). PGD-A was performed on 23 BF-TE pairs; PGD-M was performed on 38 BF-SBM-TE trios, 19 BF-TE pairs and 4 SBM-TE pairs. TE biopsy results were used as control to assess the reliability of BF- and SBM-based diagnosis.

Participants/materials, setting, methods: SBM (25ul) and BF samples were collected from expanded blastocysts, PGD-A on BF was performed by next-generation sequencing (NGS) and compared to qPCR outcomes generated by the corresponding TE. PGD-M analysis included 10 different disorders. Genotyping analysis was performed for the three study groups using 59 TaqMan probes: 48 for informative SNP and 11 for direct mutation analysis. A total of 311 probes were tested for TE, 286 for BF and 242 or SBM.

Main results and the role of chance: PGD-A in BF showed 60.9% amplification failure (AF) rate (n = 14/23;95%IC=38.5–80.3); discordance between BF and TE was 17.4% (n = 4/23;95%IC=4.9–38.8) and concordance 21.7% (n = 5/23; 95%IC=7.5–43.7). Sensitivity per chromosome was 66.7% (n = 4/6;95% IC=11.8–61.6) and specificity 91.1% (n = 185/203;95%IC=95%IC=86.6–94.7). For PGD-M genotyping assays, 69.6% (n = 199/286; 95%IC=63.9–74.9) and 10.7% (n = 26/242; 95%IC=7.1–15.3) of probes showed AF on BF and SBM, respectively. Discordant results in 14.3% of BF (n = 41/286; ,95%IC=10.5–18.9) and 35.5% of SBM (n = 86/242; ,95%IC=29.5–41.9) were due to allele drop-out (ADO) and artifacts/contamination. ADO occurred for 12.2% (n = 35/286; 95% IC=8.7–16.6) of probes in BF; artifacts/contamination occurred in 2.1% (n = 6/286; 95%IC=0.8–4.5). For amplified probes from SBM, ADO occurred in 17.4% (n = 48/242;95%IC=12.8–22.7) while artifacts/contamination occurred in 15.7% (n = 38/242;95%IC=11.4–20.9). TE analysis reported just 0.3% of ADO (n = 1/311;95%IC=0.01–1.8) and no amplification failure (n = 0/311). Overall, concordant results were obtained for 16.0% (n = 46/286;95%IC=12.0–20.9) and 53.7% (n = 130/242;95% IC=47.2–60.1) of probes on BF and SBM, respectively. Haplotype reconstruction for PGD-M has been successful and consistent compared to TE in only 3.5% of BF (n = 2/57;95%IC=0.4%-12.1%) and 21.4% of SBM (n = 9/42; 95% IC=10.3–36.8). SBM showed higher amplification and consistent results compared to BF (P < 0.05). Considering probes for direct mutation analysis, AF in SBM was 18.3% (n = 9/49; 95%IC=8.7–32.0) and concordance 51.0% (n = 25/49;95% IC=36.4–65.6); while in BF 70.7% (n = 41/58;95%IC=57.3–81.9) and 15.5% (n = 9/58;95%IC=7.3–27.4) respectively.

Limitations, reasons for caution: It does not exist a standard protocol for BF and SBM samples' retrieval. This may limit the reproducibility and reliability of the procedure across different studies. DNA in BF and SBM may originate from apoptotic cells and contamination and this hypothesis has not been tested in the study.

Wider implications of the findings: BF and SBM cannot be considered reliable sources of eDNA for diagnostic purposes, especially due to significantly lower amplification rates compared to TE biopsy. However, BF and SBM can still be considered important specimens for research purposes, which could contain novel biomarkers of reproductive competence beyond chromosomal constitution.

Trial registration number: None.

O-028 Development and application of a novel strategy to explore blastocoel fluid and spent culture media as a source of embryonic DNA

D. Babariya[1,2], A. Manoharan[3], C. Welch[4], A. Kung[4], K. Spaeth[4], S. Munne[3], A. Coates[5], D. Wells[1,2]

[1]Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK

[3]Recombine, USA,
[4]Reprogenetics, USA,
[5]Oregon Reproductive Medicine, USA,

Study question: Is blastocoel fluid and/or spent culture media a reliable source of embryonic DNA and could they be potentially used for non-invasive preimplantation genetic testing (PGT)?

Summary answer: Blastocoel fluid and spent culture media contain embryonic DNA. The sex of all the embryos was correctly detected from spent culture media samples.

What is known already: PGT is used in many clinics to identify genetically normal IVF embryos for transfer. Genetic material is obtained via biopsy of blastomeres (cleavage stage) or trophectoderm cells (blastocysts). Embryo biopsy requires highly skilled personnel and expensive equipment, yet even in experienced hands the invasive nature of the method poses a potential risk to viability. To reduce costs associated with biopsy and minimise the possibility of damage, blastocoel fluid and spent culture media are being explored as sources of genetic material for non-invasive PGT. However, the minute quantity and degraded nature of cell free DNA poses problems for conventional amplification methods.

Study design, size, duration: A novel method was developed allowing amplification of minute quantities of DNA present in samples of blastocoel fluid and spent media (i.e. the medium in which the embryo was cultured). After validation, the method was applied to 21 blastocyst stage embryos donated for research by 5 IVF patients undergoing PGT for aneuploidy (PGT-A). A total of 16 blastocoel fluid samples and 21 spent media samples were investigated for the presence of embryonic DNA.

Participants/materials, setting, methods: Cryopreserved blastocysts were warmed and incubated in ~3 μl culture media droplets overnight. Blastocoel fluid samples were aspirated, added to ~2 μl drops of buffer, then placed in microcentrifuge tubes. Thereafter, embryos were transferred to new drops of medium and the spent media was collected. Additionally, control media droplets (no embryo exposure) were collected. The samples were amplified using a novel multiple displacement amplification strategy, optimised for degraded DNA, and subsequently subjected to next generation sequencing.

Main results and the role of chance: Initial validation of the new method was done using a heterogeneous mixture of over 200 short DNA fragments (70-100 bp) at different concentrations ranging from 1 pg to 1000 pg. Following amplification, next generation sequencing (NGS) showed that >90% of the fragments had been successfully amplified.

Moving onto analysis of embryo samples, successful amplification was observed in all the blastocoel fluid and spent culture media samples (100%). To assess the extent of genome amplification in these samples, PCR was used for the detection of 224 distinct sequences, including multiple sites on each chromosome. In general, fewer targets amplified from blastocoel fluid samples. Amplification and analysis of the control media droplets confirmed absence of human DNA.

The embryos were also tested using NGS applied to biopsied trophectoderm cells and the results compared to data from blastocoel fluid and spent media. A PCR-based assay for detecting the presence of the Y-chromosome successfully identified all of the male samples (5/5) in spent media samples. Conversely, Y-chromosome material was only identified in 25% of blastocoel fluid samples (1/4). Preliminary analysis of NGS data from spent media samples showed the chromosomal copy number concordance of 95.65% with the trophectoderm samples of the embryos.

Limitations, reasons for caution: At the time of writing the sample size is relatively modest. Additionally, assessment of concordance between blastocoel fluid/spent culture medium and results following traditional embryo biopsy overestimates discrepancies as the assumption is that none of the embryos are mosaic, which is unlikely to be true.

Wider implications of the findings: Noninvasive PGT would be revolutionary, reducing risks to the embryo and increasing patient access by lowering costs. Spent culture media appears to be a superior source for embryonic DNA as compared to blastocoel fluid. Moreover, it represents the least invasive and least expensive approach for sampling genetic material.

Trial registration number: not applicable.

O-029 Non-Invasive PGS reveals the existence of complementary aneuploidy between DNA obtained from trophectoderm biopsy versus DNA in spent culture medium in the same embryo

M. Vera-Rodriguez[1], A. Diez-Juan[1], S. Martinez[1], V. Peinado[1], A. Mercader[2], I. Moreno[1], D. Valbuena[1], D. Blesa[1], C. Simon[1,2,3,4,5], C. Rubio[1]

[1]IGENOMIX, Valencia, Spain
[2]Instituto Valenciano de Infertilidad, IVI, Valencia, Spain
[3]Department of Obstetrics and Gynecology, Valencia University, Valencia, Spain
[4]Department of Obstetrics and Gynecology, School of Medicine, Stanford University-CA, U.S.A.
[5]Department of Obstetrics and Gynecology, Baylor College of Medicine, TX, U.S.A.

Study question: What are the aneuploidy concordance rates within the same embryo between trophectoderm biopsy (PGS) and DNA analysis of the embryo spent culture medium (NI-PGS).

Summary answer: The chromosomal diagnosis obtained by non-invasive PGS is possible, revealing complementary aneuploidies in gains or losses to the obtained by PGS in a trophectoderm biopsy.

What is known already: Preimplantation genetic screening (PGS) 2.0 is gaining momentum in reproductive care with several randomized studies demonstrating its usefulness. Nevertheless, this technique requires an embryo biopsy, which results in an invasive procedure for the embryo and increases the workload for the clinic. The non-invasive diagnosis methods are the main goal of the current personalized medicine. Non-invasive PGS (NI-PGS) aims to diagnose the chromosomal status of the embryo from the DNA present in the spent culture medium in which the embryo has been cultured. However, the efficiency and reliability of NI-PGS are yet to be determined before its clinical application.

Study design, size, duration: We evaluate aneuploidy concordance rates within the same blastocyst (n = 6) between the PGS diagnosis from trophectoderm biopsy versus the results obtained from DNA in spent culture medium analyzed using NI-PGS. Then, whole blastocysts were disassembled into single cells and analyzed by fluorescent in situ hybridization (FISH) for those aneuploid chromosomes by PGS or NI-PGS, with a total of 8 chromosomes analyzed. This study was performed between September 2016 and January 2017 with IRB approval (#1501-IGX-003-CS).

Participants/materials, setting, methods: Trophectoderm biopsies underwent whole genome amplification, a library was generated from dsDNA and loaded into a PGM (Thermo Fisher Scientific Inc.). For NI-PGS, 20 µl of spent culture medium in which the embryos were cultured were amplified, libraries were generated and sequenced in a S5 (Thermo Fisher Scientific Inc.). Finally, whole blastocysts were fixed and individual cells were analyzed by FISH (7.5 ± 3.1 cells per embryo) using telomeric/centromeric probes (Abbott) for the affected chromosomes.

Main results and the role of chance: From the 6 aneuploid embryos analyzed (Table 1), three (#1, #2, #4) showed complementary aneuploidies between day-5 PGS and NI-PGS. Whole-blastocyst FISH for these embryos confirmed PGS diagnosis and the mirror image of NI-PGS further revealing the mosaic constitution for the indicated chromosomes. Two embryos (#3, #5) were diagnosed with mosaic aneuploidies in the trophectoderm biopsy, but these aneuploidies were not confirmed by NI-PGS. Nevertheless, after FISH analysis, these two blastocysts were shown to be mosaics at low-medium degree (20–50% aneuploid cells) for the chromosomes of interest. Finally, embryo #6 had one extra aneuploidy detected by NI-PGS in comparison to PGS, and the FISH corroborated the information observed by NI-PGS, although with a mosaic pattern.

Table 1 Chromosome results per technique.

Blastocyst	Day-5 PGS	NI-PGS	Chromosome analyzed (FISH)	1 copy (FISH)	2 copies (FISH)	3 copies (FISH)	Result (FISH)
#1	+10+15	-10-15	10	0%	0%	100%	Trisomy
			15	25%	0%	75%	Mosaic
#2	+19	-19mos	19	25%	12.5%	62.5%	Mosaic
#3	+2 mosaic	46 XX	2	0%	80%	20%	Mosaic
#4	+15	-15mos	15	10%	0%	90%	Mosaic
#5	+13q mosaic	46 XX	13q	0%	50%	50%	Mosaic
#6	+16	-1 +16	1	0%	33.3%	66.7%	Mosaic
			16	0%	71.4%	28.6%	Mosaic

Limitations, reasons for caution: This study was limited by the sample size and the number of cells analyzed by FISH. In addition, we cannot discard maternal contamination, especially in those cases in which NI-PGS showed an euploid female pattern, masking the proper analysis of aneuploidy discrepancies and the potential identification of mosaicism.

Wider implications of the findings: Here we show that NI-PGS diagnosis is possible, and can be complementary in term of gains/losses to the obtained by day-5 PGS. Our results from the same whole-blastocyst analysis provides explanation for the discordances and supports that maternal DNA contamination needs to be reduced to provide a consistent NI-PGS diagnosis.

Trial registration number: NA.

O-030   Superiority of array Comparative Genome Hybridization (aCGH) over Next Generation Sequencing (NGS) for PGD for reciprocal translocations

T. Escudero[1,2], A. Erin[3], M. Santiago[2]

[1]Reprogenetics, aCGH Team, Livingston- New Jersey, U.S.A.
[2]Reprogenetics- A CooperSurgical Company, Research, Livingston- New Jersey, U.S.A.
[3]Reprogenetics- A CooperSurgical Company, Genetic Counselor, Livingston- New Jersey, U.S.A.

Study question: Is the telomeric resolution of Next Generation Sequencing (NGS) always superior to aCGH?

Summary answer: Though NGS resolution is superior to aCGH, specific genomic areas are better targeted for one technique; rendering aCGH a better technique in some circumstances.

What is known already: The incorporation of Complete Chromosome Screening (CCS) techniques has revolutionized the PGD/PGS worlds. The ability to identify aneuploidy, partial aneuploidy and mosaicism has helped select normal embryos for transfer, thus increasing pregnancy rates. CCS has also opened the door for a variety of patients carrying structural chromosome abnormalities which previously were not amenable to PGD, even with tailor made FISH protocols (deletions, insertions, inversions, etc). The resolution of these techniques in the telomeric regions of the chromosomes will determine their usefulness in cryptic translocations or translocations with telomeric breakpoints.

Study design, size, duration: This retrospective study compare two groups. aCGH group has 20,720 embryos from 3,733 cycles from centers all over USA. Likely the NGS group has 20,720 embryos from 3,926 cycles from centers all over USA. The span of the study is from May 2015 to June 2016.

Participants/materials, setting, methods: Embryo samples were collected for these two groups and were processed by NGS or aCGH depending on each group. The samples were analyzed for partial aneuploidies and the position of the breakpoint was noted.

Main results and the role of chance: For aCGH group, 1,720 partial aneuploidies were detected. Of those partials only 24 were located in a telomeric band. For the NGS group, 3,358 partials were obtained out of those 52 were located in a telomeric band. This study shows the specificity of each technique for different telomeres (table 1).

Telomere	aCGH	NGS	Telomere	aCGH	NGS
1p	NO	YES	1q	YES	NO
2p	YES	YES	2q	NO	YES
3p	YES	YES	3q	YES	NO
4p	NO	YES	4q	YES	NO
5p	YES	YES	5q	NO	NO
6p	NO	YES	6q	NO	YES
7p	NO	YES	7q	NO	YES
8p	NO	NO	8q	NO	YES
9p	NO	YES	9q	YES	YES
10p	NO	YES	10q	YES	YES
11p	NO	NO	11q	NO	YES

Continued

Telomere	aCGH	NGS	Telomere	aCGH	NGS
12p	NO	YES	12q	NO	YES
			13q	YES	NO
			14q	NO	YES
			15q	NO	YES
16p	NO	YES	16q	NO	YES
17p	NO	YES	17q	NO	NO
18p	NO	YES	18q	NO	YES
19p	NO	NO	19q	NO	YES
20p	YES	YES	20q	YES	NO
			21q	YES	YES
			22q	YES	NO
Xp	NO	NO	Xq	NO	NO
Yp	NO	NO	Yq	NO	NO

Limitations, reasons for caution: aCGH and NGS were performed following Illumina protocols. Other protocols from other companies may have different results.

Wider implications of the findings: Preparatory tests of the anticipated technique in a PGD case for small terminal translocations are crucial. While new technologies such as NGS allow for more detailed information regarding some embryo characteristics (e.g. mosaicism), the importance of older technologies, e.g aCGH, particularly in structural chromosome aberration cases, should not be discounted.

Trial registration number: N/A.

O-031 Development, validation and first clinical application of a novel ultra-rapid comprehensive chromosome screening technique utilising an array based nano scale quantitative DNA amplification technology

K. Spath[1,2], N. Kubikova[1,2], M. Whitney[3], M. Vaid[3], G. Rozis[3], V. Couchman[3], K. Glynn[3], S. Batha[3], S. Alfarawati[1], E. Fragouli[1], D. Wells[1,2]

[1]Reprogenetics UK, Institute of Reproductive Sciences, Oxford, United Kingdom
[2]University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Oxford, United Kingdom
[3]The Lister Fertility Clinic, Lister Hospital, London, United Kingdom

Study question: Can a low-cost methodology be created, which is capable of simultaneously performing ultra-rapid aneuploidy detection and mitochondrial DNA (mtDNA) quantification in blastocyst biopsy specimens?

Summary answer: The technique developed enables rapid, high-accuracy aneuploidy detection, at comparatively low cost and has the capacity to quantify mtDNA, providing extra information on embryo viability.

What is known already: Morphology-based embryo selection is incapable of revealing aneuploidy, one of the principal causes of implantation failure and miscarriage. Therefore, aneuploidy screening has been proposed to assist in the identification of euploid embryos. However, most widely used techniques typically require 24-hours or more. Given that some blastocysts are not ready for biopsy until late on day-5 or even day-6, cryopreservation is necessary to provide sufficient time for testing. The addition of cryopreservation represents an extra risk to the embryos and a further cost to the patients. High costs, complex cycles and treatment delays associated with testing, combine to restrict patient access.

Study design, size, duration: Prior to clinical implementation the methodology was extensively validated. Initially, a total of 111 3-cell and 5-cell samples isolated from two euploid and 13 different established aneuploid cell lines were tested. The test was then applied to 30 donated surplus embryos. Following embryo biopsy at the blastocyst-stage, trophectoderm samples were tested and the results compared to results obtained from the corresponding embryos

which were assessed utilising a well-established highly validated next generation sequencing (NGS)-based technique.

Participants/materials, setting, methods: Following validation, the method was clinically applied to 37 patients referred for chromosome screening due to either previous miscarriage(s), IVF failure(s) or advanced maternal age. Average female age was 38.9 ± 3.4, ranging from 31 to 45 years of age. Blastocyst-stage embryos were biopsied on day-5 post fertilisation. 25 patients had at least one euploid embryo available and received a fresh embryo transfer early in the morning of day-6.

Main results and the role of chance: Of the cell samples tested during the initial validation phase, 99.1% (110/111) were correctly identified as euploid or aneuploid. Among all chromosomes analysed, copy number was assigned correctly to 99.9% (2660/2664). Of the blastocysts analysed during the preclinical validation phase, 96.7% (29/30) gave results consistent with those obtained following testing of a separate biopsy specimen using NGS, while at the level of individual chromosomes agreement was seen for 99.7% (718/720). Clinical implementation, saw the application of the method to 173 blastocysts. No result was obtained from eleven embryos (6.4 %). The aneuploidy rate was 63.6 % (103/169). 25 patients had at least one euploid embryo available and received a fresh embryo transfer in the morning of day-6 post-fertilisation. In total, 28 embryos were transferred (1.12 per cycle), of which 18 (64.3 %) implanted, resulting in a pregnancy rate of 64 % (16 patients). Two patients miscarried, hence ongoing pregnancy rate was 56.0 % (per transfer). Overall ongoing pregnancy rate per cycle was 37.8 % (14/37). Interestingly, a significant correlation (r=0.3; p = 0.0013) between advancing female age and increasing mtDNA copy number was observed. Moreover, aneuploid embryos carried significantly (p = 0.0002) higher mtDNA quantities as compared to euploid embryos, independently of female age.

Limitations, reasons for caution: The reported method is likely to be less sensitive than some others (e.g. NGS) for the detection of segmental abnormalities and chromosomal mosaicism. Comparing results generated using the new method with those obtained using a separate biopsy specimen likely overestimates discrepancies, since it is known that some blastocysts are mosaic.

Wider implications of the findings: We report the first application of a chromosome-screening technique, providing results at relatively low cost and substantially reduced turn-around times (5 h) compared to most methods, potentially improving the logistics of utilisation in IVF clinics. The fact that cryopreservation is not essential further simplifies the procedure and reduces costs for patients.

Trial registration number: Not applicable.

O-032 A novel next generation sequencing (NGS)-based comprehensive chromosome screening (CCS) platform that provides accurate copy number and genotyping in parallel from a single trophectoderm biopsy

D. Marin[1], R. Zimmerman[2], C. Jalas[2], X. Tao[2], Y. Zhan[2], R. Scott[1], N. Treff[1]

[1]Reproductive Medicine Associates of New Jersey, Molecular Biology, Basking Ridge, U.S.A.
[2]Foundation for Embryonic Competence, Clinical Genetics, Basking Ridge, U.S.A.

Study question: Can an NGS-based CCS methodology simultaneously provide correct evaluation of aneuploidy and precise single nucleotide polymorphism genotyping in human blastocysts from a single trophectoderm biopsy?

Summary answer: This novel NGS-based CCS platform provided 98.7% concordant aneuploidy diagnoses and 99.8% concordant genotype predictions. Genotypes provided for accurate polyploidy detection and sibling embryo discrimination.

What is known already: Most contemporary NGS-based CCS platforms require whole genome amplification (WGA). As a result, only shallow sequencing is obtained, preventing simultaneous analysis of genotypes. Genotyping data from SNP arrays has been shown to provide an opportunity for detection of contamination, triploidy, uniparental disomy, and parental origins of aneuploidy. In addition, genotyping data has been used to determine siblingship of embryo biopsies allowing for the co-development of new biomarkers of reproductive potential. Targeted amplification of specific locations in the genome, instead of WGA, allows for deep sequencing to obtain accurate genotypes.

Study design, size, duration: Diagnostic test. 128 blinded samples of 12 different cell lines were tested by targeted (t)NGS and compared for consistency

with their known karyotypes. 32 human embryos diagnosed as aneuploid by qPCR-based CCS were rebiopsied, blinded and processed by tNGS. 6-cell samples from a cell line were compared to purified gDNA from the same cell line to determine genotyping accuracy. Multiple biopsies were performed on each of 10 blastocysts to further validate genotyping precision.

Participants/materials, setting, methods: Samples were processed by a proprietary tNGS platform. Copy number results of all blinded samples were compared to either cell line karyotypes or previous qPCR-based CCS diagnoses. Accurate genotyping of 2690 single nucleotide polymorphisms (SNP) obtained after tNGS was validated by comparing consistency between samples from same cell line or between biopsies from the same blastocysts. Genotyping data was used to identify triploid samples based on altered allele ratios and to perform DNA fingerprinting.

Main results and the role of chance: 99.2% (123/124) of the randomized blinded samples of 12 cell lines presented concordant results across all chromosomes. Overall consistency of chromosome copy number assignment was 99.97 (2975/2976). Consistency of normal vs abnormal diagnosis between qPCR and tNGS-based CCS of rebiopsied blastocysts was 98.7 % (76/77). TNGS-predicted a median allele ratio in known triploid cell line controls of 0.336 (0.329–0.343; 95% CI), while diploid samples was 0.437 (0.428–0.448)(p=8.3e-19). A blastocyst triploidy frequency of 0.43% was observed, with 32 out of 7516 embryos falling within the triploid range. Embryos with available parental DNA were used to confirm triploidy and all were found to be of maternal origin. Genotyping concordance among 12 6-cell-aliquot samples and purified gDNA from the same cell line was 99.839 (99.707–99.907, 95% CI). When genotypes of multiple biopsies from the same embryo where compared, the concordance rate was 99.857 (99.734–99.979, 95% CI). Genotypes of 188 embryo biopsies and gDNA of the delivered baby of 32 single embryo transfers were compared to confirm identity of the transferred embryo among siblings. In all cases the transferred embryo was correctly identified showing a mean genotype similarity of 99.73% (99.70–99.76, 95% CI) and a sibling similarity of 93.34% (93.15–93.52, 95% CI).

Limitations, reasons for caution: Although reduced in costs per diagnosis, the workflow of this novel platform requires cryopreservation of all embryos per cycle after biopsied.

Wider implications of the findings: This novel tNGS approach provides a unique opportunity to use accurate genotyping data in support of accurate copy number data in parallel, allowing for the ability to fingerprint embryos as a tool to develop new biomarkers of reproductive potential, and to identify polyploid embryos.

O-033   **Weight and waist circumference of IVF children at the age of 9 years still affected by embryo culture medium**

H. Zandstra[1], F. Feron[2], L. Smits[3], L. Brentjens[4], B. Spauwen[1], R. Van Golde[1], J. Evers[1], J. Dumoulin[4], A. Van Montfoort[4]

[1]Maastricht University Medical Center, Obstetrics & Gynaecology, Maastricht, The Netherlands
[2]Maastricht University Medical Center, Social medicine and youth health care, Maastricht, The Netherlands
[3]Maastricht University Medical Center, Epidemiology, Maastricht, The Netherlands
[4]Maastricht University Medical Center, IVF department, Maastricht, The Netherlands

Study question: Do embryo culture media used during an IVF/ICSI treatment have an effect on growth and body composition of 9-year-old singleton IVF children?

Summary answer: Nine-year-old children from the Vitrolife group have a higher bodyweight and a higher waist circumference and waist/hip ratio compared to the Cook group.

What is known already: Children born after IVF/ICSI have a lower birthweight and adverse perinatal outcome compared to children born after natural conception. Previously, we have shown that the culture medium used in an IVF/ICSI treatment affects birthweight (Dumoulin et al. 2010). After alternating assignment to embryo

culture in either G1™ Version3 (Vitrolife group) of K-SCICM (Cook group), birthweight of the resulting children was significantly higher in the Vitrolife group. This weight effect persisted during the first 2 years of life (Kleijkers et al. 2014).

Study design, size, duration: In this observational cohort follow-up study (MEDIUM-KIDS), parents of all singletons from the abovementioned study were approached after the ninth birthday of their child to participate in a further follow up. Measurements were performed between March 2014 and December 2016. Of the 294 eligible children included in the original study, 136 children (75 Vitrolife and 61 Cook) participated in the current study.

Participants/materials, setting, methods: Parents were invited to attend our clinic with their child for a single visit lasting approximately 2.5 hours. Two experienced clinicians performed the anthropometric measurements as a part of the MEDIUM-KIDS study for which also several cardiovascular parameters were collected. The following anthropometric measurements were performed by two experienced clinicians in a standardized way: height and weight of the child using calibrated scales, 4-point skinfold thickness measurements in threefold and waist/hip circumference.

Main results and the role of chance: Baseline characteristics between the participating children from the Vitrolife and Cook group were similar (mean age 9.5 years in both groups). Data (mean ± SEM) were compared using the Student's t-test. Height and height corrected for age and gender (SDS scores) were similar for the Vitrolife vs Cook group (139.3 cm ± 6.0 vs 138.8 cm ± 7.8 and -0.21 vs -0.28). Weight and weight SDS scores were higher in the Vitrolife group as compared to the Cook group (34.2 kg ± 6.6 vs 32.1 kg ±5.9 (P = 0.06) and -0.51 vs 0.11 (P = 0.02)). After correction for several potential confounding factors among which age, length and gender of the child and anthropometrics of the parents, the difference in weight attributable to culture medium was 1.7 kg (P = 0.047). Furthermore, waist circumference and waist/hip ratio were significantly higher in the Vitrolife group (61.4 cm vs 58.0 cm, (P = 0.01) and 0.86 vs 0.83, (P = 0.02), respectively) as well as subscapular skinfold (7.9 mm vs 6.6 mm P = 0.02) and truncal adiposity (1.94 cm ±0.99 vs 1.63 cm±0.88 (P = 0.05)). The peripheral skinfolds biceps and triceps were similar. After correction for confounders the difference attributable to culture medium was 2.7 mm (P = 0.044) and 0.030 (P = 0.015) for waist and waist/hip ratio and 0.15 cm (P = 0.08) for truncal adiposity.

Limitations, reasons for caution: The most important limitation of this study is the relatively low participation rate of 46%. However no differences were seen in baseline characteristics between participants and non-participants.

Wider implications of the findings: The results of our study underline the importance of structured follow-up of IVF/ICSI children to further elucidate possible long-term health effects. They should urge embryologists and manufacturers to focus on culture conditions since the early embryo is in a stage where possible long-term health effects can be triggered.

Trial registration number: NL45845.068.13.

O-034   **Effect of culture medium on cardiovascular characteristics of 9-year-old IVF/ICSI singletons**

A. Van Montfoort[1], H. Zandstra[1], L. Smits[2], J. Bons[3], A. Mulder[4], R. Touwslager[5], B. Spauwen[1], R. Van Golde[1], J. Evers[1], J. Dumoulin[1]

[1]Maastricht University Medical Center, Obstetrics and Gynaecology- GROW – School for Oncology and Developmental Biology, Maastricht, The Netherlands
[2]Maastricht University, Epidemiology, Maastricht, The Netherlands
[3]Maastricht University Medical Center, Clinical Chemistry, Maastricht, The Netherlands
[4]Antwerp University Hospital, Neonatology, Antwerpen, The Netherlands
[5]Maastricht University Medical Center, Pediatrics, Maastricht, The Netherlands

Study question: Do culture media have an effect on cardiovascular characteristics of 9-year old children born after an IVF/ICSI treatment?

Summary answer: No significant differences were observed between the Cook and Vitrolife group for bloodpressure, fasting glucose, insulin, cholesterol and TSH, nor for endothelial or glycocalyx function.

What is known already: Children born after IVF/ICSI are known to have an increased risk of adverse perinatal outcomes such as low birthweight, if compared to children born after natural conception. The Developmental Origin of Health and Disease (DOHaD) hypothesis states that lower birthweight and poor perinatal outcome can affect postnatal growth, glucose metabolism, fat distribution and vascular function. Furthermore, studies have been published in which 12-year-old IVF children already show a significantly higher systolic and diastolic blood pressure and

higher fasting glucose levels compared to naturally conceived children. Our group has shown that culture media can affect birthweight (Dumoulin et al. 2010).

Study design, size, duration: In this observational cohort study (MEDIUM-KIDS), parents of the singletons from our previous study (Dumoulin et al.) were approached for further follow up after the ninth birthday of their child. The singletons were born after an IVF/ICSI treatment performed between July 2003 and December 2006 in our clinic, when two different culture media were used alternately: either G1™ Version3 (Vitrolife) or K-SICM (Cook). Follow up measurements were performed between March 2014 and December 2016.

Participants/materials, setting, methods: Parents were invited to attend our clinic with their child for a single visit lasting approximately 2.5 hours. Two experienced clinicians performed all measurements as part of the MEDIUM-KIDS study. The following cardiovascular parameters were measured in a standardized way: blood pressure, heart rate, endothelial function by skin laser-Doppler and iontophoresis with vasodilatory drugs and glycocalyx function using Glycocheck™. A blood sample was taken after an overnight fast for insulin, glucose, TSH, and lipid analysis.

Main results and the role of chance: Of the 294 eligible children, 136 children (75 Vitrolife and 61 Cook) participated in the study. Baseline characteristics between the participating children from the Vitrolife and Cook group were similar (mean age 9.5 years in both groups). Data (mean $\pm$ SD) were analysed by Student's t-test. Both systolic and diastolic blood pressures (mmHg) were comparable: 101.2 ± 7.2 and 60.3 ± 6.5 for Vitrolife and 99.8 ± 7.6 and 60.0 ± 7.3 for Cook ($P = 0.31$ and $P = 0.81$). After an overnight fast, cholesterol, glucose, insulin, LDL, HDL and triglycerides were normal and similar between the two groups. Also TSH (mU/L) did not differ between the groups (Vitrolife 3.1 ± 1.8 and Cook 2.8 ± 1.2, $P = 0.29$). Endothelial function in the microcirculation was compared with maximum perfusion units corrected for the baseline value as a measure for vasodilation capacity. After correction for baseline, the difference for nitroprusside was -7 for Vitrolife compared to Cook ($P = 0.458$). For acetylcholine, after correction, the difference was only 0.19 for Vitrolife compared to Cook ($P = 0.98$). Also glycocalyx function was tested in a small group of the children, the results for the two groups were comparable as well (PBR 5–25 was 2.0 ± 0.33 for both groups).

Limitations, reasons for caution: The most important limitation of this study is the relatively low participation rate, however no differences were seen in baseline characteristics between participants and non-participants. With the current number of participants, this study had a power of 80% to detect a difference in systolic blood pressure of 3.6 mmHg.

Wider implications of the findings: The normal and comparable cardiovascular results for the two groups of children are reassuring for this moment. However, further research with a larger study population and the addition of a spontaneously conceived control group is necessary to gain more insight and reassurance in the cardiovascular development of IVF children.

Trial registration number: NTR4220.

O-035   Assisted reproductive technology might affect the growth of children: A prospective cohort study on 3,509 babies

Study question: What is the difference between the growth and development of singleton children conceived after infertility treatments and those conceived naturally at 6 years of age?

Summary answer: At 6 years of age, the weight and height of children conceived through assisted reproductive technology (ART) are higher than those of children conceived naturally.

What is known already: Several large cohort studies have shown a similar or even better outcome for babies conceived after frozen embryo transfer (FET) than

those conceived after fresh embryo transfer (FrET) and natural conception (NC). Meanwhile, recent studies have reported that the birth weight of FET children was significantly higher than that of NC children. Some researchers suggest that ART might affect the development of children with respect to gene expression.

Although the safety aspects of different ART techniques are important, few studies have investigated the long-term prognosis of children born through ART.

Study design, size, duration: This was a nationally representative prospective cohort study conducted in Japan, a racially homogeneous country. A total of 4,095 mothers who conceived through ART at the Japanese Institution of Standardizing Assisted Reproductive Technology (JISART), a group of ART clinics in Japan, participated in the study between October 1, 2008 and November 30, 2009. A total of 3,509 babies born at these clinics in 2009 were targeted for follow-up.

Participants/materials, setting, methods: This study was conducted in 26 ART clinics in Japan. Each baby was born after FET (n = 1,223), FrET (n = 1,005), or NC (n = 1,281). Embryo freezing was performed by vitrification. The data on their growth and development (KIDS developmental scale) at 18 months and 6 years of age were obtained using a questionnaire. Weight, height, and KIDS scale score were compared between each treatment group by analysis of variance.

Main results and the role of chance: Finally, 1,830 (52.2%) participants undertook the follow-up survey.

The birth weight of singleton children conceived via FET, FrET, and NC was 3080, 3024, and 2998 g; that after 18 months was 10451, 10517, and 10375 g; that at 6 years of age was 20.3, 20.4, and 19.7 kg, respectively. The birth height of singleton children conceived via FET, FrET, and NC was 49.1, 49.1, and 48.4 cm; that after 18 months was 80.2, 80.5, and 80.4 cm; that at 6 years of age was 114.8, 115.3, and 114.2 cm, respectively.

After adjustment for confounders (gestational weeks at delivery, sex, child's age-in-days from delivery, parity), the statistical analysis between three groups was performed.

Although FET singleton babies had a significantly higher birth weight and height than the NC singleton babies (P < 0.001), the average individual weight curves showed that this difference disappeared before 18 months of age and reappeared at 6 years of age. In contrast, there was no significant difference in the KIDS score between each treatment group at 6 years of age.

Limitations, reasons for caution: Slight differences in the ART procedure and the culture medium at each IVF clinic might affect childhood growth. As it was a volunteered survey, the response rate was relatively low; therefore, it is necessary to consider the effect of selection bias on each group.

Wider implications of the findings: Although there was no evidence of adverse effects on health up to 6 years of age, it might be necessary to reconsider the effect on growth and epigenetic implications in children born through ART.

Trial registration number: None.

O-036   Effect of parental and treatment aspects of IVF/ICSI on perinatal outcomes: a nationwide study of IVF/ICSI singletons born in The Netherlands between 2000 and 2011

Study question: Do parental and treatment aspects of in vitro fertilization with or without intracytoplasmic sperm injection (IVF/ICSI) affect perinatal outcomes in singleton pregnancies?

Summary answer: Both parental characteristics and treatment aspects of IVF/ICSI have effects on perinatal outcomes in singleton pregnancies.

What is known already: Previous studies have shown that singleton pregnancies resulting from IVF/ICSI are at risk of preterm birth, and children born after IVF/ICSI have a lower birth weight and an increased risk for congenital abnormalities. To date, it remains to be fully elucidated, which aspects of IVF/ICSI treatment impact perinatal outcomes and whether these are independent of parental characteristics.

Study design, size, duration: All 13 IVF clinics in The Netherlands provided data on all assisted reproductive technology (ART) treatment cycles performed between January 1st, 2000 and January 1st, 2011 that resulted in an ongoing pregnancy (n = 37.683). Using probabilistic data-linkage, these data were linked to the Perinatal Registry Netherlands which includes all children born in The Netherlands in the same time period (n = 2.548.977). 31.184 treatment cycles were successfully linked to their perinatal outcome (83%).

Participants/materials, setting, methods: Analysis were limited to singletons born after IVF, ICSI or frozen-embryo transfers (FET) (n = 23.588). In order to assess independent effects, multivariable logistic or linear regression models were constructed including parental characteristics (i.e. age, subfertility duration, treatment indication) and treatment characteristics (i.e. treatment type, culture medium, number of embryos transferred). We assessed the impact of parental and treatment aspects of IVF/ICSI on perinatal outcomes (birth weight, occurrence of premature birth, congenital malformation and perinatal death).

Main results and the role of chance: Longer subfertility duration was associated with lower birth weight (adjusted difference [adj β] -7 gram birth weight for each added year of subfertility, 95% CI -11 to -4). "Male factor" as indication for treatment was associated with a higher birth weight compared to "tubal factor" (adj β 36 g, 95% CI 10 to 61) and lower risk of premature birth (adj OR 0.7, 95% CI 0.6 to 0.8). "Female non-tubal factor" as indication for treatment was associated with a higher risk of congenital malformations compared to "tubal factor" (adj OR 1.6, 95% CI 1 to 2.6). Birth weight was higher in children born after FET as compared to children born after fresh embryo transfer (adj β 96 g, 95% CI 79 to 112). ICSI (fresh embryo) babies had higher birth weight than IVF (fresh embryo) babies (adj β 25 g, 95% CI 9 to 41) and were less likely to be born prematurely (adj OR 0.8, 95% CI 0.7 to 0.9). The risk of very premature birth or perinatal death was not affected by duration of subfertility, indication for treatment or any ART treatment characteristics.

Limitations, reasons for caution: Due to limited information on parental characteristics we cannot exclude the possibility of residual confounding by lifestyle factors, and due to the observational nature of our study we cannot assess causality.

Wider implications of the findings: Parental and treatment aspects of IVF/ICSI both affected perinatal outcomes. This highlights the sensitivity of the early embryo for parental conditions and for the in vitro environment. Whether to embark on ART and which procedures to follow, should take chances of ongoing pregnancy aswell as perinatal outcomes into account.

Trial registration number: Not applicable.

O-037   How to compare outcomes of IVF/ICSI patients with different backgrounds and treated by different regimens

Study question: Is it possible to compare ovarian stimulation outcomes in patient groups with different background characteristics and stimulation regimens?

Summary answer: Total gonadotropin dose per oocyte is associated with the quality of ovarian stimulation and is useful when comparing outcomes of patient groups with different origins.

What is known already: The selection of patients for IVF/ICSI as well as ovarian stimulation protocols vary between clinics and countries, which makes it difficult to compare outcomes of treatments with differing practices. Total gonadotropin dose per number of oocytes retrieved (dose/oocyte) is a measure of ovarian response to stimulation. Previous research from our group has shown that a lower dose/oocyte indicates better odds for live birth than a higher dose/oocyte. In this study, we wanted to examine the usefulness of this parameter in cases where direct comparison of outcomes is impossible.

Study design, size, duration: Retrospective cohort study of 17,728 first-time ovarian stimulation cycles for non-donor IVF/ICSI performed in 2008–2012 in the U.S. (National Assisted Reproductive Technology Surveillance System, n = 14,230) and Finland (LUMI database, n = 3,498). Women aged ≤40 years undergoing stimulation with long gonadotropin-releasing hormone (GnRH) analogue (n = 9,175) or with GnRH antagonist protocols (n = 5,630) were included. All had >3 oocytes retrieved before elective single embryo transfer on day 2/3 or day 5/6, followed by cryopreservation of supernumerary embryos.

Participants/materials, setting, methods: We compared three groups of patients treated in different settings: transfer on day 2/3 in Finland (Group A, n = 3,498), transfer on day 3 in the United States (Group B, n = 1,756), and transfer on day 5/6 in the U.S. (Group C, n = 12,474). Differences in patient and stimulation characteristics, and cumulative live birth rates using embryos from the same stimulation (cLBR) were examined. Total gonadotropin dose/oocyte was analysed using generalized linear equations accounting for confounding factors.

Main results and the role of chance: Group A had the highest proportion of patients aged ≥35 years (35.3% vs. Group B: 23.6% vs. Group C: 22.1%, P < 0.0001). However, subjects in Group A received the lowest gonadotropin doses (1756.7 ± 698.8 (mean ± SD) vs. 2218.8 ± 1167.4 vs. 2314.9 ± 1083.3 IU, respectively, P < 0.0001) and had the lowest numbers of oocytes retrieved (12.4 ± 6.0 vs. 14.6 ± 7.1 vs. 18.8 ± 8.2, respectively, P < 0.0001). Patients in Group C were treated with the highest gonadotropin doses and had the highest numbers of oocytes retrieved. cLBR was lowest in Group A (1639/3498, 46.9%), intermediate in Group B (933/1756, 53.1%) and highest in Group C (8702/12474, 69.8%, P < 0.0001).

Due to multicollinearity, analysis of raw data could not determine whether the high numbers of oocytes in Group C could be explained by higher stimulation doses, by better ovarian reserve or by another factor. Dose/oocyte was different across the groups (Group A: 188.9 ± 142.3; Group B: 201.7 ± 183.4; Group C: 155.9 ± 176.4 IU/oocyte, P < 0.0001). After correction for confounding factors, dose/oocyte was similar in Groups A and B (238.1 ± 286.3 vs. 234.0 ± 275.8, P = 0.6) but was significantly lower in Group C (155.2 ± 130.7, P < 0.0001).

Limitations, reasons for caution: Due to classification differences, infertility diagnoses were not accounted for in the present analysis.

Wider implications of the findings: The lowest dose/oocyte in the blastocyst group indicates that this group had the highest odds for live birth already after oocyte retrieval. Adjusted data show that these patients also had the best ovarian reserve. Dose/oocyte is a useful tool for comparison when the groups examined are not directly comparable.

Trial registration number: not applicable.

O-038   The number of oocytes retrieved during IVF: a balance between efficacy and safety

A. Magnusson[1], K. Källén[2], A. Thurin-Kjellberg[3], C. Bergh[4]

[1]Institute of Clinical Sciences- Sahlgrenska Academy, Department of Obstetrics and Gynecology- Reproductive Medicine, Göteborg, Sweden
[2]Tornblad Institute- University of Lund, Department of Reproduction Epidemiology, Lund, Sweden
[3]Institute of Clinical Sciences- Sahlgrenska Academy, Obstetrics and Gynecology- Reproductive Medicine, Gothenburg, Sweden
[4]Institute of Clinical Sciences- Sahlgrenska Academy, Department of Obstetrics and Gynaecology- Reproductive Medicine, Gothenburg, Sweden

Study question: How does the number of oocytes retrieved in one IVF cycle influence live birth rates and safety?

Summary answer: Live birth rates increased up to 20 oocytes retrieved, when assessed cumulatively, including fresh and frozen cycles and severe side effects followed a similar pattern.

What is known already: Previous studies have shown that the number of oocytes retrieved for IVF is a positive predictor of live birth in fresh cycles. With an increasing single embryo transfer (SET) policy in the world more embryos are available for freezing and thawing cycles (FET). Thus, the cumulative pregnancy and LBR after fresh and subsequent FET become more important as an efficacy variable.

Study design, size, duration: Data were collected from The Swedish National Quality Registry of Assisted Reproduction (Q-IVF) and included all fresh cycles, using patients own gametes, performed during 2007–2013 and the accompanying FET cycles. In total, 39 387 women undergoing 77 956 fresh IVF/ICSI cycles and 36 270 FET cycles were included. For investigating the association between number of oocytes and severe complications the data from Q-IVF were cross linked with the National Patients Registry.

Participants/materials, setting, methods: Generalized Estimating Equations analyses were used to explore the association between the number of oocytes retrieved and live birth rates for fresh cycle and cumulatively after fresh and consecutive FET cycles. Both linear and quadratic models were used. Adjustments were made for maternal age, year of treatment, number of previous failed fresh cycles, previous children, and IVF /ICSI. The association between the number of oocytes retrieved and severe complications was investigated in a similar way.

Main results and the role of chance: The median number of oocytes retrieved was 9 (intequartile range 5–12). The median age of women was 34 years The rate of fresh SET in this cohort was 73%. LBR in fresh cycle increased by the number of oocytes retrieved with a plateau from 11 oocytes., where the LBR was 30.3% for a 34 year old woman. Cumulatively, a steady increase in LBR was observed, up to around 20 oocytes, where the cumulative LBR was 45.8%. The observed rates and the predicted, second degree curves fitted well both for fresh cycles and on a cumulative basis. In the linear multivariate model, a significant increase in cumulative LBR was observed per oocyte retrieved (OR 1.064, 95% CI 1.061 to 1.067). Maternal age, previous failed cycles and ICSI (vs IVF) affected cumulative LBR negatively while year of treatment and previous live birth after IVF affected LBR positively, though adjusting for these factors had only a marginal impact on the estimates of the association between the number of retrieved oocytes and LBR. The presence of the severe complications ovarian hyperstimulation syndrome (OHSS) and tromboembolic events were mainly observed when a high number of oocytes were retrieved and the treatment resulted in pregnancy.

Limitations, reasons for caution: Even though most frozen embryos are thawed and transferred within a year from retrieval there is still some cryopreserved embryos left unused giving a possibility that the cumulative LBR for the cycles performed 2010–2013 might be slightly higher.

Wider implications of the findings: The results from this large, national study including all fresh IVF/ICSI cycles and their subsequent FET cycles performed in private and public clinics in Sweden 2007–2013 are of crucial importance for the IVF society as well as for patients undergoing IVF, by taking both efficacy and safety into account.

O-039   Mitochondrial transfer- can it improve oocyte quality?

J. Cohen

Tyho-Galileo Research Laboratories, Livingston- New Jersey, U.S.A.

Abstract text

Changes in genomic expression may occur after assisted reproduction, but such alterations are rarely intentional and may be transitional. One of the mechanisms that could lead to generational changes involves cytoplasmic or mitochondrial donation. The proposition of mitochondrial transfer into human oocytes and early embryos has been contemplated for decades. Yet relatively few births have been reported. Efficacy is complex and often considered inadequate from an evidenced-based medicine point of view. These experimental procedures may have profound consequences as generational changes may be transmitted through the germline. The first clinical experiments followed observations in the mouse during the 1980 s, to alter genomic expression by cytoplasmic transfer between normally dividing and blocked mouse embryos. Four different approaches have been reported resulting in live birth in patients with repeated or suspected implantation failure: (1) Heterologous injection of a small volume of MII donor cytoplasm into a mature oocyte (ooplasmic transplantation), (2) autologous injection of isolated somatic mitochondria from granulosa cells into mature oocytes, (3) autologous injection of Egg Precursor Cell (EggPC) mitochondria into mature oocytes and (4) Reconstitution after spindle transfer or pronuclear transplantation similar to the technique used for mitochondrial replacement therapy (MRT) or cytoplasmic donation. These modalities aim to suppress purportedly poorly functioning mitochondria by supplementing or replacing with presumably normally functioning mitochondria. Artificial gene sequence alterations of deleterious mitochondrial mutations are also being considered for clinical application, but studies remain limited to mouse models. Many questions remain about patient selection, diagnosis of mitochondrial insufficiency, mitochondrial replication, heteroplasmy, safety and follow-up. How should patients be selected? A simple survey follow-up study was only recently published after the use of approach 1, cytoplasmic transplantation. No other follow-up studies have been reported from the other modalities. Based on the follow-up survey study of 13 teenagers, there do not seem to be significant effects on pregnancy, birth, health and academic performance, but sample size is small. Patients rarely disclosed the procedure to their children, possibly indicating the difficulty performing more invasive follow-up of such children as has been advocated by the UK panels advising on MRT. Although early case series show promises, there seem to be considerable limitations. Possible solutions will need to be evaluated and an in-depth debate on the ethics of these approaches must be encouraged.

O-040   Improving ovarian response through ovarian tissue activation

Abstract text

In patients with primary ovarian insufficiency (POI), early exhaustion of ovarian follicles was evident due to genetic, immunological, iatrogenic, or other causes. POI affects 1% of women and is characterized by high circulating levels of gonadotropins along with amenorrhea before 40 years of age. They are infertile due to a lack of follicle growth and ovulation; oocyte donation is the only effective treatment option, because residual ovarian follicles in these patients are not responsive to traditional gonadotropin treatments. Recently, we developed a method for activation of dormant follicles by using in vitro culture of ovarian fragments treated with PI3K stimulators following disruption of Hippo signaling pathway (IVA, in vitro activation).

Under laparoscopic surgery, ovaries were removed and cut into strips. Ovarian strips from POI patients were vitrified. After thawing, strips were fragmented into 1–2 mm cubes before treatment with PI3K stimulators. Two days later, cubes were autografted under laparoscopic surgery beneath serosa of Fallopian tubes. Follicle growth was monitored via transvaginal ultrasound and serum estrogen levels. After detection of antral follicles, patients were treated with FSH followed by hCG when preovulatory follicles were found. Mature oocytes were then retrieved and fertilized with the husband's sperm in vitro before cyropreservation of four-cell stage embryos. Patients then received hormonal treatments to prepare the endometrium for implantation followed by transferring of thawed embryos. When we published second paper in Human Reproduction (2015 Mar;30(3):608–15), three pregnancies were achieved based on serum hCG after IVF and embryo transfer. Although one was a miscarriage, two healthy IVA babies have been born with the first one being more than four year of age now. Two other pregnancies by two other centers have also been achieved.

In this presentation, I will introduce our IVA procedure and update clinical outcome of IVA so far. Also, I will show some recent progresses in the IVA approach.

O-041   Data from the ESHRE PGD Consortium

[4]*Maastricht University Medical Centre, Department of Clinical Genetics, Maastricht, The Netherlands*

Abstract text

Preimplantation genetic testing for aneuploidy has been suggested to improve live birth rates in reproductive treatment.

In 2009, the ESHRE PGS Task Force undertook a pilot study to analyse 300 oocytes by polar body (PB) array comparative genomic hybridisation (aCGH) and to transfer embryos developing from euploid zygotes, with the aim to assess the feasibility of an RCT. PB analysis was chosen, because it circumvents the issue of mosaicism occurring later in development, and most meiotic abnormalities are maternal in origin.

In 2011, two back-to-back papers were published on the results of this pilot study, a clinical paper (Joep Geraedts et al., "Polar Body Array CGH for Prediction of the Status of the Corresponding Oocyte. Part I: Clinical Results" Human Reproduction 26: 3173-80) detailing the outcome of transferred embryos, and a technical paper (M Cristina Magli et al., "Polar Body Array CGH for Prediction of the Status of the Corresponding Oocyte. Part II: Technical Aspects" Human Reproduction 26: 3181-85) detailing the optimal techniques for first and second polar body analysis.

The outcome of the pilot study was positive, and an RCT named the ESHRE Study into the Evaluation of oocyte Euploidy by Microarray analysis (ESTEEM) was initiated.

The experimental questions addressed by this trial are: in women aged 36 to 40 years (1) does aCGH in the first and second PB to select euploid embryos for transfer increase the likelihood of a live birth within one year, compared to IVF without aCGH, and (2) is aCGH in the first and second PB in women with no euploid embryos in a first cycle indicative of the probability of having no euploid oocytes in a subsequent cycle?

Importantly, it was decided that ESTEEM was to allow for an intention-to-treat analysis as well as to include data on cumulative pregnancies from cryopreserved embryos. Patients were recruited by IVF centres in seven countries.

All patients underwent conventional ovarian stimulation followed by ICSI. In the study arm simultaneous PB biopsy was performed followed by array comparative genomic (aCGH) hybridization. Subject to availability of embryos, single or double embryo transfer was performed.

The study was performed between June 2012 and December 2016. Two hundred and five patients were allocated to chromosome screening versus 191 patients to the control group. Baseline characteristics were similar between trial arms. In both groups, the mean age was 38.6 and the mean BMI was 23.2. Fifty-eight percent in both groups had not received IVF treatment before. Sixty-one percent (612/994) of the zygotes analysed were aneuploid.

The results of this multicenter RCT will be presented during the meeting. This is the largest RCT to date addressing the potential benefit of PGT-A by aCGH in patients of advanced maternal age.

O-043   New strategies for ovarian preservation during cancer treatment: Elimination of PUMA confers protection against chemotherapy-mediated oocyte loss

Abstract text

The rapid rise in cancer survivorship over recent decades has brought with it a pressing need to address the late effects of treatment. DNA-damaging radiotherapy and chemotherapy can cause female infertility and ovarian endocrine failure by depleting the ovarian reserve of primordial follicles, which once destroyed, cannot be replaced. However, the mechanisms by which chemotherapy-induced DNA damage lead to primordial follicle death are still unclear.

Using mouse knockout models, we have previously shown that primordial follicle oocyte apoptosis is mediated by the potent pro-apoptotic BH3-only protein, PUMA. PUMA is transcriptionally activated by TAp63 in response to DNA damage caused by g-irradiation, and $Puma^{-/-}$ mice retain a proportion of their primordial follicles following a radiation dose that is sterilizing in wildtype (WT) mice, and are fertile.

In the current study we aimed to examine the role of PUMA and TAp63 in mediating depletion of the ovarian reserve following treatment with cyclophosphamide or cisplatin. Adult female C57BL/6 $Puma^{-/-}$ or wild-type (WT) mice received IP injection with saline (control), cisplatin (Cis) 5 mg/kg, or cyclophosphamide (Cy) 300 mg/kg (n = 5/group). Ovaries were harvested 5 days after treatment, follicles quantified by stereology, and follicular morphology assessed. Control WT females contained 4982 ± 760 (mean±SEM) primordial follicles per animal. As expected, treatment with cisplatin or cyclophosphamide caused a dramatic reduction in this number, with 27% surviving cisplatin (control WT: 4982 ± 760 vs Cis WT: 1365 ± 308, $p < 0.05$), and only 4% surviving cyclophosphamide (control WT: 4982 ± 760 vs Cy WT: 212 ± 79, $p < 0.05$). In marked contrast, primordial follicles were completely preserved in cyclophosphamide-treated $Puma^{-/-}$ females compared with $Puma^{-/-}$ controls (control $Puma^{-/-}$: 6294 ± 955 vs Cy $Puma^{-/-}$: 7251 ± 995, $p = 0.78$). A similar effect was observed for cisplatin treatment (control $Puma^{-/-}$ vs Cis $Puma^{-/-}$: 5035 ± 574, $p = 0.66$). By comparison, $TAp63^{-/-}$ females were protected from oocyte depletion after cisplatin, but not cyclophosphamide, indicating that cyclophosphamide induces PUMA via an alternative, non-$TAp63$-mediated pathway (control $TAp63^{-/-}$: 4060 ± 497 vs Cy $TAp63^{-/-}$: 957 ± 171, $p < 0.05$; vs Cis $TAp63^{-/-}$: 3918 ± 754, $p = 0.98$). A second cohort of female mice was treated similarly, but held for continuous breeding with proven males. Results of the fertility study showed that cyclophosphamide-treated WT females had a shortened fertile lifespan (-192 ± 6 days; $p < 0.0001$) and fewer litters overall (-4 ± 1 litters; $p < 0.01$). This was ameliorated in cyclophosphamide-treated $Puma^{-/-}$ females (age at last litter; control $Puma^{-/-}$: 283 ± 20 days vs Cy $Puma^{-/-}$: 320 ± 8 days, $p = 0.19$; number of litters; control $Puma^{-/-}$: 7 ± 1.1 vs Cy $Puma^{-/-}$: 7.33 ± 1.2, $p = 0.85$).

In summary, we show for the first time that $Puma$ is the key apoptotic trigger in primordial follicle oocytes in mice following treatment with a single dose of

cyclophosphamide or cisplatin. Elimination of PUMA rescues 100% of the ovarian reserve following administration of either drug, although the pathways via which *Puma* is transcriptionally activated differ between them, with cyclophosphamide acting via a non-*TAp63*-mediated pathway. Crucially, we have shown that this translates to a complete preservation of fertile potential and the fertile lifespan in these mice, with no obvious ill effects on offspring. Collectively, these data further strengthen the argument that inhibition of oocyte apoptosis is a promising potential means of fertility preservation in females following DNA-damaging cancer therapies.

Abstract text

For the past 25 years we have been successful in treating male infertility with intracytoplasmic sperm injection (ICSI), while diagnosis and aetiology of the underlying problem has not been completely understood. The origin for the poor spermatogenesis can be explained by anatomical (b.v. cryptorchidism), iatrogenic causes (e.g. chemotherapy), lifestyle factors (e.g. smoking/drugs) or genetic anomalies (e.g. Klinefelter, Y-chromosome AZF deletions) but still in almost 60% of cases, infertility is categorized as unexplained. The percentage of genetic causes involved in male infertility increases with the severity of the oligospermia, been highest in azoospermia. The latest publications show that a genetic cause is found in approximately 15% of males tested by karyotyping, Y-chromosome deletions, CFTR point mutations. More rare, but most probably also of genetic origin, are the monomorphic sperm anomalies such as globozoospermia, acepahlic spermatozoa, tail anomalies, etc. Up to the present, only a few causative genes for azoospermia of monomorphic anomalies has been described (e.g. CFTR, DDX3Y, TEX11, DPY19L2, AURKC, SYPCP3 genes); unfortunately these genes are not routinely tested before enrolment of patients for ICSI-treatment.

In the recent years the feasibility of approaches such as targeted disease gene panel sequencing, whole exome- and even whole genome- sequencing has dramatically increased the potential of genetic approaches in male infertility. During the presentation, an overview of the different novel genetic techniques will be given (targeted gene sequencing, WES, WGS), and advantages and disadvantages of each methodology are discussed. Exome and genome sequencing can be used to identify novel disease genes, whereas targeted gene sequencing is useful to follow-up novel candidate genes in large cohorts. An example of this strategy is our ongoing study, an international collaboration, in which a panel of 6 causative and 101 candidate male infertility genes have been sequenced in a cohort of more than 1000 extreme oligospermic/azoospermic males. This validated method will be discussed in both research and diagnostic applications. Also, we will discuss the unexpected finding of pathogenic mutations in the CFTR gene in males which were not previously suspected of CBAVD by physical exploration for the presence/absence of the vas deferens.

Why should we focus on the diagnosis of male infertility when ICSI is still successful even in azoospermia or in cases with 100% abnormal sperm morphology? Increasing the knowledge of the underlying anomalies in the spermatogenesis pathways will be useful (1) to avoid taking unnecessary testicular biopsies in case of sertoli cell only (SCO) or completely maturation arrest (MA), or when sperm produced is unable to produce a healthy/viable embryo, (2) to predict and prevent the risk of passing on the infertility to the next generation, and (3) to learn more about normal and abnormal human reproduction in general, which may aid in developing novel treatment strategies.

O-045   Evaluating oocyte activation potential of sperm using calcium pattern analysis

B. Heindryckx[1], M. Ferrer[2], F. Vanden Meerschaut[2], P. De Sutter[2]

[1]*Ghent University Hospital Ghent Fertility and Stem cell Team, Department for Reproductive Medicine, Gent, Belgium*
[2]*Ghent University Hospital, Department for Reproductive Medicine, Ghent, Belgium*

Abstract text

Fertilization failure, especially after intracytoplasmic sperm injection (ICSI), still occurs in up to 5% of the ICSI cycles. When a normal number of oocytes is retrieved in the presence of motile sperm, the main reason of fertilization failure after ICSI is an oocyte activation deficiency. Oocyte activation is characterised by a series of intracytoplasmic calcium (Ca^{2+}) rises released from the inositol triphosphate receptor (IP3R) present in the oocyte, and induced by the sperm-borne factor phospholipase C zeta (PLCz), which produces inositol triphosphate (IP3). It remains challenging to determine whether a sperm or an oocyte factor is the cause of fertilization failure after ICSI. Heterologous ICSI has been used in the past to determine the activation potential of human sperm, for example by injection into mouse oocytes. Given the higher activation potential of human PLCz compared to mouse PLCz, this test might not be sensitive enough to reveal more subtle abnormalities in PLCz. Importantly, a correct series of Ca^{2+} oscillations has been correlated with the early events of fertilization, but also with later stages such as embryonic developmental potential and even post-implantation events in animal models. Therefore, assessment of the precise Ca^{2+} pattern caused by the sperm could be of added value to indicate more accurately the cause of failed or low fertilization after ICSI or later stage problems in some couples. Using specific fluorochromes, the calcium pattern can be visualised after fertilization. Indeed, recent evidence has shown that although human sperm from some couples can activate mouse oocytes, they cause aberrant calcium patterns after injection into mouse or human oocytes, leading to failed fertilization after ICSI. Especially when mutations are found in PLCz, the generated Ca^{2+} patterns are very abnormal, in contrast to control sperm. So calcium pattern analysis of human sperm provides a more sensitive test than heterologous ICSI to reveal causes of fertilization failure after ICSI. Given the scarcity of human oocytes for research, this calcium analysis is mostly done using animal derived oocytes. It remains to be determined how to extrapolate these results to human oocytes.

INVITED SESSION

SESSION 12: THE SCIENCE AND ETHICS BEHIND GERMLINE GENOME EDITING

Monday 3 July 2017   Plenary 2   14:00–15:00

O-046   Gene editing in the human germ line - risks and possibilities

R. Lovell-Badge

The Francis Crick Institute, London, United Kingdom

Abstract text

The human genome is far from static. It changes with some 40 to 80 base pair substitutions and perhaps 4 or 5 small insertions or deletions each generation due to de novo germline mutations. While this only affects a small part of the genome and many of these mutations will be silent, this has contributed to human variation and to selection for specific traits, as well as to the burden of genetic disease. The possibility that we might be able to deliberately alter our own genes has been debated for decades with each new relevant method, from recombinant DNA, transgenics, IVF, homologous recombination in embryonic stem cells or via cloning or iPS cells. But it has always been possible to dismiss the notion because the methods have been too inefficient, inaccurate, and unsafe. But in the last few years with the development of genome editing methods, notably those involving the CRISPR/Cas9 system, these arguments may no longer hold. They are now ubiquitous in basic research and have proven to be immensely invaluable. They can be used to make precise genetically altered animals with efficiencies approaching 100%. The methods are also already proving to be valuable tools clinically for somatic gene therapies. I will discuss the use of the methods to address questions

about the biology of human germ cells and of pre- and peri-implantation human embryo development. I will also discuss the possibility of their use clinically, to make heritable changes for the purposes of avoiding disease. There are, of course, other potential uses. For this reason it is critical that genome editing is only employed to make heritable changes in those jurisdictions that have appropriate regulation and oversight, and following acceptance of a core set of principles that include established notions of fairness and of avoiding harm, and with appropriate levels of public support. I will discuss ideas of how this might be achieved.

O-047   Should we edit the genomes of our future children?

S. Wilkinson

Lancaster, United Kingdom,

Abstract text
Should we edit the genomes of our future children?
This lecture reviews some of the main ethical objections to 'editing' the genomes of our future children by intervening to modify early embryos or gametes.

Having noted that this possibility raises various practical concerns, notably concerning safety, it proceeds first to describe some of the many different reasons why people may wish to do this. It is argued that the ethics of genome editing depends, to a large extent, on what ends it is designed to achieve. There may, for example, be a huge difference between seeking to prevent painful and life-threatening diseases in future generations and seeking merely to satisfy prospective parents' aesthetic preferences.

The lecture argues that, while there are genuine moral concerns about using genome editing to avoid disease (such as worries about eugenics and about the effects on existing people with disabilities) these concerns can, for the most part, be assuaged provided that the motivation for the practice is clearly and sensitively communicated. Such measures would however need to be allied with continued or strengthened social and political support for existing people with disabilities.

The position of genome editing for other purposes (such as enhancement or satisfying parents' aesthetic preferences) is more complex. Not all such practices are wrong but they are liable to objections which are less forceful when genome editing is used to improve health outcomes.

O-048   Individualised ovarian stimulation for IVF: balancing cumulative outcome, safety, burden and costs

A.N. Andersen

Copenhagen University Hospital Rigshospitalet, The Fertility Clinic- section 4071, Copenhagen, Denmark

Abstract text
Presently we have fairly good predictors (AMH and AFC) of ovarian response when exposing patients to conventional ovarian stimulation with high FSH doses. The clinical difficulty is how we translate our knowledge on response predictive factors into FSH dosing algorithms.

Individualization is only meaningful, if you accept that for IVF, as for many other health technologies there exist an optimal balance of benefits (pregnancies/births) versus risks (OHSS and burdens). The present status seems to be that individualization of the FSH dose and protocol can maintain, but does not increase, pregnancy rates but diminish the risks and burdens of IVF.

The first choice in treatment naïve patients is which protocol has the best benefit/risk ratio. Meta-analysis shows that the antagonist protocol provide the same pregnancy rates and simultaneously reduce the OHSS risk to around 50% compared to the agonist protocol. A recent large trial of more than 1000 cycles in a broad selection of women under 40, using the same FSH starting doses in the two protocols showed, that a) the cumulative live birth rates (Fresh and FER cycles within 24 months) were the same b) the OHSS risk was reduced to half c) the gonadotropin consumption was reduced by 25% and the psychological burden was also reduced in antagonist cycles. There is thus good evidence that in order to improve the balance between benefit, risk, and burden the first choice to make is to use the antagonist protocol.

Regarding individualization of the FSH dose two huge randomized controlled multicenter trials are now available. The Dutch "OPTIMIST" trial (n = 1503) where FSH dosing was determined by AFC and the "ESTHER" Trial (n = 1329) where FSH dosing was based on AMH and bodyweight. In both studies the patients predicted to be in the lower response segment (either by AFC < 10 or by AMH < 15 pmol/l) had an increased yield of oocytes with 1.1 more in the OPTIMIST trial and 1.0 in the ESTHER trial, after individualized up-dosing of the daily FSH dose. However, the modest increase in number of oocytes was not associated with any increase in delivery rates. Among patients predicted to be in the normal to high response (ESTHER trial) or high response (OPTIMIST) segment down-dosing of the daily FSH dose lowered the number of oocytes by 2–4. Both studies showed that "down-dosing" shift the egg distribution to the left and that a number of patients end up being under-dosed. Overall both studies showed that individualized dosing had no benefits in terms of higher ongoing pregnancy rates (ESTHER and OPTIMIST) and cumulative live-birth rates (OPTIMIST). The number of cryopreserved blastocysts was unchanged by individualized stimulation in the ESTHER trial, so the cumulative outcome will most likely be the same. A possible advantage of the individual dosing was the finding that patients exposed to individual dose achieved the same pregnancy rates following fewer treatment cycles (OPTIMIST). The cost-effectiveness has been studied in the OPTIMIST trial, and the conclusion was that AFC-based dosing offered no advantage over standard dosing. In terms of risks, major risks like OHSS are infrequent, and may be graded and analyzed differently – both OHSS and secondary preventive measures like agonist triggering seem lowered by individualized dosing.

In summary individual dosing models using either AFC or AMH and bodyweight maintain cumulative success rates in terms of live pregnancies, the impact of FSH dose adjustments on the number of oocytes is modest, but sufficient to lower the risks of severe adverse effects as OHSS and presumably the overall burden for the patients – but economic cost-effectiveness seems unchanged.

O-049   The evolution of treatment approaches in PCOS: management of ovulation and metabolism

R. Anderson

University of Edinburgh The Queen's Medical Research Institute, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

Abstract text
Polycystic ovary syndrome is a pleiotropic condition, and as befits the most common endocrinopathy, there is a corresponding range of treatment options, including surgical, medical and lifestyle modification approaches. Treatments address the woman's presenting complaint, ie how it affects her at that stage in her life, rather than addressing the underlying pathology. This reflects our limited understanding of the aetiology and pathogenesis of the condition, although a unifying hypothesis is perhaps doomed to failure given the heterogeneity of the condition. Both the initial surgical approach, the wedge resection of the ovary, and the subsequent development of clomifene citrate were very successful, and clomifene remains the first line treatment for anovulation due to PCOS today. The wedge resection has evolved into laparoscopic ovarian diathermy, with high quality evidence supporting its efficacy, but our understanding of how it works has not changed from 'no idea'. Medical ovulation induction is seeing the increasing use of aromatase inhibitors, which may be more effective than clomifene for very obese women, if not for most. Gonadotropin therapy for mono-ovulation remains very effective and can achieve a cumulative birth rate of around 70% with <10% multiple pregnancies in clomifene non-responders, but it is challenging to both doctor and patient and appears increasingly bypassed in favour of IVF. For those not wishing to conceive, there is a wide range of combined contraceptive pills to regulate menses and perhaps improve hirsutism and acne, although the less androgenic pills have an increased venous thrombosis risk compared to 2nd generation pills, and some women's BMI may preclude this approach. Weight loss remains the mainstay of approaches to the metabolic manifestations of the condition, and when achieved can be very effective in improving fertility as well. Medical therapies designed to improve the well-documented insulin resistance have been largely disappointing in their impact. A novel approach currently in clinical trials is based on slowing GnRH

secretion, and thus lowering LH and testosterone levels, through administration of neurokinin B antagonists. This does seem to address one of the key abnormalities underlying the reproductive (although not metabolic) aspects of PCOS, so if effective, may have value whether or not a women is wishing to conceive.

INVITED SESSION

SESSION 14: DEBATE: DEEP ENDOMETRIOSIS: TO OPERATE OR NOT IN INFERTILE WOMEN

Monday 3 July 2017   Room B   14:00–15:00

O-050   Pro

H. Roman[1], I. Chanavaz-Lacheray[2]

[1]Rouen University Hosp. Charles Nicolle, Gynecology and Obstetrics, Rouen Cedex, France
[2]Rouen University Hospital, Expert Center in the Diagnosis and Multidisciplinary Management of Endometriosis, Rouen, France

Abstract text

One of the most interesting debates surrounding deep endometriosis concerns the management of patients with colorectal lesions and pregnancy intention, for which no strong first level of evidence data exists to recommend performing surgical excision of deep endometriosis or ART. Worldwide meetings on endometriosis thrive on debates, with conclusions varying significantly from one conference to another according to speaker experience and views. An absence of consensus and inevitable divergent advice leave patients routinely confused with hesitation further delaying accurate management of the disease. Studies assessing the policy of primary IVF in women with colorectal endometriosis have recorded pregnancy rates inferior to 45% and estimated cumulative pregnancy rates after up to 3 cycles or IVF as high as 68%. Other authors have reported pregnancy rates over 60% in patients undergoing primary surgery for colorectal endometriosis, with spontaneous conception representing up to 60% of pregnancies. Recent studies suggest that surgical management of deep endometriosis would increase cumulative pregnancy rate up to 78% in patients undergoing 3 postoperative IVF cycles. In addition, questions remain as to whether delaying surgery for months or years impairs health. Delaying surgery may lead to bowel occlusion, dysuria, higher rates of radical colorectal procedures, increased postoperative morbidity and postoperative complications and prolonged painful complaints. As data available in the literature suggest that the current policy of systematic IVF prior to surgery in patients with deep colorectal endometriosis is questionable, we propose a custom made management of pregnancy wish, based on complete assessment of both fertility and deep endometriosis characteristics.

SESSION 15: PARAMEDICAL SESSION - LISTENING TO THE PATIENT

Monday 3 July 2017   Room W+X   14:00–15:00

O-052   Endometriosis: Why am I feeling pain?

M. Uny[1], J.M. Wenger[2], S. Baudry[3], S. Campione[2], S. Constantino[2], N. Pluchino[2]

[1]University Hospital of Geneva, Gynécologie / obstétrique, Geneva 14, Switzerland
[2]University Hospital of Geneva, Gynécologie/ Obstétrique, Genève, Switzerland
[3]University Hospital of Geneva, Gynécologie /Obstétrique, Genève, Switzerland

Study question: Can we improve the quality of endometriosis care by systematically offering a validated information and support?

Summary answer: Information sessions led by a nurse specialist help patients to better understand the cause of pain, to cope with disease and increase compliance to treatment.

What is known already: Endometriosis is a complex disease often diagnosed in advanced stages and with unclear etiologies. Patients may have long medical history with important repercussions on the quality of life. During medical consultations, patients receive specific medical information and a detailed treatment plan that often requires surgery, IVF procedures and hormonal treatment. Their care requires also answers to specific needs in terms of listening, understanding and support. Moreover, it is essential for patients to understand the heterogeneity of the disease and symptoms in order to improve the sense of frustration caused by a chronic disease and better adhere to treatment.

Study design, size, duration: Since the end of 2014 at the University Hospital of Geneva endometriosis center, a specialized nurse manages monthly sessions of information dedicated to patients and to their close relatives. Clear simple language is used to explain the physiopathology of endometriosis, symptoms, diagnosis tools and treatments. The nurse also explains the impact of the disease on fertility and quality of life. The quality this activity has been evaluated over a period of 6 months

Participants/materials, setting, methods: Patients are invited to participate by the medical team. Participation is free. Patients can be accompanied by their close relatives. The registration is made by e-mail or phone. At the end of each meeting an anonymous questionnaire is given to every participant. It evaluates the relevance of the session, the quality of the information and if sessions meet patient needs. The role of such sessions in the therapeutic course has been also evaluated.

Main results and the role of chance: 110 patient have attended the sessions. Results of questionnaires show that informative sessions offer a clear advantage for a better understanding of medical condition and proposed treatments.

57% of patients declared that the information is adequate and useful, 7 % of them too complicated abd 7% simplistic. The patients also express their wish of having additional information concerning management of the pain (28 %), complementary medicine (28 %), infertility (26 %) and also practical strategies for improving daily activities (35 %). The organization of sessions is considered adequate in term of schedule and duration. All patients have defined the session helpful for a better understanding of treatment options.

Limitations, reasons for caution: Patients included are heterogeneous and they differ in terms of disease characteristics and treatment plan. Each participant has also a different level of knowledge of the disease.

Wider implications of the findings: Validated and consistent informative sessions may meet crucial needs of endometriosis patients and their family members, representing an additional instrument for improving quality of care.

Trial registration number: none.

O-053   Follow-up of oocyte donors ten years after donation: what we are doing well and what we could improve

M. Perul[1], M. Corral[1], M. Caballero[1], C. Conti[1], J.M. Gonzalo[1], S. Brazal[1], D. García[2], R. Vassena[1], A. Rodríguez[1]

[1]Clínica EUGIN, EUGIN, Barcelona, Spain
[2]Fundación EUGIN, EUGIN, Barcelona, Spain

Study question: How do oocyte donors regard their experience in a long term follow up, a decade after the donation?

Summary answer: Most oocyte donors regard their donation as a positive experience a decade later, and would recommend being a donor to other women.

What is known already: Oocyte donation in Spain is altruistic and anonymous and can be performed by healthy women between the ages of 18 and 35. Few reports investigated the psychological impact of donating oocytes and motivation to donate in potential donors, or in donors immediately after the donation. Treatment management, healthcare staff involvement, and personal satisfaction were considered positive by most women at the time of donation. However, whether this experience remains positive in the long-term, or

whether contradictory and painful feelings emerge, has not been evaluated yet. Reports of negative feelings should especially be investigated and could help adjust pre-donation counselling.

Study design, size, duration: Anonymous telephone survey of 121 women in their 40 s having donated their oocytes in their 20 s-30 s. Surveys consisted of 20 structured questions and were carried out by 3 ART nurses with extensive experience interacting with oocyte donors, in the period between June and November 2016. One-hundred and twenty-one former oocyte donors out of 141 (85.5%) were contacted by phone and agreed to participate in the survey.

Participants/materials, setting, methods: Participants were between 40–49 years old (average 41.6) at the time of the survey and between 26–35 years (average 32.2) at the time of donation. Most of them were Spanish (99.2%), had high school (50.4%) or university (27.3%) education and had children (69.4%) at the time of interview. Inclusion criteria were to be $\geq$40 to encompass most of the donor reproductive life, and speaking Spanish as mother tongue to ensure questions understanding.

Main results and the role of chance: Most former donors highlighted positive aspects and feelings about their donation (113, 93.4%), while less than half (53, 43.8%) mentioned some negative ones. Former donors reported feelings of altruism (84, 69.4%) and personal satisfaction (13, 10.7%) in relation to the donation. Economical compensation was also reported as a positive aspect of donation by some (18, 14.9%). Negative aspects reported were mainly related to the physical discomfort at the time of donation: injections (20, 16.5%), pain (17, 14.1%) and hormones (10, 8.3%). Participants also valued the reproductive care received; for instance, one woman reported being grateful for the identification and treatment of a cervical dysplasia during the donor screening process. In general, former donors have shared their donation experience with friends (76, 62.8%), family (55, 45.5%), partner (24, 19.8%), and colleagues (13, 10.7%). Most participants (56.2%) have performed more than one donation cycle and 96.7% would recommend the donation to other women. About one third of donors reported physical discomfort during the treatment (43, 35.5%), and, some, concerns about the destiny of their oocytes (13, 10.7%). For these same reasons, 8 women (6.6%) reported to regret having donated. Finally, 101 participants (83.5%) reported that oocyte donation increased their awareness about infertility.

Limitations, reasons for caution: A limitation of the current study is that all women performed their donation after the age of 25; experiences of women having donated their oocytes at a younger age may be different due, for instance, to unfinished education trajectories, unstable work or incomplete family composition.

Wider implications of the findings: The great majority of former donors regard their donation as positive with the passing of the years, while few negative aspects, related mostly to the treatment physical discomfort, emerge. More user friendly and comfortable stimulation protocols should be developed, in order to increase both short and long term donor experience.

Trial registration number: NA.

O-054　Patient-friendly insemination with homologous and donor sperm positively influences clinical pregnancy rates

H. Bijnens[1], A. Thijssen[2], P. Jacobs[3], S. Theys[3], C. Pascale[3], V. Vandewal[3], W. Cools[4], G. Mestdagh[3], N. Dhont[3], R. Campo[3], W. Ombelet[3]

[1]GIFT VZW - Dr. W. Ombelet, Fertility, Genk, Belgium
[2]Hasselt University, Department of Physiology, Hasselt, Belgium
[3]Ziekenhuis Oost-Limburg, Department of Obstetrics and Gynecology, Genk, Belgium
[4]Hasselt University, Center for Statistics CENSTAT, Hasselt, Belgium

Study question: Does a patient friendly approach increase the clinical pregnancy rate (CPR) after intrauterine insemination with homologous or donor semen?

Summary answer: CPR increased from 9.5% to 14.6% per cycle with homologous and 16.7% to 21.1% per cycle with donor semen when insemination was performed by midwives.

What is known already: In many studies, it has been proven that fertility patients want a sensitive fertility staff and need sufficient emotional support. Patients also appreciate continuity of care and do not want to be treated by too many different fertility clinic staff members. They prefer an individualised approach. Most studies performed focus on the psychological aspect, but not on success rates.

Nurses/midwives are in a potentially unique position in the assisted reproductive technology environment in that, unlike other professionals, they maintain a more direct contact with the patient.

Study design, size, duration: The study was performed as a prospective cohort study. During the period of July 2011 until July 2016, data from 1711 insemination cycles with homologous semen in 688 women and 1579 insemination cycles with donor semen in 473 women were collected prospectively in a tertiary referral infertility centre. As from February 2016, the insemination procedure at our centre was performed by midwives instead of medical doctors.

Participants/materials, setting, methods: Homologous insemination was performed in couples with unexplained or moderate male factor infertility. As from February 2016, the insemination procedure at our centre was performed by the midwife instead of medical doctors. This resulted in a slower injection of the inseminate and a more relaxed contact with the patient or the couple. Above this, more time was spent on the procedure. Results were analysed with Chi-square analysis.

Main results and the role of chance: Clinical pregnancy rates (i.e. presence of fetal heart beat at 6-7 weeks of gestation) following homologous insemination increased significantly from 9.5% to 14.6% (p = 0.038) in the study group. In case of donor inseminations, clinical pregnancy rates increased from 16.7% to 21.1%, (p = 0.088), a non-significant increase.

Limitations, reasons for caution: Results were analysed in a prospective cohort study; however, a prospective randomised trial is needed to confirm our findings.

Wider implications of the findings: According to our preliminary results, it seems that a more patient-friendly approach might increase the clinical pregnancy rates after intrauterine insemination. Future studies should investigate the importance of slow versus rapid intrauterine injection of the inseminate and the possible value of patient-centred measurements to achieve better success-rates after insemination.

Trial registration number: NA.

O-055　Are nurse-led consultations of benefit to patients? Evidence of effectiveness from a UK clinic specialising in IUI

B. Woodward, D. Littlehales, N. Cotgreave-Keates, S. Deb, M. Tomlinson

Nottingham University Hospital, Fertility Unit, Nottingham, United Kingdom

Study question: Are nurse-led consultations a cost-effective way to improve the standard of patient care by expediting access to lower technology fertility treatments such as IUI?

Summary answer: The majority of patients were satisfied with nurse-led consultations, stating that this approach improved continuity of care and that their needs were adequately met.

What is known already: UK state-funding for IUI was reduced following the NICE guideline recommendation that IVF should be offered as an initial treatment for unexplained infertility. This has led to less physician time allocation for initial consultations in our IUI clinic, with resources preferentially allocated to IVF. Fertility nurse practitioners spend significant time interacting with patients, yet there is limited research on this interaction, and in particular patient perception. Nurse-led consultations increase clinic capacity and patient choice. Physician to nurse task-shifting has gained increasing interest in health policy but little is known about how patients perceive its effectiveness, particularly with regard to consultations.

Study design, size, duration: Patient perception of nurse-led consultations was evaluated via a questionnaire sent to a random sample of treated couples, whether successful or not, to seek their views on the nurse-led consultation for our IUI service.

Participants/materials, setting, methods: This study included couples (n = 50) with unexplained infertility, anovulation problems and/or borderline male factor who received a nurse-led consultation for IUI treatment, at a fertility clinic specialising in IUI with partner sperm. The questionnaire was

posted to couples who had previously attended the clinic regardless of the outcome. No identifying information was requested to assure anonymity of the respondents.

Main results and the role of chance: The response rate to the survey was 54.0% (27/50). 85.2% couples stated they were informed in advance that their consultation would be with a nurse rather than a physician, and 11.5% stated they would have preferred at consultation with a doctor. 96.3% felt sufficient information was provided and were happy with the nurse's medical knowledge. 88.9% felt their needs adequately met and 96.2% felt the nurse-led consultations improved their continuity of care. 92.3% graded that the explanation and organization of investigations and treatment by the nurse as either excellent or very good. 96.2% stated that they would recommend nurse-led consultations to others. When asked about the preferred timing of consultation, a high proportion preferred the consultations to be held at either end of the standard working day, with 32.2% preferring before 9 am and 19.8% after 6 pm, or at the weekend (21.5%).

Limitations, reasons for caution: Only 27 patients from 50 responded to the survey. A wider survey might reveal different responses, although from the data provided, there was an overwhelming trend for patients supporting access to nurse-led consultations. Our setting of a small fertility clinic specialising in IUI may have influenced responses.

Wider implications of the findings: Provided patients expectations are met, then nurse–led consultations appear to be an effective resource allocation in terms of both costs and time, allowing physicians' skills to be utilised elsewhere. This action must be supported by detailed accounts of fertility nurses' competencies and training in this area.

Trial registration number: N/A

SESSION 16: OPTIMIZING THE EMBRYO ENVIRONMENT
Monday 3 July 2017   Plenary 1   15:15–16:30

O-056   Ultra-low (2%) oxygen tension significantly improves human blastocyst development and quality

A. Ferrieres-Hoa[1], K. Roman[2], T. Mullet[2], A. Gala[2], S. Hamamah[2]

[1]CHU Montpellier- Hôpital Arnaud de Villeneuve, Biologie de la Reproduction, Montpellier Cédex 5, France
[2]CHU Montpellier, Biologie de la Reproduction, Montpellier, France

Study question: The present study investigated the effect of ultra-low (2%) O_2 tension on blastocyst development and on the rate of useful blastocysts (UBs).

Summary answer: This study shows that ultra-low O_2 tension is a successful technique to improve both blastocyst development and the rate of useful blastocysts (UBs).

What is known already: Improving the ex-vivo culture conditions of early embryos is still the main challenge in ART. The oxygen concentration is one of the criteria that influence protonated culture. In the uterus, early embryos are exposed to an ultra-low (1.5%) O_2 atmosphere. Moreover, embryo damage caused by reactive oxygen species (ROS) is related to the O_2 tension during in vitro culture. Currently, the traditional 6%/20% of CO_2/O_2 or 6%/5% CO_2/O_2 conditions are the most currently culture parameters used for early human embryo culture. However, few studies investigated the in vitro culture conditions under more physiological O_2 tension.

Study design, size, duration: This is a single-center observational study, performed from January to December 2016.

The endpoint for the study was whether O2 tension could enhance blastocyst development. The relationship between the oxygen tension and standard morphological evaluation according to the Gardner grading system was also examined: at day 5/6, full (grade 3), expanded (grade 4), hatching (grade 5) or fully hatched (grade 6) blastocysts with at least a grade B trophectoderm quality were considered as UBs.

Participants/materials, setting, methods: Day 1 embryos were cultured in 6% CO_2 and 5% O_2 for three days; and then in 6% CO_2 and 2% O_2 atmosphere from day 3 to day 5/6 (ultra-low O_2 group, n = 238 embryos, n = 42 patients, age 33.09 ± 4.71) or in 6% CO_2 and 5% O_2 (controls, n = 169 embryos, n = 42 patients, age 33.10 ± 4.66).

Main results and the role of chance: Blastocyst formation rate was 60.1% (143/238) in the ultra-low O_2 group and 52.1% (88/169) in the control group (p = 0.1078). The UB rate was significantly higher in the ultra-low O_2 group (103/143; 72.0%) than in the control group (40/88; 45.5%) (p < 0.0001). There is no significant different in patient's age between groups.

Limitations, reasons for caution: This preliminary results need to be completed with a prospective randomized controlled trial including the living birth rates to ensure the efficiency of these in vitro culture conditions.

Wider implications of the findings: Our study demonstrates that ultra-low O_2 tension is associated with higher blastocyst formation and better blastocyst quality compared to low O_2 tension, supporting the hypothesis that more physiological culture conditions improve early embryo development.

Trial registration number: .

O-057   The composition of human preimplantation embryo culture media and their stability during storage and culture

M. Tarahomi[1,2], J.P. Van Straalen[3], F.M. Vaz[4], F.M.P. Schrauwen[3], G. Hamer[1], M. Van Wely[1], S. Repping[1], S. Mastenbroek[1]

[1]Center for Reproductive Medicine, Academic Medical Center, University of Amsterdam
[2]Reproductive Biotechnology Research Center, Avicenna Research Institute, ACECR
[3]Department of Clinical Chemistry, Academic Medical Center, University of Amsterdam
[4]Laboratory Genetic Metabolic Diseases, Academic Medical Center, University of Amsterdam

Study question: To analyze the concentration of thirty seven components of seventeen commercially available human preimplantation embryo culture media and their stability during storage and culture.

Summary answer: The composition was different for each culture medium. There is an effect of storage and culture on the concentration of some of the components.

What is known already: In vitro fertilization (IVF) is currently the most commonly used intervention in subfertile couples. During IVF, embryos are cultured for several days in embryo culture medium. It is has recently been established that the type of embryo culture medium used in IVF can affect treatment success as well as the health of the future child. The exact composition of specific media are often not disclosed by the manufacturers. Furthermore, it is unknown whether the composition of these media changes during storage or during culture.

Study design, size, duration: Between October 2014 and October 2015, all ready-to-use human preimplantation embryo culture media (n = 17) that were commercially available at that time were purchased from eight suppliers in the Netherlands. Osmolarity and the concentration of thirty seven components were tested upon arrival in the IVF laboratory, after three days of culture without embryos (sham culture) starting from the arrival day, at the expiry date, and after three days of sham culture just before the expiry date.

Participants/materials, setting, methods: Osmolarity was analysed by Advanced 3320 Micro-Osmometer [Advanced Instruments inc., Norwood, Massachusetts,USA]. Ions, metabolites, immunoglobulins, albumin and total protein were quantified using Roche Cobas chemistry analyzer (Cobas 8000) [Roche Diagnostics, GmbH, Mannheim, Germany], and pyruvate and 21 amino acids were analysed by Ultra- Performance Liquid Chromatography Mass Spectrometry [Acquity-Quattro Premier XE, Waters, Milford, Massachusetts, USA]. Statistical analysis was performed using general linear models.

Main results and the role of chance: The composition varied between media, no two media had the same concentration of components. Storage led to significant changes in 17 of the 37 analyzed components, i.e. magnesium chloride, phosphate, albumin, total protein, tyrosine, tryptophan, alanine, methionine, glycine, leucine, glutamine, asparagine, arginine, serine, proline, and threonine. Storage also significantly affected the osmolarity in 3 of the 17 media,

but for all media combined this change in osmolarity was not significant ($p = 0.051$). Sham culture of the analyzed media had a significant effect on the concentrations of 15 of the 37 analyzed components, i.e. phosphate, iron, albumin, total protein, tyrosine, tryptophan, alanine, methionine, glycine, isoleucine, glutamine, asparagine, arginine, proline and histidine. Sham culture significantly affected the osmolarity in 10/17 culture media (overall p-value <0.001).

Limitations, reasons for caution: Embryo culture media could contain components that were not analyzed in this study, and the clinical relevance of the varying concentrations are yet to be determined.

Wider implications of the findings: The wide variation in composition between the culture media indicates the optimal composition is still unknown. Companies of culture media should fully disclose the components and their concentrations. The clinical relevance of the observed differences as well as the effect of storage and culture needs to be evaluated.

Trial registration number: Not applicable.

O-058　Potential contamination of fresh embryo cell culture medium with cell free DNA

A. Thierry[1], R. Tanos[1], A. Petiton[2], S. Hamamah[3]

[1]INSERM U1194, Institut de Recherche en Cancérologie de Montpellier, Montpellier, France
[2]university hospital Arnaud de Villeneuve, ART PGD, MONTPELLIER, France
[3]Inserm U1203- Hôpital Arnaud de Villeneuve- CHU Montpellier, Département de Médecine et Biologie de la Reproduction/DPI, Montpellier, France

Study question: Is there a potential contamination of embryo culture medium with cell free DNA (cfDNA) by the in embryo cell culture medium of human serum albumin?

Summary answer: Contamination of the embryo culture medium by cfDNA is not excluded.

Thus, the possibility to contaminate human embryos under ex vivo culture conditions still asked.

What is known already: Free extracellular nucleic acids are now highly scrutinized with regards to their potential as a molecular tool in the diagnostic field. In particular, clinical validation of circulating cell free DNA was recently shown in oncology or prenatal diagnosis. They are present in circulating fluids, non-circulating and in cell culture media. We are investigating the value of cell free DNA analysis towards improving embryo culture and pre-implantation diagnosis. We used an ultrasensitive Q-PCR based assay. The aim of this study was to determine if the embryo culture media, G-1 PLUS and G-2 PLUS contains detectable level of nuclear/mitochondrial derived cfDNA.

Study design, size, duration: Nuclear and mitochondrial derived cfDNA were extracted from drops with the QIAamp kit and quantified by RT-qPCR (IntPlex). 89 drop samples from 3 patients underwent IVF/ICSI and 10 controls were included in the analysis. Data are expressed in mean +/− SD.

Participants/materials, setting, methods: We used, G-1 PLUS and G-2 PLUS embryo culture media (Vitrolife, Sweden). Drops performed during the ICSI procedure were obtained from patients (n = 6). Then, all drops of embryos culture media were frozen until the cfDNA and mitochondrial derived DNA analysis.

Main results and the role of chance: We observed that embryo culture media, G-1 PLUS and G-2 PLUS (Vitrolife), of freshly open flasks under laminar flow hood, consistently contains detectable level of mitochondrial derived DNA (Mean = 0.215 ng/ml; SD=0.09). Nuclear DNA was detected in one out of ten G2 culture medium with a concentration of 3.65 ng/ml. Note, cfDNA was not detectable in all our negative controls. This observation point out the contamination of circulating cfDNA from either the serum used for preparing albumin or from the manufacturer manipulator. These medium contain in addition to bicarbonate buffer, human serum albumin, hyaluronan and gentamicin. This implies the need of using a detection threshold when analyzing cfDNA in series of embryo cell cultures. No contamination due to the manipulator was detected in the control drops for nuclear DNA media (3 different patients; 89 samples and 10 controls), whereas a possible manipulator contamination was found in one control drop for mitochondrial DNA; p-value is near the statistical significance (P value = 0.058).

Limitations, reasons for caution: Further investigations with a larger number of culture media drops are in progress to confirm theses results.

Wider implications of the findings: Our results seriously impact the determination of cfDNA level and might raise concerns with regards to the foreign cfDNA potential biological effect on embryo culture and growth.

Our data strongly open the possibility to develop a new quick and low-cost test for embryo culture safety.

Trial registration number: Not applicable.

O-059　A novel three-dimensional environment for human blastocyst development up to 10 days post-fertilization

F. Arjmand[1], S. Kazemnejad[2]

[1]Avicenna Research Institute, Avicenna Infertility Clinic, Tehran, Iran
[2]Avicenna Research institute, -Director of Tissue Engineering Department -Head of Reproductive Biotechnology Research Center in Avicenna Research Institute- ACECR, Tehran, Iran

Study question: The objective was development of an in vitro system to culture human embryo beyond blastocyst stage to future study of factors regulate post-implantation embryo upgrowth.

Summary answer: Co-culturing of embryos with endometrial cells in alginate hydrogel and media supplementation with melatonin creates an environment for blastocyst development up to 10 days post-fertilization.

What is known already: In comparison with 2D culture system, three-dimensional (3D) culture provides structural integrity of embryos and offers direct physical and chemical interactions of embryos with their surrounding environment, similar to that experienced in vivo. 3D culture system has been extensively used for the development of follicles or oocytes, and a number of studies have examined the culture of bovine and porcine embryos in vitro using agarose gel tube system or alginate hydrogel encapsulation device. To the extent of our knowledge, there is no report on human embryo development beyond the blastocyst stage.

Study design, size, duration: Ethical approval was granted by the Avicenna Research Institute Bioethics Committee. A luteal phase endometrial biopsy was performed in five women with regular menstrual cycle and no pathologic disorder. Sixty human preimplantation embryos in blastocyst stage were included in the study. The embryos were nondemanding ones with opposite sex provided from the couples referred for sex selection after signing the informed consent. Seven different culture systems were considered for blastocyst culture.

Participants/materials, setting, methods: The EnSCs were mitotically inactivated and then decidualized by 8-Br-cAMP. Blastocysts were co-cultured with EnSCs or encapsulated in alginate (ALG) beads. The embryos were treated with conventional culture media (CCM) with or without melatonin (Mela). The embryos were monitored post-encapsulation. To find out the proportion of cells originated from inner cell mass (ICM) or trophectoderm (TE), the embryos were stained using PI/Hoechst. The secretion levels of of 17b- oestradiol (E2) and hCG were measured.

Main results and the role of chance: - The alginate beads were stable and did not rupture during the study period. At 5 days post-encapsulation, 85 ± 3 % of the alginate-encapsulated EnSCs remained viable.

- 23 % (2 embryos out of 9) of the encapsulated blastocysts survived until day 4 in CCM/ALG culture condition.

- Melatonin fortification of CCM (CCM/ALG/Mela) remarkably improved the maintenance rate (44 %) and survival time (day 5) of expanded embryos in alginate hydrogel. Moreover, co-encapsulation of EnSCs increased the maintenance rate of blastocysts by 44 %.

- Based on this differential staining, embryos cultured in CCM/ALG/EnSCs/Mela or CCM/ALG/Mela were composed of live cells originated from both TE and ICM cells at day 5.

- The gastrula-like morphology was marked on the fourth day post-encapsulation especially in CCM/ALG/EnSCs/Mela group.

- E2 hormone levels in CCM/ALG/Mela group and CCM/ALG/EnSCs/Mela groups at day 4 post- encapsulation were averagely two folds more than those at day 2 (P≤0.025 andP≤0.003, respectively). Levels of hCG hormone in CCM/ALG/Mela group and CCM/ALG/EnSCs/Mela group at day 4 were 14.43 (P≤0.024) and 48.01 (P≤0.004) respectively.

- The levels of the hCG hormones were significantly greater in CCM/ALG/EnSCs/Mela group in contrast to CCM/ALG/Mela culture system in the same day (P≤0.028).

Limitations, reasons for caution: More technical assessments like molecular analysis could be helpful to get more insights about molecular properties of developed embryos. However, problem with providing enough human embryos (no big sample size to analysis) caused to withdraw the molecular evaluation.

Wider implications of the findings: In vitro culture of human embryos would facilitate monitoring of human embryo development and consequently understanding the mechanisms such as molecular and hormonal ones, underlying human embryo growth.

Trial registration number: It was not a trial, it was a basic science research.

O-060   Cell allocation patterns during pre-implantation embryo development are not perturbed by blastomere removal in mouse and bovine embryos

L.P. Sepulveda-Rincon[1], P. Marsters[1], B.K. Campbell[1], N. Beaujean[2], W.E. Maalouf[1]

[1]University of Nottingham, Child Health- Obstetrics and Gynaecology, Nottingham, United Kingdom
[2]INSERM, Stem Cell and Brain Research Institute, Bron, France

Study question: Are embryo cell-allocation patterns disturbed by single blastomere removal at cleavage stage in mouse and bovine embryos?

Summary answer: Cell allocation patterns are not disturbed by embryo biopsy in mouse and bovine embryos. However, embryos following different cell allocation patterns present different compensatory mechanisms.

What is known already: It has been suggested that cell fate might be predisposed in early embryos. The first cleavage plane in mouse embryos has been related with the embryonic-abembryonic (Em-Ab) axis at blastocyst stage, hence the first cell lineage specification. Cell allocation patterns during pre-implantation embryo development have been related with further developmental potential. Thus, cell removal at cleavage stage might shift these cell allocation patterns; perturbing development.

Study design, size, duration: Two different species (mouse and bovine) were used during more than 5 repetitions of the experiment. Embryos were injected with a lipophilic tracer at the 2-cell stage and then divided into two groups: control and biopsied group. A single blastomere was removed around the 8-cell stage on the biopsied group. Embryos were cultured up to the blastocyst stage where cell allocation patterns were noted as well as total cell counts (TCC).

Participants/materials, setting, methods: A single blastomere of the 2-cell embryos was injected with Dil tracer. Within the biopsied groups a single blastomere was removed around the 8-cell stage. Blastocysts were classified into: orthogonal, if the borderline of two clusters of cells (stained and non-stained) was orthogonal ±30° to the Em-Ab axis; deviant, if the borderline was parallel ±30°; and random, if more than two clusters were observed and stained/non-stained cells were intermingled. TCC was performed by DAPI staining.

Main results and the role of chance: A total of 287 and 214 blastocysts were analysed on mouse control and biopsied group respectively, whereas 346 and 107 blastocysts for bovine embryos. Incidence of random cell allocation pattern was predominant in both species (>58%, $p < 0.05$). Whereas deviant and orthogonal pattern incidence was around 20% in both species. Incidence of cell allocation patterns was not disturbed by embryo biopsy (p>0.05). Nonetheless, TCC at blastocyst stage decreased significantly after biopsy in embryos following the deviant pattern in mouse (55 vs 42 cells respectively) and bovine (140 vs 95 cells respectively) embryos ($p < 0.05$). This tendency was not observed in orthogonal embryos (45 vs 41 cells and 91 vs 136 cells for mouse and bovine embryos respectively) or random embryos (47 vs 43 cells and 108 vs 90 cells for mouse and bovine embryos respectively). It is worth noting that deviant embryos in control groups present significantly higher TCC ($p < 0.05$) when compared with orthogonal or random embryos. In conclusion, cell allocation pattern incidence is comparable in mouse and bovine embryos, thus it might represent a conserved mechanism among mammals and they

should be established before 8-cell stage. Also, deviant group might have a different coping mechanism(s) against cell removal at cleavage stage.

Limitations, reasons for caution: Even though the results suggest that incidence of cell allocation patterns might be a conserved mammalian process, this theory has not yet been studied in human embryos. Also, the mechanism(s) driving cell allocation patterns in mammalian embryos still remain to be discovered.

Wider implications of the findings: Embryos following the deviant cell allocation pattern might present different coping mechanisms against in vitro manipulations, which in turn might affect further embryo development. New embryo de-selection strategies could be developed in order to avoid deviant embryos, and therefore improve clinical success after ART.

Trial registration number: Not applicable

Study question: Does a lifestyle intervention prior to infertility treatment compared to prompt infertility treatment lead to better cardiometabolic health and quality of life in obese infertile women?

Summary answer: A lifestyle intervention among obese infertile women has immediate beneficial effects on cardiometabolic health and physical quality of life.

What is known already: The prevalence of obesity, an important cardiometabolic disease risk factor, is rising in women. Obesity reduces fertility, regardless of ovulatory status. Lifestyle improvements are the first step in the prevention and treatment of obesity. The success of improving lifestyle depends on factors like timing and motivation. Women are especially receptive to advice about lifestyle before and during pregnancy. Therefore, the prepregnancy period may be a window of opportunity to improve health and quality of life (QoL) of obese infertile women by means of a lifestyle intervention.

Study design, size, duration: The LIFEstyle study, a multicenter RCT was conducted between 2009 and 2012 in 23 medical centers in the Netherlands. 577 participants were randomised 1:1 to a 6 month lifestyle intervention prior

to infertility treatment (intervention group; n = 290) or to prompt infertility treatment (control group; n = 287). Randomisation was stratified according to trial center and ovulation status with an online program. The intervention consisted of dietary counselling, increasing physical activity and an individualised behavioral modification plan.

Participants/materials, setting, methods: Participants were infertile women aged between 18 and 39 years with a Body Mass Index (BMI) of $\geq$ 29 kg/m^2. The goal of the intervention was 5–10% weight loss or a BMI < 29 kg/m^2. Cardiometabolic outcomes were measured by research nurses at randomisation, 3 and 6 months. QoL was assessed by the short form 36 questionnaire and was also measured at 12 months. Mixed effects regression models analyses were performed.

Main results and the role of chance: Based on the data at 3, 6 and 12 months, results are given as estimated mean differences between the intervention and control group. Weight (-3.1 kg 95% CI: -4.0 - -2.2 kg; P < .001), waist circumference (-2.4 cm 95% CI: -3.6 - -1.1 cm; P < .001), hip circumference (-3.0 95% CI: -4.2 - -1.9 cm; P < .001), BMI (-1.2 kg/m^2 95% CI: -1.5 - -0.8 kg/m^2; P < .001), systolic blood pressure (-2.8 mmHg 95% CI: -5.0 - -0.7 mmHg; P = .01) and HOMA-IR (-0.5 95% CI: -0.8 - -0.1; P = .01) were lower in the intervention group as compared to controls. Hs-CRP and lipids did not differ between groups. Based on the 2001 revised criteria of the National Cholesterol Education Programme ATP III, after the intervention, the odds ratio for metabolic syndrome (MetS) in the intervention group was 0.53 (95% CI: 0.33–0.85; P < .01) compared to controls. The lifestyle intervention led to a relative risk reduction of 29.4% for MetS. Physical QoL scores were higher in the lifestyle intervention group (2.2 95% CI: 0.9 – 3.5; P = .001) while mental QoL scores did not differ.

Limitations, reasons for caution: No power calculation was performed for the reported outcomes. However, based on comparable studies, the sample size was sufficient to find relevant effects. Prompt start of infertility treatment after randomisation in the control group could have affected cardiometabolic health. However, adjustment for receiving infertility treatment did not change the results.

Wider implications of the findings: A lifestyle intervention among obese infertile women has immediate beneficial effects on cardiometabolic health and physical quality of life. Optimizing preconceptional lifestyle could potentially lead to a healthier intrauterine environment. Based on the principles of fetal programming, improving lifestyle before conception might lead to improved long-term health of the offspring.

Study question: Does an intensive weight reduction program prior to IVF increase live birth rates for infertile obese women?

Summary answer: An intensive weight reduction program prior to IVF, resulted in a substantial weight loss, but did not improve live birth rates in obese women.

What is known already: Among obese women fertility and obstetric outcomes are influenced negatively with increased risk of miscarriage and a higher risk of maternal and neonatal complications. A recent large randomized controlled trial found no effect of life style intervention on live birth in infertile obese women.

Obese women performing in vitro fertilization (IVF) have lower live birth rate than normal weight women. Despite the fact that only a few small trials, not powered for pregnancy and live birth rates, have been performed it has often been suggested that weight reduction interventions should be considered for obese infertile women before IVF treatment.

Study design, size, duration: A prospective, multicenter, randomized controlled trial was performed between 2010 and 2016 in the Nordic countries. In total, 962 women were assessed for eligibility and 317 women were randomized. Computerised randomization with concealed allocation was performed in the proportions 1:1 to one of two groups; weight reduction intervention followed by IVF-treatment or to IVF-treatment only. One cycle per patient was included.

Participants/materials, setting, methods: Nine infertility clinics in Sweden, Denmark and Iceland participated. Women under 38 years of age planning for IVF, and having a body mass index (BMI) $\geq$30 and <35 kg/m^2 were randomized to two groups. An intervention group (160 patients) with weight reduction before IVF, starting with 12 weeks of a low calorie liquid formula diet (LCD) of 880 kcal/day and thereafter weight stabilization for 2–5 weeks, or a control group (157 patients) with IVF only.

Main results and the role of chance: In the full analysis set (FAS) the live birth rate was 29.6% (45/152) in the weight reduction and IVF group and 27.5% (42/153) in the IVF only group. The difference was not statistically significant (difference 2.2, 95% confidence interval 12.9 to -8.6, p = 0.77). The mean weight change was -9.44 (6.57) kg in the weight reduction and IVF group as compared to +1.19(1.95) kg in the IVF only group being highly significant (p < 0.0001). Significantly more live births were achieved through spontaneous pregnancies in the weight reduction and IVF group, 10.5% (16) as compared to 2.6% (4) (p = 0.009). Miscarriage rates and gonadotropin dose used for IVF stimulation did not differ between groups. In two subgroup analyses, comparing women with PCOS in the two randomized groups and women in the weight reduction group reaching BMI $\leq$25 kg/m^2 or reaching a weight loss of 5 BMI units to the IVF only group, no statistical differences in live birth rates between groups were found.

Limitations, reasons for caution: The study was not powered to detect small increase in live births by weight reduction and was not blinded for patients or physician. Further, the intervention group had longer time to achieve a spontaneous pregnancy, but was also slightly older than the control group at IVF.

Wider implications of the findings: The study does not support that obesity (BMI 30–35) in women has a detrimental effect on IVF outcome, nor does it show that an intensive weight reduction with LCD treatment negatively effects the results.

Trial registration number: ClinicalTrials.gov number, NCT01566929.

O-063 Impact of dramatic weight loss linked to bariatric surgery on ovarian response and pregnancy rates after in vitro fertilization (IVF): a case-control study

V. Grzegorczyk Martin[1], A. Finet[2], P. Landais[3], E. Bonnet[4], I. Cedrin-Durnerin[5], M. Merzouk[5], J. Roset[2], R. Wainer[6], C. Avril[2]

[4]Clinical Research University Institute- Montpellier University, UPRES EA 2415, Montpellier, France

[5]Hôpital Jean-Verdier, ART, Bondy, France
[6]Centre Hospitalier Intercommunal Poissy Saint Germain, ART, Poissy, France

Study question: Is there any difference in IVF results in women having undergone bariatric surgery as compared to women of identical age and body mass index (BMI)?

Summary answer: Ovarian response to stimulation and pregnancy rates are comparable between the two groups, even after adjustment for confounding variables.

What is known already: Morbid obesity is associated with higher gonadotrophin consumption, lower embryo implantation, and higher miscarriage rates in IVF. Bariatric surgery leads to long term significant weight loss and improves spontaneous fertility and obstetrical and neonatal prognosis in obese women. So far, the few articles concerning IVF women after bariatric surgery included small cohorts and were unable to establish the surgery's effect on IVF outcome among infertile women. To our knowledge, no previous study has compared IVF results between women having undergone bariatric surgery to matched women of identical BMI.

Study design, size, duration: This case-control study was performed from retrospective analysis of three IVF centre databases. Data from 10,287 IVF/ICSI cycles between January 1st, 2012 and September 30th, 2016 were extracted and retrospectively analysed.

Participants/materials, setting, methods: All cases with previous history of bariatric surgery undergoing their first IVF cycle within three IVF centres were included and matched with two controls of similar BMI and age. Main outcome measures were cumulative pregnancy rates, average number of mature oocytes and embryos obtained in the first IVF cycle. Ovarian response was compared between groups for possible confounding variables. Univariate and multivariate conditional logistic regression analysis were carried out using R statistical software.

Main results and the role of chance: Data analysis included 249 women (83 cases, 166 controls) of similar BMI (28.60 ± 5.54 vs. 28.78 ± 4.52; p: NS) and age (33.08 ± 4.44 vs. 32.95 ± 4.36; p: NS). No significant difference in cumulative pregnancy rates per transfer was found between cases and controls (29.90% vs. 26.61%; p: NS), nor were differences observed in average number of mature oocytes (6.88 ± 4.85 vs 7.37 ± 4.85; p: NS) nor in average number of embryos obtained (4.43 ± 4.18 vs. 4.85 ± 3.79; p: NS). Among measured confounding variables, cases were observed to have significantly higher anti-müllerian hormone (AMH) levels (4.56 ± 5.38 vs. 3.29 ± 2.43; $p = 0.02$), antral follicle count (AFC) (17.06 ± 11.53 vs.13.9 ± 9.85; $p = 0.001$), and end-of-cycle estradiol (E2) levels (1662 ± 973 vs 1930 ± 1084; $p = 0.00004$) as compared to controls. Multivariate conditional logistic regression analysis found no significant difference in cumulative pregnancy rates between both groups after adjustment for AMH, AFC, E2, number of stimulation days, polycystic ovary syndrome status, and number of top embryos. Additionally, miscarriage rates were found to be 37.9% in cases and 25.0% in controls, but this difference was not significant ($p = 0.31$).

Limitations, reasons for caution: This is the largest study matching IVF patients having undergone bariatric surgery to patients of identical BMI and age; however, further analysis including cumulative live birth rates is underway. Cases included consulted for infertility, and results cannot be extended to all women candidates for bariatric surgery, regardless of fertility status.

Wider implications of the findings: Infertile obese women can be reassured as to effects of dramatic weight loss on IVF outcomes. Yet, the question of fertility preservation before bariatric surgery should be raised in light of negative ovarian reserve impacts due to the time delay needed to achieve weight stabilization before a pregnancy is allowed.

Trial registration number: not applicable.

O-064 A concise infertility work-up reduces pregnancy chances: a historical cohort study

J. Hamilton[1], J.W. Van der Steeg[2], J.P. De Bruin[2], C. Hamilton[2]

[1]Jeroen Bosch Hospital, Center of reproductive medicine, The Netherlands, The Netherlands
[2]Jeroen Bosch Hospital, Center of reproductive medicine, 's-Hertogenbosch, The Netherlands

Study question: Is the outcome after a concise infertility work-up (IW) the same as after an extensive IW?

Summary answer: The ongoing pregnancy rate within a follow-up of one year after a concise IW is significantly lower than after an extensive IW.

What is known already: Based on cost-effectiveness studies, which have mainly focused on diagnosis, IWs have become less comprehensive. Many centers have even adopted a onestop approach to the IW.

Study design, size, duration: We performed a historically controlled cohort study. In 2012 and 2013 all new infertility couples (n = 795) underwent an extensive IW (Group A). In 2014 and 2015 (n = 752) all new couples underwent a concise IW (Group B). The follow-up period was one year for both groups.

Participants/materials, setting, methods: The concise IW was mainly based on history taking, a gynecological ultrasound and semen analysis. A hysterosalpingography (HSG) was only performed if tubal pathology was suspected or before starting therapy. Laparoscopy and hormonal tests were only performed if indicated. The extensive IW also included ultrasonongraphic cycle monitoring, timed postcoital testing, timed progesterone and chlamydia antibody titer. A HSG was done routinely. Ongoing pregnancy rates in both groups were calculated.

Main results and the role of chance: The descriptive data like age, duration of infertility, type of infertility, lifestyle habits in both groups were comparable. In Group A many more infertility investigations were done. HSG was performed less frequently in Group B (29,8% versus 41,6%) and at a later stage. The diagnosis cervical infertility was only made in group A (9,3%). The definition of unexplained infertility 23,6% versus 31,9% (P < 0,001), therefore, was not the same in both groups.

Couples were treated according to the diagnosis with either expectant management (Hunault prognostic score > 30% or ovulation disorders, IUI in natural (cervical factor) or stimulated cycles (Hunault <30%) or IVF/ICSI (tubal factor, advanced female age, severe male factor).

Ovulation induction was more often started in Group A (35,8% versus 31,6% p < 0.05). Expected management was less often started in Group A (18,9% versus 24,8% p < 0.01), because in Group A more couples conceived during the IW (17,5% versus 9,7% p < 0.001). A significantly higher ongoing pregnancy rate within a follow-up of one year was found in Group A (60,2% versus 49,3% in Group B (p < 0.001)).

Limitations, reasons for caution: This was a controlled cohort study, introduction of bias cannot be ruled out. The drop-out rate differed 2,5% (A: 1,5 versus B: 5%) but this was not sufficient to explain the differences in pregnancy rate.

Wider implications of the findings: (Re-)introduction of an extensive IW should be considered as it may lead to higher ongoing pregnancy rates within a year, as the therapeutical effects of HSG and postcoital test have to be taken into account. This finding should be verified in an RCT.

Trial registration number: none.

O-065 Maternal obesity programs transgenerational mitochondrial dysfunction via the original, maternal oocytes, not due to exposure during gestation

K. Moley[1], A. Boudoures[2], S. Scheaffer[2]

[1]Washington University School of Medicine, St. Louis, U.S.A.
[2]Washington University in St. Louis, Obstetrics and Gynecology, Saint Louis, U.S.A.

Study question: Are the effects of maternal high fat/high sucrose diet on offspring predisposition to cardiometabolic diseases due to oocyte specific changes or exposure during gestation?

Summary answer: Mitochondrial metabolic changes in the F0 oocytes are carried over to the next generations as evident by IVF and embryo transfer into control females.

What is known already: Maternal obesity impairs offspring health, but the responsible mechanisms are not fully established. Previously, we have shown that feeding a high fat/high sugar diet to C57Bl/6 mice results in dysfunctional and misshapen oocyte mitochondria which appear for 3 generations of offspring conceived via normal mating. To confirm that this was an oocyte event and not due to the diet throughout gestation, we retrieved the oocytes from 10 week old female mice fed the diet for 6 weeks, performed IVF with sperm from males fed a regular diet and transferred the blastocysts into control ICR females on a regular chow diet.

Study design, size, duration: This was an observational, basic science experiment with inbred mice.

Participants/materials, setting, methods: Mice were placed on a normal chow diet (22% fat, 3% sucrose) or a high fat/high sucrose diet (59% fat, 23% sucrose) for 6 weeks after which time the oocytes were retrieved, fertilized and the embryos were transferred into control mice on a normal chow diet. At least 5 mice per group were used for the experiments. All experiments were repeated 3 times.The skeletal muscle and cardiac muscles were removed and subject to electron microcopy.

Main results and the role of chance: Remarkably the same abnormal pattern of mitochondrial dysfunction and misshapen mitochondria was seen in the off-spring from HF/HS moms that underwent IVF and embryo transfer into mice on a regular diet, as had been seen in the offspring of mice fed the HF/HS diet from prior to and throughout gestation. In both cardiac and skeletal muscle which have high mitochondrial demands, mitochondria with severely disarrayed cristae, bloated abnormal shapes and decreased mitochondrial matrix density were seen in the IVF pups from HF/HS moms as compared to control moms. Mitochondrial respiration in isolated cardiac and skeletal was abnormal in the same group of mice using an Oxygraph 2 K (OROBOROS Instruments). ECHO of the hearts of the IVF pups from the HF/HS moms showed fractional shortening of the muscle of the left ventricle indicating early heart failure. None of these changes were seen the IVF pups from oocytes of mothers fed the normal chow diet.

Limitations, reasons for caution: This is a mouse study, not a human study but the epidemiological data strongly suggests that children of obese mothers are predisposed to developing cardiometabolic diseases and obesity much earlier than the children from lean mothers.

Wider implications of the findings: Our results suggest that maternal programming of metabolic disease can be passed through the maternal oocyte and that the transfer of aberrant oocyte mitochondria to subsequent generations may contribute to the increased risk for developing obesity and cardiometabolic disease in their offspring.

Trial registration number: Not applicable

SESSION 18: UPDATES ON PCOS
Monday 3 July 2017   Room A   15:15–16:30

O-066   Follicular ADAMTS-1 and aggrecan in polycystic ovary syndrome (PCOS)

E.N. Tola[1], D. Karatopuk[2], N. Koroglu[3], M. Ergin[4], H.B. Oral[1]

[1]Suleyman Demirel University- Faculty of Medicine, Department of Gynecology and Obstetrics- In vitro Fertilization Unit, ISPARTA, Turkey
[2]Suleyman Demirel University- Faculty of Medicine, In vitro Fertilization Unit, ISPARTA, Turkey
[3]3Kanuni Sultan Suleyman Training and Research Hospital, -Department of Gynecology and Obstetrics-, Istanbul, Turkey
[4]Gaziantep 25 Aralık State Hospital, Department of Biochemistry, Gaziantep, Turkey

Study question: Do follicular ADAMTS-1 and aggrecan have any possible role in anovulation and predictor effect on in vitro fertilization (IVF) success rate in women with PCOS?

Summary answer: This study revealed the role of ADAMTS-1 and aggrecan in the etiopathogenesis of PCOS and the predictive effect of ADAMTS-1 level on implantation.

What is known already: Polycystic ovary syndrome (PCOS) is the most common cause of anovulatory infertility. Proteoglycan degradation by a disintegrin- like and metalloproteinase with thrombospondin type motifs (ADAMTS-1) is essential for ovulation and fertilization. Matrix metalloproteinases are involved in follicular fluid (FF) and the cumulus oocyte complex (COC) and regulate extracellular matrix (ECM) remodeling. Proteoglycans, the basic components of the ECM and FF proteoglycans—such as versican, aggrecan- and

hyaluronan are important during folliculogenesis. An essential role of versican cleavage by ADAMTS-1 during ovulation, as well as abnormal morphogenesis of versican in ADAMTS-1 null mice, has been demonstrated.

Study design, size, duration: The present study was a prospective cross-sectional clinical trial performed in the assisted reproduction clinic of a tertiary center between August, 2016 and December, 2016. A total of 43 patients undergoing IVF treatment—21 diagnosed as PCOS according to the Rotterdam consensus (the PCOS group) and 22 diagnosed as normal ovulatory women (the control group)—were recruited.

Participants/materials, setting, methods: The control group received IVF for tubal factor and/or male infertility, except azoospermia and severe oli-goasthenospermia. Patients were prepared using antagonist protocol. Oocytes were considered fertilized when two pronuclei were observed. The fertilization rate (FR) was calculated as the number of fertilized oocytes divided by the number of metaphase (MII) oocytes. Implantation was determined by serum HCG levels. Aggrecan and ADAMTS-1 levels were analyzed using human aggrecan and ADAMTS-1 ELISA kit, respectively.

Main results and the role of chance: Age, body mass index, hormone levels at the 3rd day of the cycle (except estradiol) and the percentage of MII were distributed homogeneously. E_2 levels, oocyte, MII, and MI numbers were significantly higher in the PCOS group ($p = 0.003$, $P < 0.001$, $p = 0.003$ and $p = 0.011$, respectively). ADAMTS-1 levels were higher in the PCOS group (33.84 ± 17.7 ng/ml) than in controls (23.58 ± 5.67 ng/ml, $p = 0.013$). Aggrecan levels were higher in women with PCOS (8.05 ± 4.78 ng/ml) than in controls (3.63 ± 2.18 ng/ml, $p < 0.001$). For the prediction of the diagnosis of PCOS, when the cut-off level of aggrecan was taken as 4.10 ng/ml, the sensitivity was 72.7%, and the specificity was 76.1% ($p = 0.001$). For ADAMTS-1, when the cut-off level was taken as 27.50 ng/ml, the sensitivity was 72.2%, and the specificity was 68.0% ($p = 0.013$). Our study failed to identify any predictor effect of aggrecan or ADAMTS-1 on FR in the PCOS group or among all patients ($p>0.5$). When implantation was evaluated, there was a statistically significant positive predictor effect of ADAMTS-1 ($p = 0.036$, $\beta = 0,331$) levels. However, there was no statistically significant effect of aggrecan on implantation. Age, BMI, and the percentage of MII were not predictive of implantation.

Limitations, reasons for caution: The lack of evaluation of oocyte quality, which is closely associated with fertilization and the small sample size are the limitations of this study.

Wider implications of the findings: The increase of ADAMTS-1 and aggrecan in the FF could be a pathogenic mechanism of anovulation in PCOS patients. Follicular ADAMTS-1 is a potential predictor marker for implantation capacity. Further studies are needed to investigate the underlying causes of anovulation and to improve IVF success rates in PCOS patients.

Trial registration number: none.

O-067   Randomized controlled trial of combined lifestyle and herbal medicine in women with polycystic ovary syndrome

S. Arentz[1], C. Smith[2], J. Abbott[3], P. Fahey[4], B. Cheema[5], A. Bensoussan[6]

[1]Western Sydney University, National Institute for Complementary Medicine, Penrith South DC, Australia
[2]Western Sydney University, National Institute of Complementary Medicine, Penrith South DC, Australia
[3]University of New South Wales, School of Women's and Children's Health, Randwick, Australia
[4]Western Sydney University, School of Science and Health, Penrith South, Australia
[5]Western Sydney University, School of Science and Health- National Institute of Complementary Medicine, Penrith South DC, Australia
[6]Western Sydney University, National Institute of Complementary Medicine, Penrith South, Australia

Study question: Does combined lifestyle intervention and a novel herbal formulation improve oligomenorrhoea compared to lifestyle alone in overweight community based women with polycystic ovary syndrome (PCOS)?

Summary answer: At three months, women in the combination group recorded a reduction in oligomenorrhoea of 32.9% (95% CI,23.3–42.6, p < 0.01) compared to controls, estimated as a moderate-large effect.

What is known already: Lifestyle intervention is first line treatment for overweight women with polycystic ovary syndrome (PCOS) and may regulate menstruation, reduce hyperandrogenism, treat hyperinsulinaemia and improve quality of life. However, the strength of evidence for lifestyle is limited by high attrition in RCTs and clinical uptake remains impeded by the lack of evidence for optimal dietary and exercise practices. In addition, physical and psycho social barriers are commonly observed in overweight women, particularly those with established obesity. Many women use additional complementary medicine including herbal medicines, however despite potential positive endocrine effects in PCOS, there is no evidence of effectiveness or safety.

Study design, size, duration: This study examined the relative effectiveness of combined lifestyle intervention and herbal medicine compared to lifestyle alone for oligomenorrhoea in overweight women with PCOS in a prospective, randomized controlled trial conducted between in August 2012 to June 2014. We consented and randomized 122 women to three months of lifestyle plus herbal medicine (n = 60) or lifestyle intervention alone (n = 62).

Participants/materials, setting, methods: The interventions were delivered in urban and regional communities in Australia. Participants were overweight women with PCOS (Rotterdam criteria), not taking contraceptive pills or antidepressants. Energy deficit, personalized lifestyle plans were revised fortnightly. The herbs included daily dosed Cinnamomum verum, Glycyrrhiza glabra, Hypericum perforatum, and Paeonia lactiflora with Tribulus terrestris on menstrual cycle days 5–14. The primary outcome was oligomenorrhoea. Secondary outcomes were serum hormones, anthropometry, quality of life, psychology, pregnancy, birth and blood pressure.

Main results and the role of chance: At three months the mean menstrual cycle length was 43 days (95% CI, 21 to 65, p < 0.001) lower for women in the combination group compared to those in the lifestyle only group.Secondary outcomes were significantly improved for women taking combined herbal medicine and lifestyle compared to controls for BMI (MD -1.0 95% CI -1.6 to -0.5, p < 0.01), increased oestradiol (MD 68.9 pmol/L, 95% CI 5.5 to 132.3, p = 0.03); lowered LH (MD -1.82IU/L, 95% CI -3.5 to -0.1, p = 0.04), fasting insulin (MD -5.9mU/l, 95% CI -10.9 to -1.0, p = 0.02; systolic (MD -3.6 mmHg, 95%CI-6.3 to -0.9, p = 0.01) and diastolic (-5.1 mmHg, 95%CI -7.8 to - 2.4, p < 0.01) blood pressure; PCOSQ score (MD -31.1, 95% CI -41.4 to -20.7, p < 0.01), depression (-4.3, (95% CI -5.9 to -2.7, p < 0.01), anxiety (-4.0, 95% CI -5.4 to -2.6, p < 0.01) and stress (-5.0, 95% CI -6.5 to -3.5, p < 0.01) scores and increased conception rates (RR 3.9, 95% CI 1.1 to 13.1, p = 0.01). The residual effect of loss of body weight on the primary outcome (number of days in the menstrual cycle) after controlling for baseline menstrual variation was not significant (p = 0.07). Two women in in the herbal medicine group were withdrawn due to non-serious adverse effects.

Limitations, reasons for caution: The lack of a placebo group prevents identification of the active component of this herbal and lifestyle intervention that has generated these outcomes. The lack of blinding could have influenced the estimated treatment effect size and confounded the outcomes particularly for subjective outcomes such as self-reported QoL, psychology and compliance.

Wider implications of the findings: In light of the limitations for lifestyle intervention for overweight women with PCOS, changes demonstrated in this study, with both specific gynaecological, physical and mental health improvements are an important finding.There were no serious adverse events during the trial, and non-serious adverse effects were fewer compared to pharmaceutical interventions.

Trial registration number: Australia and New Zealand Clinical Trial Registry (ANZCTR) 126 12000 122 853.

O-068 Comparative effectiveness of 9 ovulation-induction therapies on patients with clomiphene citrate-resistant polycystic ovary syndrome: a network meta- analysis

Y. Yu[1], L. Fang[1], R. Zhang[1], J. He[1], Y. Xiong[2], X. Guo[1], Q. Du[1], Y. Huang[1], Y. Sun[1]

[1]The First Affiliated Hospital of Zhengzhou University, Reproductive medical center, Zhengzhou, China
[2]The Chinese University of Hong Kong, Obs. & Gyn., Hong Kong, China

Study question: How are the comparative efficacies of ovulation-induction treatments in clomiphene citrate-resistance (CCR) PCOS and which is the most efficacious one?

Summary answer: The co-treatment of metformin with letrozole (metformin+letrozole) is proved to be the most efficacious therapy among the included treatments.

What is known already: Between 15 and 40% of PCOS patients are termed as CCR because of their failure to ovulate with CC. Gonadotropins, including follitropin (FSH) and human menopausal gonadotropin (hMG), and laparoscopic ovarian diathermy (LOD) are recommended as efficacious options for CCR PCOS. Apart from that, letrozole, metformin, metformin+letrozole and metformin+CC are reported to be efficacious on ovulation induction in PCOS who are CCR. However, there has been no network meta-analysis to compare and rank the above therapies.

Study design, size, duration: It is a network meta-analysis. The Cochrane Library, PubMed, and EMBASE was searched to identify randomized clinical studies for the treatment of clomiphene citrate-resistance PCOS. After electronic and manual searching and screening, we ultimately included 26 randomized clinical trials including 2722 participants and investigating 9 types of therapies: CC, metformin, letrozole, FSH, hMG, unilateral LOD (ULOD), bilateral LOD (BLOD), metformin+letrozole, and metformin+CC. The treatment duration of included trials ranged between 3 to 6 months.

Participants/materials, setting, methods: The network meta-analysis was performed using the Markov Chains Monte Carlo method based on the Bayesian framework and using the non-programming software of the Aggregate Data Drug Information System version 1.16.7. The endpoints we focused on included reproductive outcomes (pregnancy rates per intention to treat (ITT), live birth rates per ITT, abortion rates per pregnancy, ovulation rates per cycle, and multiple pregnancy rates per pregnancy) and adverse events (side effects and the occurrence of OHSS).

Main results and the role of chance: The FSH and metformin+letrozole therapies were all identified as more efficacious than CC in improving pregnancy rates and live birth rates. The pregnancy rates in the hMG groups were significantly higher than those of the BLOD, ULOD and CC groups. The ovulation rates were significantly higher in the metformin+letrozole groups than BLOD, CC, letrozole, metformin and metformin+CC groups. The abortion rates in the metformin+letrozole groups were significantly lower than metformin+CC groups. The occurrence of OHSS was mainly observed during gonadotropins therapies. Based on the ranking probability results, the hMG and metformin+letrozole therapies had the highest probabilities of ranking the first in the comparisons of pregnancy rates (0.71, 0.17, respectively) and live birth rates (0.26, 0.64, respectively) and the highest probability of ranking the last in the comparisons of abortion rates (0.27, 0.42, respectively). The metformin+letrozole and FSH therapies had the highest probability of ranking first in comparisons of ovulation rates per cycle (0.89, 0.1, respectively). In conclusion, gonadotropins (FSH, hMG) and metformin+letrozole are the most effective therapies with regard to reproductive outcomes.

Limitations, reasons for caution: The majority of the trials were of low to moderate quality. The exclusion of conference abstracts and inclusion of only English articles in this analysis might account for the observed publication bias. Conclusions should be strengthened by large multicenter clinical trials under the restriction of specific PCOS phenotypes.

Wider implications of the findings: It is the first time that the efficacy of metformin+letrozole on ovulation induction is verified. The treatment of metformin+letrozole is a reasonable choice for CCR PCOS before implementing IVF.

Study question: Is there an association of pre-gestational obesity and gestational weight gain(GWG) with birth weight and what factors predict GWG in an infertile(PCOS vs. Unexplained) population?

Summary answer: Matched for weight category, only normal/overweight (and not obese) PCOS women experienced increased rates of GWG compared to controls, without differences in mean birth weight.

What is known already: Women with PCOS have more perinatal complications, including abnormal birth weight than other women, though it is difficult to separate out the roles of subfertility per se, pre-existing obesity and excessive GWG. Many infertility studies fail to capture pregnancy outcomes, both maternal and fetal, up to birth, so there are few data in this area. Similarly, GWG studies often initiate in the late first/early second trimester and therefore do not capture all GWG from conception onwards.

Study design, size, duration: Case/Control study of pregnancy and singleton live births in Polycystic Ovary Syndrome(PCOS) women and Controls (unexplained infertility) from two large multicenter randomized controlled trials (RCTs), the Pregnancy in Polycystic Ovary Syndrome II (PPCOS II) trial where patients conceived with either letrozole or clomiphene and the Assessment of Multiple Ovarian Gestations from Ovarian Stimulation (AMIGOS) trial where patients conceived with either letrozole, clomiphene or gonadotropin and intra-uterine insemination.

Participants/materials, setting, methods: Singleton pregnancies with live birth(>20 weeks) were compared(PCOS: N = 164, Controls: N = 176) from 14 participating academic health centers. Data were abstracted from clinical trial records from baseline, through participation and conception, and review of obstetric records of study participants. We compared groups(PCOS/Controls) using the Institute of Medicine BMI categories(normal, overweight, and obese) given varying recommendations for GWG by BMI group, modeled GWG by study and BMI group, and developed predictive models for GWG by study group.

Main results and the role of chance: From pre-conception baseline, normal weight(BMI<25) PCOS women gained 2.3lbs more during the first trimester(95%CI 0.3, 4.2, P = 0.02) and by the end of the second trimester gained a total of 4.2lbs more than Controls(95% CI 0.7, 7.7, P = 0.02). Overweight PCOS women(25 < =BMI<30) gained significantly more weight only by the end of the second trimester(5.2lbs, 95%CI 0.2, 10.2, P = 0.04) and obese PCOS women(BMI≥30) had similar weight gains as Controls throughout pregnancy. Mean birthweights were similar between PCOS and Controls for each weight group. The prevalence of small, appropriate, and large for gestational age babies in PCOS women(4.9%, 80.3% and 14.8%, respectively) was not significantly different than Controls(10.3%, 75.9% and 13.8%, respectively) (P = 0.21). Examining baseline GWG factors using a multivariate logistic regression model pre-pregnancy weight was inversely and significantly predictive for GWG in both PCOS(each 1 unit BMI increase correlated with a -0.54 lb GWG, 95% CI -0.83, -0.28 lb, P < 0.001) and Controls(each 1 unit BMI increase associated with a -0.57 lb GWG, 95% CI -0.95, -0.18 lb, P = 0.004). In Controls for every 1 ng/dL increase in baseline testosterone levels, there was a -0.13 lb GWG decrease(95% CI -0.25, -0.01, P = 0.03), with no additional significant predictors for PCOS women, although insulin and AMH levels approached significance.

Limitations, reasons for caution: We examined only singleton and not multiple pregnancies. These data are from prospective RCTs of patients treated for infertility and may not be generalizable to other obstetric populations.

There were more missing data from the 3rd trimester due to early delivery or incomplete office obstetric records.

Wider implications of the findings: Excessive GWG in normal/overweight women with PCOS may protect against small for gestation age(SGA) without an increase in large for gestational age(LGA) babies. Increasing BMI is associated with less GWG independent of diagnosis, therefore pre-existing obesity should be incorporated into studies of pregnancy outcomes in women with PCOS.

Trial registration number: Clinicaltrials.gov: NCT00719186(PPCOS II) and NCT01044862(AMIGOS).

O-070   Healthcare providers' knowledge, diagnosis and management of polycystic ovary syndrome (PCOS) in Europe, North America and internationally

M. Gibson-Helm[1], A. Dokras[2], T. Piltonen[3], H. Teede[1]

[1]Monash University, Monash Centre for Health Research and Implementation- School of Public Health and Preventive Medicine, Melbourne, Australia
[2]University of Pennsylvania, Division of Reproductive Endocrinology- PENN PCOS Center, Philadelphia, U.S.A.
[3]University of Oulu, Department of Obstetrics and Gynecology- PEDEGO Research Unit- Medical Research Center- Oulu University Hospital, Oulu, Finland

Study question: What are the key evidence-practice gaps in PCOS care and do these vary across world regions and between disciplines?

Summary answer: These findings suggest significant PCOS evidence-practice gaps that differ in North America, Europe and other world regions, and between gynaecologists and endocrinologists.

What is known already: Polycystic ovary syndrome (PCOS) affects 6–21% of reproductive-aged women, depending on diagnostic criteria and population studied. Women around the world report suboptimal diagnosis experiences and dissatisfaction with care and they desire high-quality information from their doctors about the full range of PCOS features. Multidisciplinary care for PCOS is recommended yet little is known about the knowledge and practices of different medical professions around the world.

With development of the first international evidence-based guideline for PCOS underway, it is timely to investigate health professionals' knowledge and practices regarding PCOS to identify evidence practice gaps and guide translation activities.

Study design, size, duration: An online, anonymous questionnaire completed by 1654 clinicians involved in PCOS care in North America (39%), Europe (43%) and other world regions (18%). Respondents were recruited through professional societies, including ESHRE, in 2015-2016.

Participants/materials, setting, methods: Almost all clinicians (92%) were obstetrician/gynaecologists (60%), reproductive endocrinologists (27%) or medical endocrinologists (5.4%). Approximately half the clinicians reported seeing over 50 women with PCOS in the last year (52%). Multivariable logistic regression analyses generated adjusted odds ratios (OR) and 95% confidence intervals (CI) for associations between clinicians' knowledge or practices regarding PCOS, and world region of residence [North America (reference category), Europe, other] and profession [gynaecologist (reference category), reproductive endocrinologist, medical endocrinologist].

Main results and the role of chance: Generally, the reproductive features of PCOS were well recognised (e.g. irregular menses=98%), followed by metabolic features (e.g. increased risk of diabetes=90%), but psychosocial features were under-recognised (e.g. depression = 49%). European clinicians were less likely to be aware of the broader features than North American clinicians (e.g. anxiety OR:0.7, 95%CI:0.5–0.9, p = 0.003), with endocrinologists reporting more awareness than gynaecologists (e.g. anxiety OR for reproductive endocrinologists:1.8, 95%CI:1.4–2.2, p < 0.001; anxiety OR for medical endocrinologists:2.0, 95%CI:1.2–3.2, p = 0.004).

The internationally-accepted Rotterdam/ESHRE diagnostic criteria were most commonly used (65%), although 17% reported not knowing what criteria they use. European clinicians were more likely to use Rotterdam criteria than North American clinicians (OR:4.0 95%CI:3.1–5.2, p < 0.001). Reproductive, but not medical, endocrinologists were more likely to use these criteria than gynaecologists (OR:3.1, 95%CI:2.3–4.1, p < 0.001).

The non-fertility treatments most commonly prescribed were oral contraceptives (76%) and lifestyle management (73%). Compared to the reference categories, European clinicians were less likely to prescribe lifestyle management (OR:0.7, 95%CI:0.6–0.9, p = 0.009) and endocrinologists were more likely (OR for reproductive endocrinologists:2.1, 95%CI:1.6–2.8, p < 0.001; OR for medical endocrinologists:3.1, 95%CI:1.7–5.7, p < 0.001).

Lifestyle management (59%) and clomiphene citrate (45%) were most commonly prescribed for fertility. Reproductive, but not medical, endocrinologists were more likely to prescribe lifestyle management than gynaecologists (OR:1.6, 95%CI:1.2–2.0, p < 0.001).

Limitations, reasons for caution: Selection bias is possible as clinicians who are more confident in their knowledge of PCOS, or who see more women with PCOS, may have been more likely to complete the survey. The findings may also be subject to recall bias as they rely on self-report rather than direct observation.

Wider implications of the findings: Variation in clinical care may be reduced by increasing clinician awareness of the broader features of PCOS and increasing the application of accepted diagnostic criteria. These findings have informed how the translation program of the first international evidence-based PCOS guideline should be tailored to different locations and professions.

[1]Iakentro Fertility Centre, IVF Laboratory, Thessaloniki, Greece
[2]IVF Centers Prof. Zech, IVF Laboratory, Bregenz, Austria
[3]Institut Médical de Champel, IVF, Geneve, Switzerland

Study question: Is beneficial the performance of laser assisted hatching prior transfer in cases with embryos deriving from vitrified/ warmed oocytes in an oocyte donation program?

Summary answer: Clinical results are significantly higher when laser assisted hatching is being performed before transfer in embryos which derive from donated vitrified/ warmed oocytes.

What is known already: Lately, studies show very promising results after vitrification/warming of donated oocytes. However, a recent review on oocyte vitrification (Potdar et al, 2014) shows great heterogeneity in the reported clinical results after oocyte vitrification/warming and thus highlights that there is space for improving the clinical outcome after the use of donated vitrified oocytes. It is hypothesized that oocyte vitrification/warming procedure induces zona pellucida hardening which eventually will result to embryo hatching failure, compromising the implantation process and the clinical result. There are not enough studies which evaluate the clinical impact of assisted hatching in human embryos deriving from donated vitrified oocytes.

Study design, size, duration: A control randomized study was performed from February 2015 to June 2016. Based on a pilot study that showed 23% higher pregnancy rate (51%vs74%) when laser hatching was used, a power analysis was performed in order to determine that 176 cases were needed in order to detect the significance of laser assisting hatching on clinical outcome. A randomization list was used in order to allocate the recruited cases in group1 or group2.

Participants/materials, setting, methods: Oocyte donation cases that used vitrified oocytes from IAKENTRO egg cryobank were included in the study. Oocytes were vitrified using a closed system vitrification. After warming,

oocytes were fertilized and cultured to day 5. All transfers performed on day 5. Two groups were formed. Group 1 embryos were transferred without assisted hatching. Group 2 embryos were hatched with the use of laser pulses two hours before transfer. Eighty eight cases were included in each group.

Main results and the role of chance: Analyzing the results of our study we showed that the mean number of embryos between Group 1 (no laser) and Group 2 (laser) was similar (1.88 ± 0.31 vs 1.85 ± 0.35, p = 0.69). The pregnancy rate was significantly higher in Group 2 (52.3% vs. 68.2%, p=.031, 95% CI: 1.06–3.61, 1.95-fold increase when laser applied, number of patients need to treat:6,28). Clinical pregnancy rate was significantly higher in Group 2 (44.3% vs. 66.3%,p=.01, 95% CI: 1.20–4.02, 2.2-fold increase when laser applied, number of patients need to treat:4,54). Accordingly, in group 2 cases we observed significantly higher ongoing pregnancy rate (37.5% vs. 59.1%, p=.004, 95% CI: 1.31–4.41, 2.4-fold increase when laser applied, number of patients need to treat:4,62) and higher delivery rate (37.5% vs. 59.1%, p=.004, 95% CI: 1.31–4.41, 2.4-fold increase when laser applied, number of patients need to treat:4,62). The mean number of gestational sacs observed in group1 was statistically lower than the one observed in group2 (0.57 ± 0.72 vs 0.97 ± 0.84, p = 0.003). Therefore the implantation rate was significantly higher in the laser group (0.31 ± 0.37 vs 0.52 ± 0.44, p = 0.0003, 95% CI: 0.351 to 0.478).

Limitations, reasons for caution: In power analysis, although it was based on a pilot study, we used a relatively big difference (23%) between control and intervention group in order to determine the sample size.

This study includes only oocyte donation cases. Our findings should not be extrapolated to any other female group.

Wider implications of the findings: Laser assisted hatching of embryos deriving from vitrified oocytes, significantly improves the clinical outcome and therefore is highly recommended when oocytes from egg donor cryobanks are used. This study shows that oocyte vitrification/warming procedure affects the implantation capacity of the resulting embryo probably due to hardening of the zona pellucida.

Trial registration number: ISRCTN21836222.

O-072 Laser-assisted hatching improves clinical outcomes of top grade, vitrified–warmed blastocysts developed in high prognosis oocyte donation cycles: a prospective randomized study

Y. Panagiotidis[1], A. Papatheodorou[1], S. Petousis[1], M. Goudakou[1],
D. Pavlidou[1], A. Gkountis[1], K. Ravanos[1], P. Vanderzwalmen[2],
N. Prapas[1], Y. Prapas[1,3]

[1]Iakentro Fertility Centre, IVF Laboratory, Thessaloniki, Greece
[2]Centers Prof. Zech, IVF-, Bregenz, Austria
[3]Institut Médical de Champel-, Infertility center, Genève, Switzerland

Study question: How does partial zona-pellucida (ZP) opening by laser-assisted hatching (LAH) affects the implantation potential of top quality vitrified–warmed blastocysts?

Summary answer: The implantation rate of vitrified-warmed top grade blastocysts is significantly increased if they undergo post warming a partial (15%-20%) ZP opening.

What is known already: Embryos undergo ZP hardening due to both prolonged in vitro culture, as well as a consequence of cryopreservation. The inefficiency of blastocysts to hatch from the ZP post-warming, within the optimal window of endometrial receptivity, may lead to low implantation rates. It is accepted that LAH generally improves the implantation potential of lower quality embryos when transferred in fresh or cryopreserved cycles or when it is applied in cases with poor prognosis, repeated implantation failures and in older women. Little information exists regarding the role of LAH in vitrified–warmed transfer (FET) of top quality blastocysts in high prognosis cycles.

Study design, size, duration: A prospective randomized study, performed in a private IVF clinic from September 2015 to August 2016, including 365 FETs of top quality blastocysts, developed in non-synchronized donor/recipient oocyte donation cycles. Embryos of each FET were randomized according to a computer-generated randomization list to either a group that had 15–20% of the ZP ablated using LAH (Group 1, n = 186) or no LAH (Group 2, n = 177). The clinicians and the patients were blinded to the assigned group.

Participants/materials, setting, methods: Embryos were cultured in single step culture medium and the developed blastocysts were vitrified using a closed vitrification protocol. If at least 2 top quality blastocysts (2BB and higher) were not developed, cycle was reinitiated. During warming, while blastocysts were still collapsed in the final washing step, LAH was applied in allocated embryos. A 20% opening was created as distant as possible from the trophectoderm cells. All blastocysts were cultured for 3 hours until ET.

Main results and the role of chance: Both groups had equal demographic and clinical characteristics (donor age, sperm quality, number of fertilizing oocytes, 2pn and vitrified blastocysts).

There was no difference between the numbers of warmed (1.90 ± 0.3 vs. 1.93 ± 0.3, p=.31) and transferred (1.83 ± 0.4 vs. 1.79 ± 0.4, p=.30) blastocysts between the two groups (LAH vs. no-LAH) respectively. Embryo implantation rate was set as primary outcome. LAH significantly increases the implantation potential of top quality blastocysts (LAH vs. no-LAH), 44.3% (151/341) vs. 33.1 % (105/317), P=.003, 95% CI: 1.17–2.2, 1.6- fold increase when LAH was applied. Similarly, β-hCG positive rates, 71.5% (133/186) vs. 57.6% (102/177), p=.006 and clinical pregnancy rates 61.2% (114/186) vs. 45.2% (80/177), p=.002 were significantly higher in LAH vs. no-LAH group, respectively. Minimizing the selection threshold to those FETs with absolutely top quality, 4AA blastocysts, produces an even higher positive impact of LAH on all the above clinical parameters.

Limitations, reasons for caution: LAH is suggested to be beneficial in low prognosis cycles. This study included FETs of good prognosis oocyte donation cycles. Live birth rate was not recorded. Moreover, findings have not been verified in fresh or homologous cycles. It is premature to recommend AH in all patients.

Wider implications of the findings: We postulate that the LAH embryos save energy to complete the hatching process, avoiding multiple expansions, ensuring that the energy stores are not depleted prior to implantation. Additionally, embryos that hatch on time could achieve better synchronization to the optimal time range of endometrial receptivity.

Trial registration number: Pending.

O-073 Clinical outcomes of blastocysts vitrified-warmed using a new semi-automated vitrification system are comparable to the gold standard open vitrification method

U. Tumurbaatar[1], N. Hobson[1], T. Roy[2], R. Woolcott[2], M. Bowman[3], S. Arthur[4], S. Brandi[2]

[1]Genea, Embryology, Sydney, Australia
[2]Genea Biomedx, Research, Sydney, Australia
[3]Genea, Clinical, Sydney, Australia
[4]Genea, Science, Sydney, Australia

Study question: Are clinical outcomes from the transfer of human blastocysts vitrified using the semi-automated closed Gavi™ system equivalent to that of the manual open Cryotop™ system?

Summary answer: Clinical outcomes of blastocysts vitrified using the Gavi system are comparable to the Cryotop system including embryo recovery, embryo survival and clinical pregnancy.

What is known already: Vitrification of embryos is an essential component of an effective assisted conception program. When successfully executed, it provides excellent embryo survival and pregnancy rates, with the gold-standard method arguably being the open Cryotop system. However, vitrification is a manual, high-skill and labor intensive procedure that is difficult to standardize, and results can vary greatly between embryologists and clinics. To address these issues, the Gavi system was designed to mechanically automate key steps in vitrification. In vitro studies using mouse and human research blastocysts have shown equivalent results to the Cryotop system (Roy et al. Hum Reprod, 2014; 29: 2431–8).

Study design, size, duration: This is an ongoing study in which preimplantation genetic screening (PGS) patients were randomly allocated to have either their best embryo vitrified using the Gavi system and their second best using the Cryotop system, or vice versa (no additional embryos included in the study). This study, which commenced in August 2015, assessed outcomes of single embryo transfers of Gavi vitrified-warmed blastocysts in comparison to Cryotop controls. Results presented are interim results.

Participants/materials, setting, methods: This study was performed at the private assisted reproductive technology (ART) clinic Genea (Sydney, Australia), which has proven expertise in Cryotop vitrification (Roy et al. Fert Steril, 2014; 101: 1294–301). Participants included infertile couples undergoing assisted conception and PGS with at least one blastocyst for vitrification. Vitrification was performed using either Gavi, as described by the manufacturer Genea Biomedx, or the open Cryotop protocol as described previously (Roy et al. Fert Steril, 2014; 101: 1294–301).

Main results and the role of chance: 665 blastocysts have been vitrified using the Gavi system and 669 using the Cryotop system. Of these, 170 euploid embryos vitrified using the Gavi system and 199 using the Cryotop system have been warmed, resulting in 168 embryos from the Gavi and 196 embryos from the Cryotop being transferred with a single embryo transfer policy. The patient and embryo demographics were similar for Gavi and Cryotop vitrified-warmed transfers; the average maternal age was 36.2 and 36.3 years, respectively, and the proportion of good quality embryos was 95.8% and 94.9%, respectively (ICM and TE grade excellent or good). Recovery rate of embryos from the Gavi system was 99.4% and the Cryotop system 100% (p = 0.28). Of those embryos that were recovered survival was 99.4% and 98.5% respectively (p = 0.39). Clinical use of Gavi vitrified-warmed embryos resulted in 65.5% biochemical pregnancy rate as compared with 66.8% for Cryotop vitrified-warmed embryos (p = 0.78). The fetal heart pregnancy rate per embryo transfer (presence of a fetal heart at 7 weeks by ultrasound) was 57.1% from Gavi system pregnancies as compared with 59.2% of Cryotop system pregnancies (p = 0.69). There are now 26 live births from Gavi vitrified-warmed blastocysts.

Limitations, reasons for caution: Clinical outcomes of Gavi-vitrified cleavage stage embryos or oocytes were not assessed.

Wider implications of the findings: The Gavi system has the potential to revolutionize embryo vitrification; standardizing the process, increasing laboratory efficiencies and improving clinical outcomes for laboratories struggling with cryopreservation. This study demonstrates it is possible to semi-automate complicated ART procedures and opens up the possibility for further improvements in efficiencies and clinical outcomes.

Trial registration number: Not applicable.

O-074 Impact of post-warming culture duration on clinical outcomes of vitrified good-quality blastocyst transfers: a prospective randomized study

C. Herbemont[1], S. Chekroune[2], S. Bonan[2], N. Sermondade[2], J. Boujenah[3], I. Cedrin-Durnerin[3], A. Seroka[3], C. Vinolas[3], C. Sonigo[3], M. Grynberg[3], C. Sifer[2]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-Biologie de la Reproduction-CECOS, Bondy, France
[2]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, Bondy, France
[3]Hôpital Jean Verdier, Médecine de la Reproduction, Bondy, France

Study question: Does post-warming culture duration (1 hour versus (vs.) 18 hours) influence implantation rates (IR) of good-quality blastocysts in a good-prognosis population?

Summary answer: IR were similar whatever the duration of post-warming culture of good-quality blastocysts. Thawing blastocysts on the day before could enable an adaptation of transfer strategy.

What is known already: Blastocyst survival after warming is difficult to evaluate. Several authors have suggested that re-expansion degree could be useful to predict survival and implantation potential of warmed blastocysts. A recent study reported that more than 75% of blastocysts re-expanded within 5 hours after warming. Nevertheless, 30% of shrunken blastocysts turned out to be viable within 24 hours post-warming. However, methodology, and especially the duration reported between warming and transfer are variable among studies (from 1–5 hours up to 20 hours). To date, a short duration between warming and transfer seems to be insufficient to properly evaluate implantation potential of blastocysts.

Study design, size, duration: This prospective randomized study was conducted between January 2015 and December 2016 in a university hospital. One hundred sixty two good-quality blastocyst transfers were included, and

randomly allocated to group A: warming on the day before transfer (n = 81); or group B: warming on the day of transfer (n = 81).

Participants/materials, setting, methods: Patients were included according to the following criteria: (i) female age <38 years on the day of oocyte retrieval; (ii) first/second IVF/ICSI attempt; (iii) <5 fresh/frozen embryos previously transferred; (iv) good-quality blastocyst(s) frozen at day 5 (expansion degree ≥B3, inner cell mass (ICM) ≥B, trophectoderm (TE) ≥B according to Gardner and Schoolcraft's classification). Re-expansion degree and blastocyst quality were evaluated after warming and immediately before transfer. Clinical outcomes were compared between both groups.

Main results and the role of chance: Patients' and cycles' characteristics were similar between groups A and B: briefly, women's mean age was 31.0 and 31.4 years, respectively, mean attempt rank was 1.1, and an average of 1.2 blastocysts was transferred for both. Quality of the warmed blastocysts at the time of transfer was comparable (39.1% of top-blastocyst [≥B4AA/AB/BA] in group A vs. 41.7% in group B, respectively; p = 0.69). After an overnight period post-warming (group A), 14/102 blastocysts (12.2%) appeared unsuitable for transfer, whereas only 1/103 (0.9%) in group B (p = 0.001), thus leading to an additional warming. As expected, re-expansion degree just before transfer was higher in group A (93.9% vs. 68.0% respectively; p < 0.0001). Likewise, the proportion of hatched blastocysts before transfer was higher after a longer culture period (37.6% in group A vs. 12.7% in group B; p < 0.0001). IR were similar in both groups (38.0% in group A vs. 36.4% in group B; p = 0.83), as well as clinical pregnancy rates (55.5% in group A vs. 50.6% in group B; p = 0.53). It may be noted that among the 9 cycles in group A requiring an additional warming, 2 patients finally got pregnant.

Limitations, reasons for caution: These findings need to confirmed and completed with live birth rates.

Wider implications of the findings: A long culture period after good-quality blastocyst warming does not seem detrimental on their implantation potential. This strategy could rather enable a better evaluation of blastocyst survival, and, if needed, an adaptation of transfer strategy in case of poor quality on the day of transfer.

O-075   Live birth after frozen-thawed blastocyst transfer is correlated with the day of blastocyst expansion

L. Ferreux[1], M. Bourdon[2], A. Sallem[1], V. Barraud-Lange[1], N. Le Foll[1], P. Santulli[2], C. Chapron[2], D. De Ziegler[2], J.P. Wolf[1], K. Pocate-Cheriet[1]

[1]Université Paris Descartes- Sorbonne Paris Cité- Faculté de Médecine- Assistance Publique – Hôpitaux de Paris AP- HP- Hôpital Universitaire Paris Centre- Centre Hospitalier Universitaire CHU Cochin, Service d'Histologie-Embryologie-Biologie de la Repro,
[2]Université Paris Descartes- Sorbonne Paris Cité- Faculté de Médecine- Assistance Publique – Hôpitaux de Paris AP- HP- Hôpital Universitaire Paris Centre- Centre Hospitalier Universitaire CHU Cochin, Service de Gynécologie-Obstétrique II et de Médecine,

Study question: The aim of this study was to evaluate the live birth rate (LBR) after frozen-thawed day 5 (D5) and day 6 (D6) blastocyst transfer.

Summary answer: LBR following frozen-thawed blastocyst transfer is significantly lower with D6 than D5 blastocyst whatever its quality.

What is known already: During fresh embryo transfer cycles, pregnancy rates (PR) are significantly higher when transferring blastocysts expanded on D5 compared with those developing on D6. According to this result, in programmed thawed blastocyst transfer (TBT) cycles, the same clinical outcomes would be expected when transferring D5 or D6 blastocysts because of the tightly controlled synchronization between endometrium and embryonic stage. However, the impact of delayed blastocyst expansion at D6 on clinical outcomes remains unclear. Some reports have shown higher PR after D5 TBT than those of D6 while others rhave shown equivalent TBT outcomes after D5 and D6 cryopreserved blastocysts transfers.

Study design, size, duration: Cohort study including 1347 frozen - thawed blastocysts transfer from non-donor cycles performed between January 2012 and December 2015 at a tertiary care center.

Participants/materials, setting, methods: All patients were scheduled for TBT and compared between 2 groups: blastocysts vitrified on D5 (n = 994) or on D6 (n = 353). The primary outcome was LBR per embryo transferred in the first warming cycle. Secondary outcomes were clinical pregnancy rate (cPR), early miscarriage rate and neonatal outcomes following TBT at D5 or D6. Statistical analyses were conducted using univariate and multivariate logistic regression model.

Main results and the role of chance: The LBR was significantly increased in the D5 group compared to the D6 group [294/994 (29.6%) vs. 60/353 (17.0%); p < 0.001]. The cPR was also higher when blastocysts were vitrified on D5 than those on D6 [429/994 (43.2%) vs. 95/353 (26.9%); p < 0.001]. No significant differences were found between groups in term of early miscarriage rate (p = 0.862). However, more good quality embryos (defined as an B3-B4 or B5 embryo ≥BB according to the grading scale proposed by Gardner) were transferred in the D5 group than in the D6 group [807 (81.2%) vs. 214 (60.6%); p < 0.001]. Concerning neonatal outcomes, the D5 group infants had a lower mean birth weight compared to those of the D6 group (p = 0.001). In addition, a significantly shorter gestational age at birth is reported in the D5 blastocyst group as compared to D6 group (p = 0.004). After multivariate logistic regression taking into account potential confounders such as women age, number of previous IVF/ICSI procedures, the day of the blastocyst vitrification (D5 or D6) and embryo quality, blastocyst expansion at D6 was independently associated with a significant decrease in LBR compared to D5 expanded-blastocyst (OR 0.52; 95% CI 0.38–0.72; p < 0.001).

Limitations, reasons for caution: The poor predictive value of the morphological approach in embryo selection could constitute a limitation in this study. However, blastocyst quality was evaluated similarly in both groups.

Wider implications of the findings: The delay in reaching the blastocyst expansion in D6 could reflect a poor intrinsic embryo quality, followed by a delayed hatching not synchronized with the endometrium during TBT cycles. These results could influence the cryopreservation policies by prioritizing D5-expanded blastocysts during TBT in order to optimize the chances to conceive.

SESSION 20: DIFFERENT TYPES OF PLURIPOTENT STEM CELLS

| Monday 3 July 2017 | Room W+X | 15:15–16:30 |

O-076   Comprehensive cell-surface protein profiling identifies novel markers of human naïve and primed pluripotent states

S. Panula[1], A. Collier[2], P. Rugg-Gunn[2], F. Lanner[1]

[1]Karolinska Institutet, CLINTEC, Stockholm, Sweden
[2]The Babraham Institute, Epigenetics Programme, Cambridge, United Kingdom

Study question: Are cell-surface markers differentially expressed between naïve and primed human pluripotent stem cells (PSCs) and thus, can be used to isolate naïve PSCs during primed-to-naïve resetting?

Summary answer: We developed an antibody panel targeting multiple cell-surface proteins that can distinguish between naïve and primed PSCs and isolate emerging naïve PSCs.

What is known already: PSCs exist in naïve and primed states, and provide important models to investigate the earliest stages of human development. Naïve cells can be obtained through primed-to-naïve resetting, however, there are no reliable methods to prospectively isolate unmodified naïve cells during this process.

Study design, size, duration: The cell-surface marker expression was compared between established primed and naïve PSCs, and further analysed during 10-day primed-to-naïve resetting.

Participants/materials, setting, methods: Three different PSC lines were used: H9, WIBR3, and H9-FiPS, with primed culture conditions and two different naïve culture conditions: 5i/L/A and t2i/L+PKCi. Human blastocyst stage

embryos were used to validate the expression of several cell-surface markers by immunocytochemistry. A comprehensive profiling of cell-surface proteins was done by flow cytometry with over 400 antibodies screened. A multicolor antibody panel for FACS was developed to isolate cells for colony formation assay, quantitative PCR and RNA-sequencing.

Main results and the role of chance: Our cell-surface marker screen identified 58 primed-specific markers, 8 naïve-specific markers, and 40 markers positive for both primed and naïve PSCs. We validated a cohort of antibodies in multiple naïve and primed PSC lines and culture conditions, and also found that several naïve-specific, but not primed-specific, proteins were expressed in the pluripotent cells of the human preimplantation embryo. We developed an antibody panel targeting multiple cell-surface proteins, and demonstrated that the panel could distinguish between naïve and primed PSCs, track the dynamics of naïve – primed interconversion, and isolate emerging naïve PSCs from a heterogeneous cell population. Molecular characterisation showed that the transcriptome of the emerging naïve cells was more similar to naïve cells than to primed cells, but was not identical to established naïve PSCs. Furthermore, our analysis revealed that X-chromosome reactivation occured primarily during the late-stage maturation of naïve cells.

Limitations, reasons for caution: We identified naïve-specific and primed-specific markers using PSCs *in vitro*. Although most of the tested naïve-specific markers were expressed in human blastocysts, not all were exclusively expressed in the epiblast. Therefore, the markers by themselves should not be considered as pluripotent-specific markers in the human blastocyst.

Wider implications of the findings: Identification of state-specific proteins provides a robust set of molecular markers to unambiguously define human PSC state, and allows new insights into the molecular events leading to naïve cell resetting.

Trial registration number: not applicable.

O-077 Wnt inhibition during hESC culture provides an improved pluripotent state starting point for directed differentiation

J. Taelman[1], L. Tilleman[2], F. Van Nieuwerburgh[2], S. Warrier[1], M. Popovic[1], M. Van der Jeught[1], D. Deforce[2], P. De Sutter[1], B. Heindryckx[1], S.M. Chuva de Sousa Lopes[3]

[1]Ghent-Fertility and Stem Cell Team G-FAST, Department for Reproductive Medicine-Ghent University Hospital, Ghent, Belgium
[2]Laboratory of Pharmaceutical Biotechnology, Faculty of Pharmaceutical Sciences-Ghent University, Ghent, Belgium
[3]Leiden University Medical Centre, Department of Anatomy and Embryology, Leiden, The Netherlands

Study question: Does Wnt inhibition by JP-Inh enhance hESC characteristics and their functional differentiation potential?

Summary answer: JP-Inh supplemented hESC are in a distinct pluripotent state, which appears to be more homogenous, while showing similar neuronal differentiation potential to conventional hESCs.

What is known already: Human embryonic stem cells (hESCs) and their ability to differentiate to specific cell types holds great promise for future therapeutic applications. Standard culture conditions maintain hESCs in a primed state of pluripotency, which harbors disadvantageous heterogeneity and spontaneous differentiation propensity. Efforts to adapt hESC to a more (mouse-like) naive pluripotent state restrict the efficiency of existing directed differentiation protocols. An alternative state has recently been described in mouse epiblast stem cells using the Wnt inhibitor JP-Inh, which seemingly induce the primed pluripotent state to one with less heterogeneity and less spontaneous differentiation.

Study design, size, duration: Two independent in-house derived hESC lines, were cultured in standard primed pluripotency conditions, our in-house naive pluripotency medium and JP-Inh supplemented medium. Subsequently, samples were collected at three consecutive passages and used for next-generation sequencing. Cells from all conditions were further differentiated towards the neuronal lineage and characterized.

Participants/materials, setting, methods: Comparative transcriptomic analysis was performed on primed, JP-Inh and naive pluripotency conditions. All three conditions were analyzed to compare differentially expressed gene profiles.

Following directed differentiation, gene expression was evaluated using quantitative PCR (qPCR), while the presence and localization of neuronal proteins was assessed by immunocytochemistry.

Main results and the role of chance: JP-Inh cultured hESCs displayed a more homogenous morphology with larger colonies and distinct colony borders compared to the primed pluripotency state. Principle component analysis clearly separated JP-Inh from primed and naive samples in both hESC lines. As such, JP-Inh hESCs harbor a distinct state of pluripotency compared to primed and naive pluripotency conditions. Our results further confirmed the downregulation of Wnt-associated genes in JP-Inh hESCs. Expression of pluripotency markers was not significantly different between primed and JP-Inh hESCs. Markers of all three germ lineages were elevated in primed pluripotency conditions, compared to JP-Inh hESCs, suggesting that JP-Inh hESC are less prone to lineage priming. Both primed and JP-Inh hESCs were able to differentiate into TUBB3$^+$/SOX9$^+$ neuronal cells, which showed close resemblance to neuronal networks. By contrast, naive hESC-generated neurons failed to form radial outgrowths from the central embryoid body after plating, but contained some sparse and irregularly spaced TUBB3$^+$/SOX9$^+$ neuronal cells.

Limitations, reasons for caution: While more homogenous cultures were observed in the JP-Inh conditions, a comparative transcriptomic analysis on the single cell level is necessary to validate this. To establish the clinical relevance of the JP-Inh alternative pluripotent state, differentiation into other cell lineages will further reveal their functional value.

Wider implications of the findings: Directed neuronal differentiation of both primed and JP-Inh hESCs appeared to be morphologically similar. As the JP-Inh condition seems to result in an intermediate state between naive and primed pluripotency, retaining advantages of both stages, it may prove a more beneficial starting point for directed differentiation towards therapeutically relevant lineages.

Trial registration number: not applicable.

O-078 Origins of Human Embryonic Stem Cell Fate: Role of the Post Inner Cell Mass Intermediate

S. Warrier[1], M. Popovic[1], J. Taelman[1], L. Tilleman[2], S. Lierman[1], M. Ferrer-Buitrago[1], S. Chuva De Sousa Lopes[3], A. Van Soom[4], L. Peelman[5], F. Van Nieuwerburgh[2], D. Deforce[2], P. De Sutter[1], B. Heindryckx[1]

[1]Ghent University Hospital, Ghent-Fertility and Stem cell Team- G-FaST- Department for Reproductive Medicine, Ghent, Belgium
[2]Ghent University, Laboratory for Pharmaceutical Biotechnology- Faculty of Pharmaceutical Sciences, Ghent, Belgium
[3]Leiden University Medical Center-, Department of Anatomy and Embryology, Leiden, The Netherlands
[4]Ghent University, Department of Reproduction- Obstetrics and Herd Health- Faculty of Veterinary Medicine, Merelbeke, Belgium
[5]Ghent University, Department of Nutrition- Genetics and Ethology- Faculty of Veterinary Medicine, Merelbeke, Belgium

Study question: What is the role of the post inner cell mass intermediate (PICMI) during the process of human embryonic stem cell (hESC) derivation?

Summary answer: Although transcriptionally similar to hESCs, the PICMI is distinct from the ICM and shows upregulation of sex-specification markers, demonstrating similarities to primordial germ cells (PGCs).

What is known already: The in vitro derivation of conventional hESCs from the ICM is preceded by an epiblast-like intermediate stage depicted as the PICMI. Studies have shown that the formation of the PICMI is predictive of hESC derivation success and shows a mixed expression profile of both early- and late-stage epiblast markers. The presence of late epiblast markers in the PICMI, similar to mouse pluripotent stem cells harvested from the post-implantation stage embryo, renders the hESCs in a primed state of pluripotency, already showing some predisposition to differentiation. The transcriptional changes occurring during its transition to hESCs are yet to be fully defined.

Study design, size, duration: To obtain more insight in the molecular signaling network in the transition of the ICM towards hESC, we analyzed genome-wide transcription profiles of 3 preimplantation ICMs, 3 well defined PICMIs

and 3 biological replicates of primed female hESC using next generation sequencing.

Participants/materials, setting, methods: Approximately 50 cells were collected from a female primed hESC cell line cultured for two feeder-free passages on Matrigel. Pure ICMs were isolated using laser assisted micro-manipulation from day 5 good quality blastocysts from frozen thawed donated day 3 embryos. The PICMIs were manually dissected from outgrowths of day 6 expanded blastocysts on mouse embryonic fibroblasts (MEFs) between day 6–10 post plating. Samples were sequenced on the NextSeq500. Statistical analysis was done in edgeR (FDR<0.05).

Main results and the role of chance: Principal component analysis confirmed a transcriptionally different state of ICM compared to PICMI and hESC. The PICMI clustered together with hESC further elucidating change in pluripotency state during in vitro derivation of hESC.

Differential gene expression analysis for protein coding genes revealed 634 and 560 genes were up- and downregulated respectively in hESC when compared to ICM (hESC/ICM). When comparing the PICMI/ICM, 471 and 296 genes were up- and downregulated in PICMI. Naïve pluripotency markers were upregulated in ICM including SOAT1 and KLF4 when compared to PICMI.

Additionally, 326 and 493 long non-coding RNA (lncRNA) were differentially expressed between the ICM/PICMI and ICM/hESC respectively. Only one lncRNA, a pseudogene to DPPA3 (Stella), a marker of early germ cell specification, was differentially expressed between PICMI/hESC.

Gene Ontology (GO) analysis for biological processes showed upregulation of terms related to neural morphogenesis in hESC and downregulation of processes related to transcription and translation when compared to ICM. When comparing PICMI/ICM, processes related to tissue morphogenesis, sexual differentiation, cell-cell adhesion and Wnt receptor signaling pathway were upregulated whereas RNA processing, oxidative phosphorylation and mitochondrial activity were downregulated. GO terms related to embryonic and tubal development were downregulated in hESC when compared to PICMI.

Limitations, reasons for caution: Since only three replicates were used for the study, the sex of the ICM and PICMI was not taken into consideration during the analysis.

Wider implications of the findings: These findings provide further insight into the underlying transcriptome-dependent transition from ICM to established hESC. This will help in gaining insight into the different states of pluripotency that exist in human, the derivation of PGCs and naïve hESCs in vitro which is still inefficient.

Trial registration number: NA.

O-079 Mitochondrial protein acylglycerol kinase orchasdrates stem cell pluripotency

Y. Ma[1], L. QI[2], J. Xinxing[2], W. Yunjian[2], W. Bangyong[2], L. Ping[2]

[1]The Affiliated Hospital of Hainan Medical College, Reproductive Medical Center, Haikou, China
[2]Hainan Medical University, Hainan Provincial Key Laboratory for Human Reproductive Medicine and Genetic Research, haikou, China

Study question: What is the potential function of Acylglycerol kinase (AGK) in regulating embryonic stem cell (ESC) self-renewal and somatic cell reprogramming?

Summary answer: AGK played a vital role on maintaining the pluripotency of ESCs and improving the efficiency of iPS reprogramming.

What is known already: Embryonic stem cell (ESC) self-renewal and somatic cell reprogramming require precise coordination of transcription factors, chromatin regulators and RNA modifiers. Many efforts have been devoted to characterizing the underlying mechanism, but it is still remained poorly understood. Acylglycerol kinase (AGK), a lipid kinase related to mitochrondria oxidative respiratory, has been recently reported as a molecular marker in cancer generation. Our preliminary data shows that it was also enriched in ESC and iPS, however, there is no report about its role in ESC. It will be interesting to find out its potential function in ESC and somatic cell reprogramming.

Study design, size, duration: Lentivirus systems were used to generate gain or loss of function ES cell models or cell reprogramming model to study the role of AGK in maintaining stem cell self-renewal, proliferation and pluripodtency.

Participants/materials, setting, methods: Human ESC lines were used to generated AGK gain and loss of function cell models. Human foreskin fibroblasts were transfected with OCT4, SOX2, KLF4, c-MYC (OSKM) with or without AGK by lentiviral system. AP staining, QPCR and immunostaining were used to check the reprogramming efficiency. Flow cytometry and MTT was used to examine the cell proliferation. RNA-seq was used to examine the gene expression panel which might be regulated by AGK.

Main results and the role of chance: In this study, we demonstrated that AGK was significantly enriched in human embryonic stem cells (hESCs) and induced pluripotent stem cells (hiPSCs) compared with HFFs. We also showed that the expression level of AGK gradually decreased in embryonic bodies (EBs), along the course of differentiation, which correlated with the decrease of NANOG and OCT4. Loss-of-function assays by AGK shRNAs exhibited about 75% knockdown of AGK in ESCs, which dramatically decreased the cell proliferation. And it also presented diverse differentiate fate compared to WT ES cells. Meanwhile, HFFs OSKM co-transfected experiment results showed that up regulation of AGK during HFFs reprogramming enhanced the number of iPSC colonies. RNA-seq results revealed that the expression of a couple of mitochrondria oxidative related genes were affected by variation of AGK.

Limitations, reasons for caution: Although we show that AGK is very important in keeping hESCs normal characteristic, the study of working mechanism of AGK in ESCs is still very limited. More studies will be performed to explore its underline mechanism.

Wider implications of the findings: This study was the first time to explore the role of AGK in human ESC. It will help us to better understand the mechanism of ESC self-renewal and somatic cell reprogramming, which might be helpful in future application of ESC and iPS.

Trial registration number: this study is not a clinical trial.

O-080 Two live birth after Stem cell ovarian auto-transplantation in Poor Responder women

S. Herraiz[1], M. Romeu[2], S. Martínez[2], P. Solves[3], I. Gómez[3], J. Martínez[4], A. Buigues[1], D. Galliano[5], C. Simón[6], C. Díaz-García[2], A. Pellicer[5]

[1]Fundación IVI, Paterna, Valencia, Spain
[2]La Fe University Hospital, Woman's Health Area, Valencia, Spain
[3]La Fe University Hospital, Hematology department, Valencia, Spain
[4]La Fe University Hospital, Radiology department, Valencia, Spain
[5]Instituto Valenciano Infertilidad IVI, IVI Roma, Rome, Italy
[6]Instituto Valenciano Infertilidad IVI, IVI Valencia, Valencia, Spain

Study question: To assess bone marrow derived stem cell ovarian autologous transplantation (SCOT) competence to optimize ovarian reserve in poor responders (PR).

Summary answer: SCOT improved ovarian function in 69% of patients. Three pregnancies were achieved and 2 healthy babies born in PR whose only option was oocyte donation.

What is known already: Advanced maternal age is the main cause of infertility nowadays; in fact both oocyte quantity and quality are seriously impaired in aged patients. These women are known as PR to controlled ovarian stimulation (COS) and oocyte donation is their only realistic option. Previous studies suggest regenerative effects of bone marrow transplant in ovarian niche of damaged ovaries and raise the possibility that dormant follicles or somatic cells may benefit from the influence of bone marrow derived cells or soluble factors.

Study design, size, duration: A prospective pilot study with 13 PR women (Age:38 yr[37,39] with 4 yr[3,5] infertility) was developed at La Fe University Hospital from 2014 to 2016. Patients were considered as their own control as cells were injected in just one ovary.

Participants/materials, setting, methods: Bone marrow derived stem cells were mobilized to peripheral blood with G-CSF and isolated by aphaeresis. A volume of aphaeresis containing 50×10^6 non-selected CD133+ cells was delivered into one utero-ovarian artery by catheterism. Serum AMH and AFC were monitored up to 5 months and compared to basal levels. COS was induced when AFC rose following standard procedures.

Main results and the role of chance: Ovarian reserve markers improved in 69.2% of the PR patients and 38.4% increased both AFC (≥3foll) and AMH

(>2 SD). Higher AFCs were seen 15–21 days after SCOT when compared to the basal AFCs(p = 0.04).

Two of the recruited patients were withdrawn from the study after SCOT. A total of 22 COS were initiated in 11 patients, starting 78 [31,109] days after SCOT (18.2% cancellation). Oocyte pick-up was successfully performed in 81.8% initiated COS and cancellation rate was 18.2%. A total of 36MII were retrieved and fertilization rate was 69.4% after ICSI. From 23 obtained embryos, 20 reached the blastocyst stage and underwent CGH analysis. Two of them were euploid and therefore transferred in single embryo tranfer (ET). A total of 3 pregnancies were achieved, 2 after ET and one spontaneous pregnancy, during the follow-up period after SCOT. Two healthy babies have been born (1 miscarriage) by the use of this procedure.

Limitations, reasons for caution: Pilot study. Confirmation of our preliminary data on a large population should be required.

Wider implications of the findings: SCOT improved ovarian function and oocyte quantity allowing pregnancy in aged and PR women whose only clinical option was oocyte donation. Nevertheless, SCOT does not modify embryo quality.

Trial registration number: NCT02240342

[11]VU University Medical Center, Epidemiology and Biostatistics, Amsterdam, The Netherlands
[12]VU University Medical Center, EMGO+ Institute for Health and Care Research, Amsterdam, The Netherlands

Study question: Which dose-related effects of different chemotherapeutic agents and radiation fields on various ovarian function parameters can be determined in a nation-wide cohort of female long-term childhood cancer survivors (CCSs)?

Summary answer: CCSs treated with procarbazine, alkylating therapy, abdominal/pelvic radiation, or TBI were at highest risk of a reduced ovarian function, but not necessarily dose-dependently.

What is known already: Cancer treatment in childhood can reduce fertile life span and induce premature ovarian insufficiency (POI). Risk of gonadal damage in female CCSs has shown to vary according to cancer type, age at treatment, and type and dose of treatment. More specifically, risk factors identified so far include: an older age at treatment, a diagnosis of Hodgkin lymphoma, treatment with alkylating chemotherapy (CT) including procarbazine, and exposure to radiotherapy (RT) involving the pelvis and abdomen

Study design, size, duration: The DCOG LATER-VEVO study is a nation-wide retrospective cohort study on female fertility of Dutch CCSs. The control group consisted of sisters of survivors and females from the general population. Data collection took place between January 2008 and May 2014.

Participants/materials, setting, methods: The study population consisted of female 5-year CCSs treated between 1963 and 2002, and at least 18 years of age at inclusion. Of 1,106 CCSs and 819 controls who participated, 552 and 387, respectively, provided blood samples and/or underwent transvaginal ultrasound. Both multivariate linear and logistic regression analyses were performed.

Main results and the role of chance: CCSs had a 6·5-fold increased risk (95%CI 1·3 to 32·5) of low AMH levels (>2 SD below age-specific cut-off level) and a 14·3-fold increased risk (95%CI 2·4 to 86·4) of high FSH levels (>10 U/l), while risks of low AFC (>2 SD below age-specific cut-off level) and low inhibin B (<20 ng/l) levels were not significantly increased. The following types of treatment were associated with one or more markers: cyclophosphamide (AMH), procarbazine (all four markers), composite group of busulfan, melphalan, chlorambucil and lomustine (AMH, AFC, and FSH), dactinomycin (AMH), doxorubicine (AFC), mitoxantrone (FSH), spinal RT (AMH), abdominal/pelvic RT (all four markers), TBI (all four markers). For the effect on AMH and FSH dose-effect relationships was found for procarbazine, while for AFC and inhibin B such a relationship was found for abdominal/pelvic RT.

Limitations, reasons for caution: AMH, AFC, FSH and inhibinB were used as a proxy for ovarian function, however, the translation to fertility and POI in CCSs has yet to be made. Not all results were consistent across the four markers, thus we discourage use of only one marker to assess ovarian function in CCSs.

Wider implications of the findings: The results of the study can help physicians counselling CCSs, as well as future patients who are about to undergo anti-cancer treatment, regarding their future reproductive potential and the need for fertility preservation interventions.

Trial registration number: NTR2922 http://www.trialregister.nl/trialreg/admin/rctview.asp?TC = 2922.

O-082   Pregnancy after cancer in girls and women in Scotland:: a population-based analysis

ABSTRACT UNDER PRESS EMBARGO

OV and OCC the most recommended procedures as both provide excellent clinical outcomes.

Study design, size, duration: The aim of the present study was to compare the efficacy of OCC as compared to that of OV in two prospective large cohorts of patients undergoing FP: 1024 patients undergoing OV and 735 OOC were recruited in between 2005 and 2015 in our FP program at IVI clinics and La Fe University Hospital; the program grants free access to OV and OCC and use the same decision-making algorithm to chose the FP technique.

Participants/materials, setting, methods: In the OV cohort, 49 patients came back to use their oocytes and 44 patients came to have their ovarian tissue reimplanted in the OCC cohort. OV was carried out using the cryotop device and OCC was done using a slow freezing protocol. Reimplantations took place orthotopically. Patients were followed up until they used all the oocytes, the lack of function of the reimplanted tissue or the achievement of livebriths.

Main results and the role of chance: No difference was found between groups regarding AMH levels at FP (OV: 11.6 [5.4–24.7] vs OCC: 11.8 [6.4-21.9]; n.s.). The most prevalent pathologies motivating FP were breast cancer (OV: 60.3%, OCT: 58.6%), Hodgkin lymphoma (OV: 14.2%, OCT: 20.7%; $p < 0.001$) and non-Hodgkin lymphoma (OV: 6.0%, OCT: 3.2%; $p < 0.001$). In the OV cohort, patients used the vitrified oocytes after a mean storage time of 3.9 years. In the OCT cohort, after a mean storage time of 5.5 years. The age at utilization of the cryopreserved material was also similar between groups (OV: 39.0 (3.8) vs OOC: 38.9 (4.1); n.s.). When clinical pregnancy rates (CPR) and live birth rates (LBR) (per patient) were compared between groups, the OV group yielded higher, but not significantly different, CPR (40.8% vs 27.3%) and LBR (32.6% vs 18.2%) than the OCT group.

Limitations, reasons for caution: In some clinical scenarios OV is not feasible and OCC offers a different profile of advantages (mainly endocrine function resumption and the possibility of spontaneous pregnancy). Therefore, recommendations on the choice of these techniques have to be based in individualized criteria, oncologist decision and time prior to treatment.

Wider implications of the findings: Both OV and OCC can be recommended as effective FP techniques.

Trial registration number: Not applicable.

O-083   Fertility preservation by oocyte vitrification or ovarian cortex cryopreservation. A prospective cohort study

C. Díaz-García[1], J. Domingo[2], S. Herraiz[3], I. Iniesta[4], A. Cobo[5], A. Garcia-Belda[6], J.M. Rubio[4], J.A. Garcia-Velasco[7], A. Pellicer[8]

[5]IVI, Valencia, Valencia, Spain
[6]La Fe University Hospital, IIS la Fe, Valencia, Spain
[7]IVI, Madrid, Madrid, Spain
[8]IVI, Rome, Rome, Italy

Study question: What is the best technique for fertility preservation (FP) for medical reasons, oocyte vitrification (OV) or ovarian cortex cryopreservation (OCC)?

Summary answer: OV and OCC yielded similar clinical and ongoing pregnancy rates (CPR, OPR) than OCC, although there is a trend to higher rates with the former.

What is known already: The increasing survival rates and success of oncological treatments make FP procedures a key step in the holistic management of the oncologic patient. FP for oncological reasons should be considered since the moment of diagnosis and it has become a major issue in young women. Counseling should be individualized based on the risk of gonadal failure that depends on patient´s age, ovarian reserve, chemotherapy drug/regimen and time prior to treatment. Different strategies have been proposed for FP, being

O-084   Severely decreased spermatogonial quantity after chemotherapy with alkylating agents in prepubertal boys

M. Poganitsch-Korhonen[1], I. Masliukaite[2], M. Nurmio[3], P. Lähteenmäki[4], M. Van Wely[2], A.M.M. Van Pelt[2], K. Jahnukainen[1], J.B. Stukenborg[5]

[3]Institute of Biomedicine. University of Turku, Department of Physiology, Turku, Finland
[4]Turku University Hospital, Department of Pediatrics, Turku, Finland
[5]Pediatric Endocrinology Unit. Q2:08. Karolinska Institutet and University Hospital, Department of Women's and Children's Health, Stockholm, Sweden

Study question: What is the effect of alkylating and non-alkylating chemotherapy agents on the numbers of spermatogonia in prepubertal human testes?

Summary answer: Malignancy treatment with alkylating agents was associated with significantly decreased numbers of spermatogonia in prepubertal testes. This effect was higher with cumulative CED above 4000 mg/m^2.

What is known already: At present, over 80% of childhood cancer patients become long term survivors, yet the majority experience long lasting side effects of the malignancy treatment including persistent sub-/infertility. Previous studies have demonstrated, that male infertility after cancer treatment depends on the extent of damage to spermatogonia. In prepuberty, the constant turnover of early germ cells in testes makes them highly susceptible to the adverse effects of chemotherapy, thereby increasing the risk of depletion. It is known, that the fertility in childhood cancer survivors can remain poor for over 20 years if germ cell pool is affected during the treatment.

Study design, size, duration: In this study, we gathered data on cancer treatment regimen in 37 prepubertal boys with acute lymphoblastic leukemia (ALL), examined histology of testicular biopsies acquired at the end of the cancer treatment and testicular function as recorded by semen analysis from those that reached adulthood.

Participants/materials, setting, methods: The patient data were identified through the records of the University Central Hospitals in Helsinki and Turku and included patient age at the end of the treatment, treatment characteristics, and semen parameters in adulthood. Testicular biopsies from each patient were fixed in formalin and H&E stained for analysis under the brightfield microscope. The numbers of spermatogonia per tubular cross-section (S/T) were counted blind by an experienced researcher. Statistical analysis was performed using polynomial regression.

Main results and the role of chance: In the analyzed patient cohort of 37 prepubertal boys with ALL, we found that the mean S/T value in patients exposed to alkylating agents (n = 16) was significantly lower (p < 0.001) than in a group exposed to non-alkylating agents, whose mean S/T (n = 19) was within a range of normative reference values. We also found a non-linear association between S/T and cumulative cyclophosphamide equivalent dose (CED), with cumulative CED above 4000 mg/m^2 associated with S/T values close to zero. Testicular function as recorded by semen analysis measurements in adulthood could be retrieved in 17 childhood cancer survivors. We did not find a statistically significant association between S/T and spermatogenic recovery. No significant differences were found between the total sperm count in patients treated with and without alkylating agents (n = 7 and n = 10, respectively) at the mean of 12.9 ± 6.7 years follow-up.

Limitations, reasons for caution: These results should be interpreted considering the small sample size, including the limited number of childhood cancer survivors who performed the follow-up measurements on testicular function.

Wider implications of the findings: Our data suggest that exposure to alkylating agents results in depletion of spermatogonial pool in prepubertal human testes. Patients with higher risk of spermatogonial depletion might be offered fertility preservation by cryopreserving a testicular biopsy before initiation of alkylating agents to avoid potential persistent sub-/infertility.

Trial registration number: Not applicable.

O-085　Assessment of testicular sperm extraction (TESE) and intracytoplasmic sperm injection (ICSI) in couples with post chemotherapy non-obstructive azoospermia (NOA)

N. Tsuji, S. Mizuta, K. Yamaguchi, Y. Takaya, R. Nishiyama, T. Takeuchi, K. Kitaya, H. Matsubayashi, T. Ishikawa

Reproduction Clinic Osaka, Department of Reproductive Medicine, Osaka, Japan

Study question: What are sperm retrieval rate (SRR) by microdissection TESE (micro TESE), fertilization rate, and pre- and post- implantation development in post chemotherapy NOA couples?

Summary answer: In patients with successful sperm retrieved, age at chemotherapy was older than failure group and their embryonic development was better than unexplained NOA patients.

What is known already: Advances in chemotherapeutic treatments can achieve high remission rates in pediatric and adolescent patients with cancer, but cytotoxic chemotherapy may lead to irreversible spermatogenic dysfunction. Patients with such diseases are often not concerned with reproductive issues at diagnosis, however, recent advances combining TESE and ICSI in patients with post chemotherapy NOA allow these males father their own genetic offspring.

Study design, size, duration: A retrospective study was conducted in 34 patients with post chemotherapy NOA (including 7 patients with bone marrow transplantation (BMT)), 330 NOA patients with 46,XY without past history (unexplained NOA; not including after orchidopexy, Klinefelter's syndrome, cryptozoospermia, mumps orchitis, etc) who who underwent micro TESE, and 107 OA patients with simple TESE between September 2013 to December 2016.

Participants/materials, setting, methods: The cancer types included testicular cancer, leukemia, malignant lymphoma, osteosarcoma, myelodysplastic

syndrome, rectal cancer, Wegener's granulomatosis, rhabdomyosarcoma, neuroblastoma, renal carcinoma, and mediastinal malignancy tumor. The age at chemotherapy and micro TESE was 15.7 ± 8.9 and 33.9 ± 5.4 years, respectively, and the mean maternal age at ICSI was 33.7 ± 3.9 years. Two pronuclear (2PN) oocytes, blastocyst development, good-quality blastocysts (Grade 3BB and more on day 5 by the Gardner scoring), and clinical pregnancy rates were examined.

Main results and the role of chance: SRR of micro TESE in post chemotherapy NOA (17/34 = 50.0%) was higher than unexplained NOA (92/330 = 27.9%) patients (p < 0.01). In males with successful sperm recovery, age at chemotherapy was older (21.0 ± 7.8 years) than failure group (10.5 ± 7.0 years) (p < 0.01). With respect to the type of cancer, there was no predictor for SRR and no significant differences in the pregnancy and live birth rates. In 3 of 7 post BMT patients spermatozoa were successfully retrieved. Two of 3 patients even showed a 46,XX karyotype (transplantation from female donor). The 17 patients who failed to obtain sperm could not find any germ cells in their testicular samples in wet preparations and histopathological sections (Sertoli cell only syndrome). Rates of 2PN oocytes, blastocysts, and good-quality blastocysts were 67.9%, 51.4%, and 45.2% in post chemotherapy NOA, 58.3%, 45.2%, and 37.8% in unexplained NOA, and 66.0%, 51.6%, and 42.8% in OA, respectively. Post chemotherapy NOA tended to be higher in clinical pregnancy rate per ET (14/32 = 43.8%) than unexplained NOA (50/177 = 28.2%) (p = 0.08). Ten children have been born and 2 patients are on going pregnancy in post chemotherapy NOA couples.

Limitations, reasons for caution: There was a lack of stratification with respect to the chemotherapeutic regimen. The neonatal outcome and development of these children has not been fully investigated.

Wider implications of the findings: Age at chemotherapy was important predictive factor for successful sperm recovery. Once sperm were obtained their reproductive performance was satisfactory. These findings provides hope for men of reproductive age who have not undergone sperm cryopreservation before chemotherapy.

Abstract text
Single-cell proteomics of human oocytes

In vitro maturation of oocytes is a crucial technology to generate mature oocytes that are utilized for IVF. Importantly, many efforts have been made to improve the efficiency of the in vitro maturation process, yet their competence is lower than of oocytes matured in vivo. Elucidating the molecular mechanisms that regulate oocyte maturation will be important to develop procedures to improve the quality of in vitro-matured oocytes, while potentially providing molecular markers that predict oocyte quality or maturation stage.

Global gene expression analysis by micro-arrays and later by next-generation sequencing have started to reveal the composition of transcriptomes of maturing oocytes, however this has not resulted in a gene signature indicating oocyte competence. One explanation is that mRNA levels often poorly correlate with protein expression, which eventually are the key determinants of cellular

function. Therefore it will be of crucial importance to use proteomic approaches to monitor and understand protein expression profiles over the course of oocyte maturation. The main challenge is to provide a sufficiently large amount of sample input (i.e number of cells) to obtain insightful information from a proteomic (e.g. mass spectrometric) experiment. This has been attempted for mouse, pig and bovine oocytes, requiring hundreds or even thousands of oocytes as an input, immediately explaining why that this cannot be applied to human cells without a drastic improvement of technologies to reach better sensitivity.

Although mass spectrometers have become much more sensitive over the last few years, further gains can be made in the preceding sample preparation step. With this in mind, we have recently designed a novel strategy to extract, purify and digest proteins in a novel magnetic bead-based procedure, minimizing sample losses and thereby increasing overall sensitivity of detection. As a result, this now allows us to routinely detect, identify and quantify ~600 proteins from single human oocytes. In this presentation we will show that quantitative, single-oocyte proteomics clearly distinguishes GV from MII oocytes by the expression of a distinct set of proteins. Furthermore, principle component analysis of proteomic data shows that oocytes that are in vitro-matured in the presence of gonadotropins FSH and HCG, and in a co-culture with cumulus cells from mature oocytes are more similar to in vivo matured cells than cells matured with FSH and HCG only thus indicating the importance of ovarian niche during the maturation process. Co-culture with cumulus cells can be efficiently replaced by addition of the protein vimentin which is an important component of mesenchymal cells including granulosa cells.

Collectively, these results demonstrate that technological advances now permit proteomic analysis of single human oocytes, which can be used as a powerful readout to optimize in vitro maturation procedures, while giving insight in underlying molecular events. Eventually, this may lead to the identification of maturation-specific markers that may be developed into an assay scoring for oocyte quality in daily clinical practice.

O-087 Deciphering developmental processes from single-cell transcriptomes

O-088 Plasticizers and male fertility

R. Sharpe[1], S. Van den Driesche[2], R. Mitchell[2]

[1]*University of Edinburgh The Queen's Medical Research Institute, Centre for Reproductive Health, Edinburgh, United Kingdom*
[2]*University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom*

Abstract text

Numerous experimental animal studies have shown that exposure to high levels of plasticizers, in particular certain phthalate esters, but in some studies also bisphenol A, can result in adverse effects on aspects of male reproductive development and function. In keeping with this, epidemiological studies have found significant associations between exposure to these compounds and changes in reproductive functions in human males similar to those found in animal studies. At face value, this concordance raises obvious human health concerns, but as this talk will demonstrate a close animal-human comparison identifies several fundamental differences that together do not add up, and which cast doubt on these particular health concerns about plasticizers. Most notably, the levels of exposure required to induce significant adverse effects in animal studies are several orders of magnitude higher than those to which humans are exposed, which either means that humans are inordinately more sensitive to plasticizers than rats or that the human epidemiological data is confounded in some way.

This talk will review the experimental animal and human epidemiological data, focussing mainly on fetal exposure to phthalate esters (diethylhexyl phthalate, dibutyl phthalate), as it is exposures during this critical period that there is most concern about. In rats, exposure during pregnancy to high doses (>100 mg/kg/day) of these phthalates causes suppression of testosterone production by the fetal testis which can result in impairment of masculinization, manifest, for example, as increased incidence of cryptorchidism and hypospadias and decreased adult size of all male reproductive organs; in addition there is a decrease in anogenital distance (AGD), which is an established marker of fetal androgen exposure during the critical masculinization programming window (MPW). Epidemiological studies in humans, which have measured maternal exposure to these phthalates (in the range 1-10ug/kg/day) and then measured AGD in boys shortly after birth have shown mixed results, some showing an association between exposure and reduced AGD, other studies finding no association.

Arguably the most conclusive (and direct) evidence comes from experimental studies that have used human fetal testis tissue in culture or in a mouse xenograft model and then exposed to phthalate levels (eg 500 mg/kg/day) comparable to those that induce adverse effects in vivo in fetal male rats. These studies have shown absolutely no effect of phthalate exposure on testosterone production by the fetal human testis. Three further pieces of evidence back this up. First, similar culture/xenograft studies with rat testes shows phthalate inhibition of testosterone production, so the model systems work okay. Second, in vivo exposure of pregnant marmoset monkeys to high levels of phthalate does not result in any adverse effects on reproductive development in resulting male offspring. Third, studies that have monitored congenital abnormalities in offspring born to mothers who were exposed to phthalate levels 150–300 times higher (350-900ug/kg/day) than population level exposure, as a result of using phthalate-containing medicines, have not revealed any evidence for reproductive abnormalities in the exposed boys. The strengths and weaknesses of these various data forms will be discussed. In addition, attempts will be made to reconcile human data that is in disagreement, by considering a possible confounding effect of maternal western diet on AGD in sons, which might also result in increased exposure to the phthalate most commonly monitored in human epidemiological studies. Finally, it will be pointed out that studies which have compared phthalate 'effects' after birth (mainly in adulthood), whether in experimental or epidemiological studies, have shown more consistent evidence that phthalate exposure may be associated with inhibition of testosterone production by the human and marmoset testis.

O-089 Plastics and miscarriage

R. Lathi

Sunnyvale- CA, U.S.A.,

Abstract text

Environmental Toxins and miscarriage

Establishment of early pregnancy is the result of complex biochemical interactions between the decidua and blastocyst. Any alteration in this chemical dialogue has the potential to result in adverse pregnancy outcomes including miscarriage. Sporadic miscarriage is the most common complication of pregnancy and can be caused by multiple factors. While the most common cause of miscarriage is genetic abnormalities in the fetus, other contributing factors certainly can play a role in early loss. One such factor is environmental exposure, in particular to endocrine-disrupting chemicals, which has the potential to interfere with endogenous hormone action. These effects can be deleterious, especially in early pregnancy when the hormonal milieu surrounding implantation is in delicate balance. The purpose of this presentation is to review the current evidence on the role of environmental toxins in reproduction.

O-090   PCOS in adolescence-to diagnose or not and future fate

K. Hoeger

University of Rochester, Obstetrics and Gynecology, Rochester- NY, U.S.A.

Abstract text
PCOS in Adolescence-to diagnose or not and future fate

PCOS is a disease that presents clinically with abnormalities evident in adolescence. However adolescence is a period of reproductive maturation and many reproductive abnormalities that in adulthood would indicate pathology are part of the maturation process in adolescence. This complicates the diagnosis of PCOS in this age group. Consensus in multiple guidelines is growing to allow for a longer period of time of observation after menarche before formal diagnosis. The Endocrine Society consensus statement of PCOS in adolescents states that both hyperandrogenism and oligomenorrhea need to persist for at least 2 years to consider the diagnosis. Ultrasound criteria are particularly challenging in adolescence due to the overlap with normal ovarian morphology in this age group. Antimullerian hormone (AMH) concentrations are known to be increased in women with PCOS. There are some data to suggest that AMH may distinguish PCOS from normal girls in obese adolescents however there is still considerable overlap to use this as a diagnostic marker. While there is rationale to delay the diagnosis and consider early features of the disease in adolescents to represent those at risk, there is clear evidence of early metabolic dysfunction in adolescents, particularly in those with elevated androgen concentrations. Therefore there is motivation to diagnose and manage the condition as early as possible to minimize long term effects. In the presence of overweight and obesity there is evidence to suggest lifestyle modification with weight loss results in improvement in metabolic features but limited impact on reproductive features. Additionally this is difficult to maintain over the long term. Prevention of weight gain in adolescence may be of most importance to minimize long term metabolic impact. Traditional treatment with combination hormonal contraceptive remains first line treatment but questions remain on the long term metabolic impact. The use of insulin sensitizing therapy may be beneficial in adolescents but controlled large scale long term data in adolescents is lacking. Importantly there is evidence of increased psychological morbidity in adolescents with PCOS. Given the development of self-image during adolescents, disturbance in mood and behaviors may have particularly long reaching impact in this population. While significant questions remain about the best diagnostic measures for PCOS in adolescence, there is enough concern regarding long term implications that timely interventions are recommended. Further research on the long term outcome of treatments in adolescence is needed.

O-091   Is there a need to increase PCOS awareness?

H. Teede

Monash University/Monash Health, Executive Director Monash Partners Academic Health Sciences CentreDirector Monash Centre for Health Research and Implementation - MCHRI, Clayton- Victoria, Australia

Abstract text

Affecting 12–18% of reproductive aged women, Polycystic Ovary Syndrome (PCOS) is a common, under-recognised, and prevalent condition, with significant health and psychosocial impacts. PCOS is the primary cause of anovulatory infertility; increases the risk of pregnancy complications (such as miscarriage, fetal anomalies, and gestational diabetes); increases obesity and quadruples type II diabetes, with younger onset; increases cardiovascular risk factors, psychological disturbance, and adversely impacts quality of life. PCOS is highly heritable and health burden extends to the next generation, with adverse impacts on children of affected mothers. Importantly, PCOS identifies women from puberty with high reproductive and metabolic risks, who appear prone to weight gain (further exacerbating their condition), and who are in need of targeted prevention and management.

We have engaged with health professionals and affected women internationally through focus groups, surveys and structured Delphi processes internationally. Primary care providers report feeling ill-equipped to manage PCOS, and report it as a high priority for education in women's health. We have also demonstrated key gaps in diagnosis, education, prevention and management among specialist health professionals. Due to the diversity of PCOS health impacts, affected women report feeling marginalised and falling between the gaps in specialty-focused health systems, reporting stigmatised and PCOS related distress. We have established key care and education gaps and priorities for women across diverse age ranges and across Europe, USA and internationally. The experiences of women and knowledge and perceptions of health professionals around PCOS ultimately leaves women feeling isolated, disempowered and underserviced, leaving a high personal and ultimately societal cost.

We have built on the activity of our National Australian PCOS Alliance and informed by gaps identified through international research with women and health professionals, we are expanding rigorous evidence based guidelines internationally and across all features of PCOS. This is supported by international collaboration with 24 professional societies and women's advocacy groups. The Australian government has provided $3 M for research, education and translation including guideline development and translation through a National Centre of Excellence in PCOS. ESHRE and ASRM have joined as leading and co-funding collaborators and 21 other societies and advocacy groups have joined in an international initiative to raise knowledge and awareness in PCOS. This will be underpinned by the development and translation of evidence based guidelines into practice for women and their health professionals.

Translation outputs include a multifaceted program of guideline outputs for women and health professionals. This is being delivered in collaboration with "Making Grade the Irresistible Choice (MAGIC) and includes a website, multifaceted resources translated into 30 different languages, podcasts, patient experience material, M- health apps, lifestyle programs and new, fully evaluated models of evidence based care for scale-up. Collaborations, progress, results of engagement with women and health professionals, evaluation and gaps in currently available education resources and research on translation and women's and health professionals education preferences will be presented, along with timelines and outputs of the international collaborative evidence based PCOS guidelines and translation program.

O-092   A time-lapse incubator is a superior incubator for excellent quality blastocyst embryo development compared to a conventional incubator

S. Ellegiers, K. Tilleman, E. Van den Abbeel, P. De Sutter

Ghent University Hospital, Department for Reproductive Medicine- Ghent Fertility And Stem cell Team G-FAST, Ghent, Belgium

Study question: Is there a difference in blastocyst formation rate and blastocyst quality in a time-lapse imaging system (TLIS) as compared to a standard incubator (SI)?

Summary answer: There is a significant higher percentage of excellent quality (category A) blastocysts in the TLIS Embryoscope™ as compared to the SI.

What is known already: TLIS is considered an important research tool for learning about embryo morphokinetics. Furthermore, TLIS is considered to be a unique incubator making undisturbed embryo development possible. Although a systematic review (Armstrong *et al.*, 2015) showed no significant difference in clinical outcome between TLIS and SI, there is still debate on whether the undisturbed development of the TLIS could be beneficial for embryo

quality. A recent RCT (Park et al., 2014) reported no significant difference in embryo quality on day 2 however, limited data exists on the potential benefit of undisturbed culture for blastocyst formation and quality.

Study design, size, duration: For the analysis, ICSI cycles with embryo transfer on day 5 were selected (February 2013 - January 2017). Sequential extended culture (Cook) was performed in either the TLIS Embryoscope™ (n = 96 cycles) or the SI (Binder CB210) (n = 801 cycles). Matching of cycles was performed automatically using SPSS v.23.0 according to patient age ($\pm$1 year), treatment type (exact), sperm collection method (exact) and number of normal fertilized oocytes ($\pm$1). This resulted in 85,4% paired matched cycles (82/96).

Participants/materials, setting, methods: Blastocysts were scored according to Gardner et al. (1998; 2001) and categorized: cat A: minimum blastocyst 4, grade A, B TE or ICM; cat B: blastocyst 3, grade A, B TE or ICM; cat C: minimum blastocyst 4 with grade C in either TE or ICM; cat D: blastocyst 3 with grade C in either TE or ICM; cat blastocyst 2; cat blastocyst 1; cat compaction. Statistical analysis was performed by Fisher´s exact-test (significance p$\leq$0.0500).

Main results and the role of chance: The cycle characteristics of the TLIS-group (82 cycles) showed 1010 cumulus oocyte complexes (COC), 745 MII oocytes underwent ICSI resulting in 570 2PN. The SI-group (82 cycles) consisted of 1021 COC, 779 MII and 545 2PN. Blastocyst outcome parameters were calculated relative to the amount of 2PN. Total blastocyst formation was 52.98% (302/570) in the TLIS-group as compared to 58.72% (320/545) in the SI-group (p = 0.0615). There was a significant difference in percentage cat A blastocysts in the TLIS-group 15.44% (88/570) versus 10.46% (57/545) in the SI-group (p = 0.0160). There was a lower percentage of cat B blastocysts in the TLIS-group 4.91% (28/570) versus 8.07% (44/545) in the SI-group (p = 0.0378). Furthermore, a significant higher percentage of cat blastocysts 1 was shown in the SI-group 15.78% (86/545) versus 9.65% (55/570) in the TLIS-group (p = 0.0022). All other blastocysts categories showed no significant differences between the TLIS and SI. Finally, no significant difference was observed in implantation rate (HCG+/cycle) in the TLIS-group 34.15% (28/82) as compared to the SI-group 40.24% (33/82) (p = 0.5183).

Limitations, reasons for caution: There was no randomization for the choice of incubator for the ART and the indications for culturing embryos in the TLIS incubator were often based on a medical history with poor or impaired implantation in previous cycles using day 3 embryo transfer, which rather strengthens the results than limiting them.

Wider implications of the findings: Although there are no differences in outcome or in early cleavage embryo quality on day 2, this study shows a difference in blastocyst quality for embryos cultured in the TLIS. This indicates that there is a potential benefit for undisturbed extended blastocyst culture.

Trial registration number: EC/2017/0086.

O-093   Effect of accurate temperature regulation during incubation on embryo quality after ICSI: a prospective sibling oocyte study on two incubation temperatures (36.6°C or 37.1°C)

R. Janssens, N. De Munck, H. Tournaye, I. Mateizel, I. Segers, G. Verheyen

UZ Brussel, Centre for Reproductive Medicine, Brussel, Belgium

Study question: Does accurate and stable incubation temperature at 36.6°C or 37.1°C affect the embryo quality after ICSI?

Summary answer: Fertilization rates and embryo quality were comparable between the 36.6°C and 37.1°C arm but ongoing pregnancy and implantation rates were higher after incubation at 37.1°C

What is known already: The primary function of an IVF incubator is to maintain an appropriate microenvironment (temperature and gas composition) for gamete function and embryo development. Although the developmental plasticity of embryos allows them to develop over a wide temperature range, the pre-implantation development is significantly affected in incubators that show a low micro-environment stability. Since most commercial IVF incubators show important temperature variations (up to 1.0°C), reliable studies that accurately determine optimal incubation temperature are scarce. So far, contradicting results on pregnancy data have been obtained when comparing culture temperatures.

Study design, size, duration: A single-centre prospective randomized controlled trial (100 cycles) was performed between May and November 2016,

after approval by the local ethical committee of the university hospital. An electronically generated randomisation list was used to allocate half of the mature oocytes to the 36.6°C or the 37.1°C arm. The primary endpoint was embryo quality on day 3 and day 5/6; secondary endpoints were fertilization and embryo utilization rates. Additionally, pregnancy outcomes were recorded.

Participants/materials, setting, methods: Ninety-nine ICSI cycles which fulfilled the following criteria were included: at least six mature oocytes, use of ejaculated sperm and extended culture to day 5/6. Sibling oocytes were cultured in the same G210 incubator (K-Systems, Denmark) at 36.6 $\pm$ 0.05°C (chamber 1 to 5) or 37.1 $\pm$ 0.05°C (chamber 6 to 10) from the time of ICSI up to day 5/6.

Main results and the role of chance: A total of 1432 cumulus-oocyte-complexes were retrieved of which 1153 were mature and randomised for culture at 36.6°C (n = 572) or 37.1°C (n = 581) after ICSI. Fertilization was comparable in the two groups (80.4% at 36.6°C and 78.3% at 37.1°C) as well as the number of good quality embryos on day 3 (78.3% and 79.6%) and the number of good quality blastocysts on day 5 (53.8% and 55.8%). Embryo utilization rates were also similar (40.0% versus 40.4%).

A fresh embryo transfer (ET) on day 5 was scheduled for 72 patients (two without ET due to insufficient embryo quality) and a freeze all strategy was scheduled for 27 patients (one without freezing). Fifty-nine single ET (SET) (28 from the 36.6°C group and 31 from the 37.1°C group) and 11 double ET were performed. The clinical pregnancy rate after SET was significantly higher when culture was performed at 37.1°C (77.4% versus 46.4%; p = 0.029, Chi Square test).

Limitations, reasons for caution: This trial was designed to detect a possible effect of incubation temperature on embryo quality and not on the treatment outcome. An RCT (36.6°C versus 37.1°C) with clinical pregnancy rate as primary endpoint is planned in order to confirm the present findings.

Wider implications of the findings: Modern direct-heat bench-top incubators with individual incubation chambers allow extreme stable temperatures and fast recovery after lid openings, which might be the future for embryo culture. Strict temperature control during incubation is indicated to obtain excellent results.

Trial registration number: NA.

O-094   Key performance indicators (KPIs-Score) based on clinical and laboratorial parameters can establish benchmarks for internal quality control (IQC) in an embryo cryopreservation programme

A.L. Mauri[1,2], C.G. Petersen[1,2], L.D. Vagnini[2], A. Renzi[2], B. Petersen[2], M.C. Mattila[1], V.A. Comar[1], J. Ricci[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr.[1,2]

[1]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis- Research and Training, Research, Ribeirao Preto, Brazil

Study question: Could a KPIs-score with clinical and laboratorial parameters be used to establish benchmarks for internal quality control (IQC) in an embryo cryopreservation IVF/ICSI programme?

Summary answer: This KPIs-score was able to define benchmarks for clinical pregnancy(CP). IQC for cryopreservation programme could utilize this KPIs-score to detect problems in the clinical-laboratorial interface.

What is known already: KPIs have been employed for IQC in the cryopreservation laboratory by using indicators such as embryo cleavage rates within 24 hours, percentage of embryo survival, and number of top-quality embryos after freezing-thawing. Laboratory conditions (solutions for freezing and thawing, temperature, pH, humidity, air quality, culture media, equipment, etc.) could modify these variables and negatively impact the final results. However, in no time, clinical KPIs (C-KPIs) such as age, AMH and number of oocytes collected are added to laboratory KPIs (L-KPIs) for analysis, despite the fact that the final endpoint is the evaluation of clinical pregnancy (CP) rates after embryo thawing.

Study design, size, duration: In this prospective cohort study, 158 patients underwent cryopreservation IVF/ICSI cycles during 2015-2016. The total KPIs-score was obtained by the analysis of the following C-KPIs(fresh cycle data): age, AMH, and number of M-II oocytes, and L-KPIs(frozen-thawing cycle data): morphological quality of cryopreserved embryo lot(MQCL) and embryo cleavage rate (ECR) after thawing. The total KPIs-score was correlated with

presence or absence of CP. The relationship between the C-KPIs-score and L-KPIs-score was analysed to establish quality standards.

Participants/materials, setting, methods: A total of 158 patients (33.8 ± 3.2years) participated in this research. The total KPIs-score was determined by the analysis of 5 parameters: age, AMH, number of M-II oocytes, morphological quality of cryopreserved embryonic lot (MQCEL) and embryo cleavage rate (ECR) after thawing. The maximum total KPIs-score was 25 points (Table I).

Main results and the role of chance: The model of logistic regression (MLR) with respect to CP and the total KPIs-score (158 patients/53 CP) resulted in an odds ratio of 1.27 (95%CI: 1.12 to 1.43). Also, there was a significant difference (P < 0.0001) with respect to the total KPIs-score mean among the group of patients with CP (KPIs-score = 21.1 ± 2.8) and the group without CP (KPIs-score = 18.9 ± 3.3). Clinical pregnancy probabilities (CPP) could be obtained using the MLR (prediction key) with the total KPIs-score as a predictor variable. Therefore, KPIs-score = 25/CPP = 62% (95%CI: 46% to 75%), KPIs-score = 20/CPP=33% (95%CI: 26% to 41%), KPIs-score=10/CPP=4% (95% CI: 1.2% to 14%), etc. Moreover, the mean C-KPIs-score obtained in the pregnancy group was 13 ± 2, and the L-KPIs-score was 8.1 ± 2.0. Routinely, in all cases where the C-KPIs-score was ≥11 after the IVF/ICSI procedure but the L-KPIs-score (freeze-thawing) obtained was ≤6 (approximately one standard deviation less than the mean), a detailed revision of the laboratory procedure was performed to check quality standards.

Table I The KPIs-score system for the cryopreservation programme.

SCORE POINTS	AGE (years)	AMH (ng/ml)	OOCYTES-MII (n)	MQCEL EMBRYOS	ECR
1	≥40	< 1	≤3	ONLY LOW-QUALITY	EMBRYOS WITH ECR<100%
3	37–39	≥1-<2	4–6	1 TOP-QUALITY OR ≥1 INTERMEDIATE-QUALITY	1 EMBRYO WITH ECR = 100%
5	≤36	≥2	≥7	≥2 TOP-QUALITY	≥2 EMBRYOS ECR=100%

Limitations, reasons for caution: One of limitations of the KPIs-score would be the necessity of each clinic to set up their own KPIs-score and future benchmarks.

Wider implications of the findings: The total KPIs-score was able to establish benchmarks for clinical pregnancy in an embryo cryopreservation programme. Also, the KPIs-score can provide insights about the clinical-laboratory interface. A comparative analysis between the values of the C-KPIs-score and L-KPIs-score can detect laboratorial problems or pitfalls in the work of clinicians and embryologists.

Trial registration number: Not applicable. All patients provided written consent, and the local Research Ethics Committee approved the study.

O-095 A quick, easy and effective sperm wash procedure for HCV+ and HIV+ patients

J. De Creus, E. Van De Voorde, E. Van den Abbeel, K. Tilleman, P. De Sutter

University Hospital Ghent, Reproductive Medicine, Ghent, Belgium

Study question: To develop a quick and efficacious semen washing protocol to remove viral HCV and HIV particles from seminal plasma.

Summary answer: A protocol comprised of 1 density gradient and 2 semen washes was able to remove viral particles and resulted in higher sperm yield after processing.

What is known already: Despite the controversy whether antiretroviral medication has a negative effect on semen quality (Garrido et al. (2004), Kehl et al.(2011), ICSI is needed when sperm quality is low. Precautions need to be taken in treatment of serologically discordant couples in ART. Many centers use a semen wash procedure like density gradient, swim up and buffer washing to effectively remove viral particles from the semen sample and selecting motile spermatozoa. Although the risk for viral transmission from parents to children is marginally low through ART procedures, techniques and protocols are also established for the safety of laboratory staff.

Study design, size, duration: Optimisation of the semen wash protocol was performed by using semen samples of consenting patients artificially spiked with HCV+ blood plasma.Four semen wash procedures were compared: P1: standard in house HIV protocol; P2 described by Molina et al. (2013); P3: Savasi et al. (2013); P4: optimised short protocol. P4 was validated using 3 different ejaculates of 1 HCV RNA+ patient and 25 ejaculates of 17 HIV+ patients.

Participants/materials, setting, methods: In total 46 samples were used: artificially HCV spiked(n = 14), negative controls(n = 4), HCV+ patient samples(n = 3) and HIV+ patient samples(n = 25).P4 was implemented in the clinic for both HCV+ and HIV+ patients. A comparative descriptive retrospective analysis was conducted to verify the sperm yield after washing in HIV patients P1(n = 18 patients) versus P4(n = 7 patients). Quantification of viral load in supernatant and sperm pellet after every centrifugation step was measured using real-time PCR on Abbott m2000sp.

Main results and the role of chance: P1, the standard rigorous HIV protocol used in the lab, consisted of wash, gradient centrifugation, wash, swim up and a final washing step. It was insufficient for the removal of HCV particles in artificially spiked samples of which the viral load ranged from $8,3*10$ IU/ml to $8,3*106$ IU/ml. Processed samples showed $1,26 \pm 0.28\%$ of initial viral load indicating a huge reduction in viral load, but without complete removal. Additionally, P2 and P3, established protocols from literature, were unable to remove the viral particles in the spiked sperm samples: $3.58 \pm 2.57\%$ remained after processing. No HCV particles were detected in the artificially spiked HCV samples processed with P4. P4 consisted of 2-layer density gradient at 400 g 20', followed by 2 washes with buffer at 400 g 10'. Most of the viral load ($97,15 \pm 2,85\%$) was removed after the density gradient. Validation of the wash protocol was performed on a HCV patient having a viral load of $3.88*105$ IU/ml. Three different ejaculates were processed, all samples were negative and the samples were released for clinical treatment. P4 was subsequently implemented for HIV+ patients (also RNA virus). Semen processing with P1 (n = 18 patients) and P4 (n = 7 patients) showed a statistically significant higher yield (Student's T-Test p = 0.04).

Limitations, reasons for caution: The viral load was measured by real-time PCR, with a quantifiable limit for HCV ≥30 IU/ml. Viral particles may still be present if concentrations are lower than the detection limit. The sample size of this study is rather low due to the specific patient cohort being studied.

Wider implications of the findings: Short and effective protocols result in fewer manipulation steps, with less possibilities for cross contamination and safer handling of the samples. A higher yield in semen after preparation can be very important for patients already compromised in semen quality like serologically positive patients.

Trial registration number: This research is conducted with the approval of the local ethics committee (2013/715).

O-096 The endometrium in women with PCOS

T. Piltonen

University of Oulu, Department of Obstetrics and Gynaecology- Oulu University Hospital- University of Oulu and Medical Research Center and PEDEGO Research Unit, Oulu, Finland

Abstract text
The endometrium in women with PCOS

Several studies suggest that the endometrium in women with polycystic ovary syndrome (PCOS) is compromised. Indeed, the women have shown to present with several endometrial abnormalities possibly explaining some of the adverse endometrium-related clinical outcomes. PCOS and an increased miscarriage rate have been suggested to coincide, but the results remain conflicting as obesity and ART are also associating factors. On the other hand, recent studies have also shown an increased risk of pregnancy-induced hypertension, preeclampsia, and premature delivery in women with PCOS that may relate to altered decidualization/placentation in these women. In fact, histological and molecular studies have shown placental abnormalities including histological findings related to inflammation and poor placental development as well as altered steroid hormone signaling pathway activation in women with PCOS. Alarmingly, the findings have been reported to occur even in uncomplicated pregnancies. Beyond fertility issues, PCOS *per se* is associated with an increased risk for endometrial cancer, with obesity aggravating the risk. Previous studies have shown for example an altered steroid receptor and their co-activator expression, inflammatory profile and changes in targets related to glucose metabolism that might also relate to endometrial stress and increased cancer risk.

Despite several endometrial abnormalities in women with PCOS, up to date no common clinically relevant markers exist as a tool to screen endometrial abnormalities in these women. The most investigated markers have been related to steroid hormone action endometrial and receptivity/decidualization, glucose metabolism, apoptosis and inflammation/immune cell migration. However, as concluded, the clinical relevance of these findings still awaits future clarification and so far no common screening protocols/recommendations for women with PCOS are established. Some recent studies have indicated that as for interventions, weight reduction, exercise and perhaps metformin could be useful tools to improve endometrial health in women with PCOS. The improvement might stem from the improved endometrial environment where endometrial regeneration from stem cells results into healthier endometrium in the subsequent cycles. However, further studies are warranted to answer some of the clinically relevant questions. In order to further develop and design interventions, the future aim should be in testing optimal methods/protocols and cell types for endometrial sample collection, validating screening tools and identifying the most severe PCOS phenotypes relating altered endometrial health.

Abstract text
The endometrium has a unique capacity to regenerate its functional layer during the menstrual cycle. Different factors, however, can cause destruction of the endometrium right through to its basal layer into the muscle layers of the myometrium. The damaged endometrium may not be repaired correctly which leads to the formation of Intrauterine Adhesions (IUA) and, therefore, lead to Asherman Syndrome (AS).

There is little high quality epidemiological data and the exact prevalence in terms of cases per 10,000 people is not reported in publications or patient associations. However, incidence and prevalence in Europe may be assessed after certain estmations.

Almost the entire majority of the causative factors on endometrial pathologies (iatrogenic and non-iatrogenic) have in common the triggering an inflammatory response. That is the reason why, some authors believe that the inflammatory pathway could play an important role in the pathogenesis of AS, resulting in the release into the intrauterine environment of factors which stimulate the formation of fibrotic tissue after endometrial trauma. On the other hand, it is determined that only 15–20% of curettages cause IUA adhesions suggesting that there may be some additional factors of susceptibility. Additionally, it is known that certain types of miscarriage or women with Müllerian duct malformation have a higher incidence of adhesions formation. All these facts, demonstrate that not only iatrogenic, but also genetic, anatomical and infection processes contribute to the ethiopahogenesis of this pathological entity.

Hysteroscopy is considered as the gold standard for diagnosis and treatment of AS. Although hysteroscopy is a technique very effective to solve mild cases of AS, the possibility of adhesion recurrence in moderate and severe cases is high according to published reports. Therefore, new strategies should be considered to treat these refractory cases.

Cells derived from bone marrow co-expressing CD133+ and vascular endothelial growth factor receptor 2 (VEGFR2) represent a subpopulation of cells known as endothelial progenitor cells (EPCs) with endothelial progenitor capacity that can be mobilized to the circulation and can improve neoangiogenesis of pre-existing endothelium. CD133+ Bone Marrow Derived Stem Cells (BMDSC) have been employed in clinical trials for regenerative medicine in non-haematological applications and have been shown to functionally contribute to neoangiogenesis during wound healing and limb ischemia, postmyocardial infarction, endothelialisation of vascular grafts, atherosclerosis, retinal and lymphoid organ neo-vascularization and tumour growth.

Some clinical and preclinical studies have shown that BMDSC CD133+ broadly act by regenerating the endometrium and thereby increasing fertility as a result of assisted reproductive treatment (ART)

In this sense, a pilot study CD133+ BMDSCs has been previously undertaken (Trial Registration Number: NCT02144987) that demonstrated that in the first 3 months, autologous cell therapy, using CD133+ BMDSCs in conjunction with hysteroscopy and hormonal replacement therapy (HRT), increased the volume and duration of menses as well as the thickness and angiogenesis processes of the endometrium while decreasing intrauterine adhesion scores and improved reproductive outcomes achieving the delivery of 5 healthy New Born after the treatment.

However, the precise molecular mechanism is still not well understood although pre-clinical and clinical studies in other pathologies can help to understand their mechanism of action. Therefore, further research and new lines of research have to be developed in order to increase the effectiveness of these novel therapy.

O-098 Integrating Psychological Care into the Infertility Clinic Setting

A. Domar

Domar Center for Mind/Body Health, Waltham, U.S.A.

Abstract text
Integrating Psychological Care into the Infertility Clinic Setting
A Domar
Domar Center for Mind/Body Health, Boston IVF, Harvard Medical School, Boston MA, USA

Recent research documents once again the prevalence of negative psychological symptoms in both men and women experiencing infertility. The majority of women reported clinical levels of both anxiety and depression and the majority of men reported clinical levels of anxiety. Studies from across the world have documented the negative psychological impact of infertility.

These psychological symptoms experienced by our patients have the potential to impact their medical care in three ways:

(1) Psychological distress is unpleasant to experience
(2) Distressed patients are more likely to drop out of treatment
(3) Anxious and depressed patients are more challenging to care for

Current recommendations include screening patients so as to identify those who are at highest risk of terminating treatment prior to achieving a pregnancy, providing written stress management materials, and streamlining the treatment protocols so as to decrease the burden of care. A mental health professional embedded into an infertility clinic setting can serve to address all three of these issues.

However, it is possible to do far more to serve the needs of patients and those who care for them. Based upon the results of a randomized controlled trial conducted in Spain, it is apparent that training physicians in empathic skills communication can have a significant impact on patient assessment of quality of care. It is not challenging for a psychologist to train all employees who have patient contact in empathic communication. Patients also benefit from structured behavioral and cognitive suggestions to decrease their stress level while cycling. Recent research showed that such interventions are associated with a decrease in treatment termination rates. Finally, the stress level of patients creates a challenging situation for the nurses who care for them. Burnout and turnover are commonly reported by infertility nurses. Mental health professionals can provide stress management training and support for nurses and others who care for patients.

This presentation will include a brief review of the research on the efficacy of psychological interventions to decrease the distress of patients, the impact on dropout rates, and methods to lower the stress levels of nurses and support staff. The main goal of the presentation however is to provide participants with concrete examples and suggestions of how to implement these changes into the infertility clinic setting.

O-099   How to help patients help themselves

D. Lancastle

University of South Wales, School of Psychology and Therapeutic Studies, Pontypridd, United Kingdom

Abstract text
How to help patients help themselves

Becoming a parent is a key personal life goal and people tend to assume that unprotected sexual intercourse will automatically lead to pregnancy as soon as they decide to conceive. For the 9% or so of couples that are infertile, however, such an assumption is challenged with monthly disappointment and the realisation that their futures will necessarily include treatment to help them conceive and/or the eventual acceptance that they will never become the parent of a child that is biologically their own. More than half of couples do seek treatment, but although treatment may enable couples to become parents this is not guaranteed and treatment itself is associated with physical, psychological, and social demands that can have a negative impact on quality of life and mental health.

The balance between the demands of life-experiences and the resources people have available to deal with those demands is a key principle of the Transactional Theory of Stress and Coping (Lazarus & Folkman, 1984). According to this approach, psychological stress is experienced when the demands of the situation exceed resources. In terms of demands, infertility and fertility treatment certainly heap a significant number of these onto the shoulders of infertile couples! There are cognitive demands such as decisions about treatment, the financial and physical demands of treatment itself, uncertainty about treatment success, worries about pregnancy, and distress from treatment failure, to name but a few. As it may not be possible, however, to alter specific treatment protocols to lessen demands and it is certainly not possible to guarantee treatment success, lessening the demands of treatment is not within the control of medical professionals. Bolstering the resources that patients have available to help them deal with those demands is therefore an appropriate way to try and redress the demands-resources balance and bolster patients' psychological wellbeing.

The ESHRE Guideline "Routine psychosocial care in infertility and medically assisted reproduction – A guide for fertility staff on the implementation of psychosocial care by healthcare professionals in infertility and medically assisted reproduction" differentiates specialised infertility counselling and psychotherapy for the minority of patients with clinically significant emotional problems or special needs, from 'routine' psychosocial care. This presentation speaks to the latter form of psychosocial support and provides information about theoretically driven self-help interventions that could provide the basis of a 'self-help tool kit' that medical professionals can guide patients towards as part of routine psychosocial care.

Effective coping is our first line of defence against stressful life experiences, and the self-help interventions presented can be broadly described as 'coping interventions' because they encourage individuals to employ coping strategies (e.g., positive reappraisal coping, distraction, relaxation, social support seeking) that have been shown to be appropriate and helpful during stressful life-experiences including fertility treatment. Such self-help interventions are a valuable adjunct to the high quality psychosocial support offered by medical professionals in face to face clinic sessions because patients can access these interventions in their own time to meet their ongoing needs when they are not in clinic. Bolstering coping resources in this way will help patients to negotiate their way through the various psychological demands of infertility and fertility treatment.

O-100   Oocyte cryopreservation: can it compete with cleavage stage and blastocyst cryopreservation?

D. Gook

The Women's Hospital, Reproductive Services /Melbourne IVF, Parkville- Victoria, Australia

Abstract text
For over 30 years embryo cryopreservation has played an important role in ART. Increasing rates of survival and the demonstration of implantation rates similar to those of equivalent fresh embryos, either at cleavage stages or after extended culture to the blastocyst stage, has influenced clinical IVF practice resulting in a major trend towards single embryo transfer in many parts of the world. More recently, the possibility of achieving improved perinatal outcomes, by transferring embryos in a menstrual cycle unaffected by ovarian stimulation, has led to a move towards the practice of cryopreserving all embryos generated in a stimulated cycle.

In contrast, oocyte cryopreservation has traditionally only been applied when embryo cryopreservation was not an option e.g. to provide a fertility preservation option in cases where there was no male partner, to circumvent legal restrictions that prohibited embryo storage and to defer insemination in cases where no sperm could be obtained in an ART cycle. This more limited application was based on a perception that outcomes from oocyte cryopreservation were likely to be inferior to those achievable with embryo cryopreservation.

Within the last decade, however, the outcomes from oocyte cryopreservation have improved significantly with the advent of reproducible vitrification techniques. Extensive application of this approach within large donor oocyte programs has demonstrated that high survival rates can be achieved and that the surviving oocytes can fertilise, develop and implant at rates indistinguishable from those of comparable fresh oocytes. This has led many to question whether oocyte cryopreservation can now match embryo cryopreservation in terms of efficiency and whether its use should now be considered for application in a wider context.

In this presentation, the evidence to support the contention that oocyte cryopreservation can compete with embryo cryopreservation in terms of overall efficiency will be analysed. In addition, if the outcomes from oocyte cryopreservation can be shown to approximate those from embryo cryopreservation, the advantages and disadvantages of extending the use of oocyte cryopreservation into other clinical contexts will be discussed.

O-101 Can automation guarantee the standardization of cryopreservation?

L.F. Rienzi

Genera c/o Clinica Valle Giulia GENERA center for Reproductive medicine, GENERA center for Reproductive medicine, Roma, Italy

Abstract text

With the introduction of vitrification in ART a substantial improvement in oocyte and embryo survival rates is obtained and, in turn, an increased live birth rate is reported with the use of vitrified embryos as compared to slow-frozen ones. Successful cryopreservation programs are essential to maximize the efficacy of ovarian stimulation cycles in IVF treatments. Moreover, cryopreservation allows cycle segmentation, fertility preservation and the use of cryopreserved oocytes for egg-donation programs.

Vitrification approach permits the solidification of cells into a glass-like state without the formation of ice crystals. This procedure, that involves multiple steps, may vary substantially from lab to lab due to the different physical and chemical conditions. Moreover, when performed manually, differences between operators are common during the stringent times pick-and-place operations. There is thus a poor standardization between centres and across operators. All these aspects may affect the overall efficacy of the technique.

With the aim to standardize vitrification procedure automation is suggested. Automatic cell manipulation has several important potential advantages including:

– Minimization of operation-caused errors and discrepancies;
– Alleviation of operators from this task with better exploitation of human resources;
– Optimization of timing controls for each step, including the vitrification itself;
– Possibility to process multiples samples contemporaneously;
– Opportunity to normalize chemical and physical conditions (including temperature and pH).

Over from vitrification process, robotic platforms combining embryo culture, evaluation and manipulation are expected in the near future. Such integrated platforms are very likely to provide the standardization of IVF, aiming at guaranteeing high standard of quality for every IVF center.

INVITED SESSION

SESSION 29: ASRM EXCHANGE SESSION

Tuesday 4 July 2017   Room B   08:30–09:30

O-102 Intention to treat: A rational approach to the management of the older and low response IVF patient

O. Davis

New York- NY, U.S.A.,

Abstract text

IVF has a high probability of success in young patients with normal ovarian reserve, due to the generation of robust numbers of euploid embryos. Patients of advanced reproductive age confront the challenges of higher aneuploidy rates coupled with fewer oocytes/embryos. Currently, many IVF clinics are restricting their treatment regimens to those of potential merit for their best prognosis patients, i.e. day 5-only transfers and, increasingly, the routine application of PGS; the obvious theoretical benefit is eSET of PGS-normal blastocysts thus mitigating the risks of dizygotic twinning. Universal codification of this approach for all IVF patients poses significant pitfalls for those women with an intrinsically poorer prognosis, however. In this presentation, a flexible approach to treating each patient according to her individual needs on an intention-to-treat basis will be explored. Simply put, the focus should be shifted from maximizing the IVF clinic's per transfer success rates to optimizing every patient's chances for achieving a successful pregnancy when she enters into treatment. This discussion will emphasize the importance of a willingness to treat the well-informed poorer prognosis patient in an individualized manner, the selection of optimal stimulation protocols, the inevitable impact of embryo attrition imposed by prolonged culture to day 5 (for fresh transfer or PGS) and the potential for misdiagnosis following PGS which may lead to further embryonic "loss". Similar to onco-fertility patients presenting with a limited time horizon in which to maximize their fertility preservation, the older/low response patient also has a limited window of opportunity during which the loss of potentially healthy embryos in an effort to promulgate only the best prognosis embryo transfers may, in fact, undermine the individual patient's chances for success. The clinical emphasis should shift back to an intention-to-treat paradigm initiated at the point of entry of the patient into an IVF clinic, and specifically at the commencement of each stimulation cycle. A policy of systematic embryo de-selection following oocyte retrieval in an effort to maintain the best possible success rate at the point of embryo transfer is better suited to the best prognosis patients.

O-103 How to counsel the older man seeking hormone and fertility therapy

R. Sokol

Ventura- Ca, U.S.A.,

Abstract text

How To Counsel The Older Man Seeking Hormone And Fertility Therapy.
Rebecca Z. Sokol, M.D., M.P.H.
Professor Emerita
Medicine and Obstetrics and Gynecology
Keck School of Medicine
University of Southern California
Evidence supports the hypothesis that reproductive potential declines with age in men, and that as men age they have a small increased chance of passing on genetic defects to their children. A gradual decline in circulating testosterone levels is reported in aging men, though the levels tend to remain within the normal range for testosterone. Cross sectional and longitudinal studies report an estimated 0.4% year decrease in total testosterone levels and 1.3% decrease in free testosterone levels. The decline in testosterone is primarily a result of reduced production of testosterone by the testes associated with a concomitant increase in LH secretion. A gradual decline of spermatogenesis also occurs with age. Daily sperm production in the testes is negatively correlated with age. Semen parameters begin to decline by age 35 years, but rarely fall into the "infertile" range. Time to pregnancy significantly increases with the age of the male partner, fecundity may decrease with age of the male partner, and the rate of miscarriage is increased in partners of older men. Testosterone replacement therapy does not improve spermatogenesis and is contraindicated for men attempting to initiate a pregnancy because it acts as a contraceptive. There is an association between increased paternal age and increased genetic diseases in the offspring of older men (Paternal Age Effect Disorders). Sperm replications increase as men age, causing an increase in point mutations and resultant genetically inherited syndromes. The incidence of schizophrenia and autism also may be increased in the offspring of older men. The etiology for this increase is multifactorial. Although the absolute number of children born with a genetic or neurogenic disorder is small, and the decline in fertility potential with age is subtle, counseling the couple about the risks of older paternal age is recommended.

V. Provoost

Bioethics Institute Ghent BIG Ghent University, Vakgroep Wijsbegeerte en Moraalwetenschap, Gent, Belgium

Abstract text

Describing embryos to patients?

Assisted reproduction takes patients on a journey through an entirely new domain. One aspect of that journey consists of the decisions patients need to make about the embryos created during in vitro fertilisation (IVF) or intra-cytoplasmic sperm injection (ICSI) treatment. They will need to decide whether to cryopreserve the embryos, whether or not to use the embryos for treatment and what to do with the embryos that are no longer wanted or needed. In light of these decisions, professionals have a duty to inform the patient in a way that is adequate and comprehensible. In this presentation, we will explore ways to describe embryos to patients by first listening to how patients conceptualise and feel about their embryos. For this, we will use research insights about patients' beliefs and views.

Although patients also express awe and marvel about embryos 'coming back to life again' during the thawing process, research has shown that for most patients making decisions about embryos is difficult and stressful. Patients usually know little about the medical or technical procedures involved in treatments with cryopreserved embryos; a lack of knowledge that is compensated for by a high level of confidence in the medical team. However, when people are dealing with matters they do not fully grasp, they tend to fill the gaps in their knowledge with information from other, more familiar, domains of experience. For infertility patients this is often compensated by using metaphors, mainly from the kitchen. For instance, cryopreservation and storage of embryos in liquid nitrogen tanks at a temperature of -196° Celsius is often compared with freezing meat by the food industry or in the freezer at home. Such comparisons might seem harmless at first glance but they do entail some dangers. Projecting characteristics of food or food storage (such as the reduction in quality during storage time) onto embryo storage can result in a belief that stored embryos had a best before or expiry date. In line with this, the use of frozen embryos has been perceived as weird and unnatural, raising doubts about the effectiveness of using cryopreserved embryos as compared to fresh ones and about the effects of freezing, storage and thawing on the health of their future children.

The dangers of these misconceptions become more clear when we look at decisions that are inconsistent with the patients' wish for a child. One example is seen in patients who want to continue storage (often linked to feelings of anticipated regret) while not wanting a(nother) child. Another example shows exactly the opposite: women who want a(nother) child but decide to end storage of their embryos. The latter group of women sometimes returns to the clinic for a new cycle of IVF to create new embryos only months after their decision to discard their cryopreserved embryos. Apart from reducing their chances of becoming pregnant, these decisions also give rise to extra (and potentially unnecessary) financial and emotional investment in their treatment. Especially the latter group appeared to have misconceptions and negative beliefs about the embryo. These are the patients most in need for appropriate information. However, it is important to note that the women who had doubts or mistrusted the use of cryopreserved embryos did not talk to the medical staff about this, which suggests that these patients' worries go unnoticed by professionals.

Findings like these demonstrate the importance of listening to patients, taking into account their feelings, conceptualisations, social contexts and the emotional basis of their decision making. Only this way, we can find the most appropriate way to describe embryos to patients.

O-110   Factors affecting embryonic mosaicism

E. Fragouli[1], S. Alfarawati[1], M. Simpkins[1], G. Cutts[1], K. Spath[1], D. Babariya[1], N. Kubikova[1], L. Rubistello[2], S. Munne[2], D. Wells[1]

[1]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, United Kingdom*
[2]*Reprogenetics LLC, Reprogenetics LLC, Livingston, U.S.A.*

Study question: Do differences in IVF procedures (e.g. culture medium, biopsy practitioner, incubator types, etc) and patient characteristics influence the frequency of mitotic errors, leading to mosaicism?

Summary answer: The type of medium used during embryo culture affects mitotic malsegregation and blastocyst mosaicism rates. Additionally, certain patients generate an excess of mosaic blastocysts.

What is known already: Mosaicism - the presence of chromosomally distinct cell lines within the same embryo - is common during preimplantation development, caused by incorrect segregation of chromosomes during mitosis. Recent innovations (next generation sequencing, NGS) have, for the first time, allowed mosaicism to be accurately detected in trophectoderm (TE) samples taken from embryos for the purpose of preimplantation testing for aneuploidy (PGT-A). Mosaic embryos have been shown to be associated with reduced implantation rates and elevated miscarriage rates. Recent data has revealed that the frequency of mosaicism in TE biopsies differs between IVF clinics. The cause of this variation is currently unclear.

Study design, size, duration: The rate of mosaicism in TE biopsies was assessed for 27 different European and US clinics, by examining NGS results obtained during PGT-A. All clinics completed a detailed survey, capturing information about embryological practices (e.g. varieties of media used for oocyte collection and embryo culture, types of incubators, oxygen concentrations, timing of embryo checks, etc). Mosaicism rates were also considered with respect to the embryologist who performed the biopsy, as well as the specific patient.

Participants/materials, setting, methods: A total of 19,719 embryos were examined (average 730 per clinic). All these embryos were biopsied at the blastocyst stage. The biopsied TE samples were composed of ~5 cells and were subjected to comprehensive chromosome analysis using a next generation sequencing strategy. The NGS method underwent extensive validation and was demonstrated, in blinded experiments, to provide accurate detection of mosaic samples, even when only one cell out of five was aneuploid.

Main results and the role of chance: A total of 15% (2,880/19,719) of blastocysts had one or more mosaic chromosome abnormalities in their associated TE specimens. 45% of embryos (8,927/19,719) were characterized as euploid, while the remaining 40% (7,912/19,719) had aneuploidy affecting all of the cells in the TE sample, with or without additional mitotic errors. The mosaicism rate differed significantly between clinics ranging from 11% to 27%. Twenty of these clinics cultured their blastocysts in a continuous medium system, using three different brands of media. One of these was associated with significantly (P < 0.05) larger numbers of mosaic blastocysts, compared to the other two. A sequential blastocyst culture system was employed in the remaining 7 clinics, and three different media were used. Significantly more mosaic embryos (P < 0.02 and 0.0001) were seen for two of the three media used. A significant difference (P < 0.0001) in mosaicism rate was also observed between continuous and sequential culture

systems, with the former associated with more mosaic embryos (17% vs.13%). There was no relationship between the frequency of mosaicism and different biopsy practitioners, neither other aspects of embryo culture. However, we did observe that patients with multiple unsuccessful IVF/PGT-A attempts had a tendency to generate more mosaic blastocysts than other patients.

Limitations, reasons for caution: Data analysis was based on NGS results obtained from a single TE biopsy specimen. This likely underestimates the true frequency of mosaicism as one TE sample cannot guarantee to contain representatives of all of the different cell lines within an embryo. Nonetheless, validation data indicates most mosaics are successfully detected.

Wider implications of the findings: This study provides evidence that different media formulations directly influence the frequency of mitotic errors and embryo mosaicism, with significant implications for IVF success. Additionally, certain patients have a predisposition to generating mosaic embryos. Our results suggest that maintenance of genetic competence should represent a new focus for media development.

Trial registration number: Not applicable.

O-111 The relationship between blastocyst morphology, euploidy, aneuploidy and mosaicism

M. Simpkins, S. Alfarawati, G. Cutts, K. Spath, N. Kubikova, D. Wells, E. Fragouli

Reprogenetics- UK, Institute of Reproductive Sciences, Oxford, United Kingdom

Study question: Does the presence of mosaic chromosome abnormalities affect the morphology of blastocysts? Do mosaic blastocysts behave more like chromosomally normal or fully aneuploid embryos?

Summary answer: Mosaic blastocysts tend to be morphologically more similar to fully aneuploid embryos, rather than completely euploid embryos.

What is known already: Mosaicism is the result of post-zygotic chromosomal malsegregation, most often occurring during the first three cleavage divisions, and leading to the presence of chromosomally distinct cell lines within the same embryo. With the recent increase in use of Next Generation Sequencing (NGS), a sensitive method capable of detecting mosaic abnormalities in trophectoderm biopsy specimens, issues have surfaced regarding the way in which mosaic embryos are dealt with clinically. Specifically, the implantation potential of mosaic blastocysts is unclear. Questions therefore have arisen about whether mosaic embryos should be treated in the same way as fully aneuploid ones, and excluded from transfer.

Study design, size, duration: The relationship between blastocyst ploidy and different morphological characteristics was assessed. These included expansion, and grade of inner cell mass and trophectoderm. The blastocysts investigated were grouped in the following categories: euploid, abnormal (non-mosaic), mosaic (euploid-aneuploid) and mosaic (aneuploid-aneuploid). The morphologies of euploid blastocysts and those carrying non-mosaic or mosaic abnormalities compatible with clinical pregnancy (i.e. certain aneuploidies involving chromosomes 13, 16, 18, 21, 22, X0, and XXY) were also compared.

Participants/materials, setting, methods: A total of 1696 embryos generated by 306 patients were examined. These patients were having IVF treatment combined with preimplantation genetic testing for aneuploidy (PGT-A) for various indications in 12 different clinics. The average female age was 38.4 years. All embryos were biopsied at the blastocyst stage of development. The trophectoderm (TE) samples removed were examined cytogenetically via a highly validated NGS strategy. The analysis of embryo ploidy and associated morphology took place retrospectively.

Main results and the role of chance: 25.5% of blastocysts (433/1696) were found to contain at least one non-mosaic aneuploidy, 25.4% (430/1696) were characterised as having one or more mosaic abnormalities, 27.0% (458/1696) contained a combination of mosaic and non-mosaic chromosomal abnormalities and the remaining 22.1% (375/1696) were euploid. Compared to the chromosomally normal embryos, blastocysts containing abnormal cells (uniformly aneuploid or mosaic) had significantly ($P \leq 0.001$) poorer blastocyst expansion scores. The same embryos were also associated with poorer inner cell mass (ICM) and TE grades ($P \leq 0.05$). The differences were insufficient to allow abnormal embryos to be clearly identified, but they do indicate that aneuploidy is already impacting embryo development at this early stage. When the

three abnormal groups of embryos were compared to one another (abnormal non-mosaic, mosaic euploid-aneuploid, mosaic aneuploid-aneuploid), no significant differences in any aspects of morphology were observed. The fact that mosaic embryos closely resembled those that are uniformly aneuploid, suggests that they too are likely to be compromised. Finally, the morphology of euploid embryos was found to be indistinguishable from that of embryos having forms of aneuploidy (mosaic or non-mosaic) potentially compatible with a viable pregnancy. This indicates that those types of aneuploidy do little to impair preimplantation development.

Limitations, reasons for caution: Cytogenetic classification was based on TE samples removed from blastocysts during PGT-A analysis. As only a fraction of the cells from each embryo are tested, inevitably some mosaic embryos will be incorrectly classified fully euploid or aneuploid. However, this misclassification is expected to have little impact on the results.

Wider implications of the findings: In morphological terms, mosaic blastocysts closely resemble those that are uniformly aneuploid. In contrast, embryos affected by types of aneuploidy compatible with survival and formation of clinical pregnancies, had morphology equivalent to euploid blastocysts. These findings add to the debate over whether mosaic embryos should be considered for transfer.

Trial registration number: Not applicable.

O-112 Frequency and clinical relevance of mosaic segmental aneuploidy in blastocyst stage human embryos

D. Wells[1], D. Babariya[2], S. Alfarawati[2], K. Spath[2], N. Kubikova[3], S. Munne[4], E. Fragouli[2]

[1]*Reprogenetics UK, Oxford, United Kingdom*
[2]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, United Kingdom*
[3]*University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Oxford, United Kingdom*
[4]*CooperGenomics, Reprogenetics, Livingston, United Kingdom*

Study question: What are the factors influencing the occurrence of segmental aneuploidy in human embryos and what is the clinical significance of such errors?

Summary answer: Specific culture media formulations affect the frequency of segmental aneuploidy, the vast majority of which arises during the first few mitotic divisions after fertilisation.

What is known already: Segmental aneuploidy is characterised by the loss or duplication of chromosomal fragments. Such abnormalities occur at a considerable frequency during preimplantation embryo development, but their underlying cause and clinical significance are poorly understood. Further investigation is required in order to establish, and perhaps one day eliminate, the causes of segmental aneuploidy and to improve management of patients with affected embryos. Next generation sequencing (NGS) is used for preimplantation genetic screening (PGS) and provides highly accurate detection of segmental aneuploidy. Furthermore, NGS is capable of detecting mosaic aneuploidy (the presence of chromosomally distinct cell lines within the same embryo biopsy specimen).

Study design, size, duration: Trophectoderm biopsies from 9,037 blastocyst stage embryos underwent comprehensive chromosome screening via NGS. Patients were referred for PGS for various reasons including advanced maternal age (AMA), recurrent implantation failure (RIF) and recurrent pregnancy loss (RPL). A questionnaire concerning IVF culture practices including culture media systems, brands, incubators, gas composition etc. was completed by all the IVF clinics that referred the patients.

Participants/materials, setting, methods: Trophectoderm biopsies were subjected to whole genome amplification followed by low-pass NGS using the Miseq platform (Illumina). Analysis of the chromosome complement was performed with BlueFuse software (Illumina). Prior to embryo analysis, mosaicism detection using this approach was validated by mixing cells from several aneuploid and euploid cell lines in specific ratios. These experiments demonstrated the accurate detection of different proportions of abnormal cells (including those with segmental aneuploidy) in small samples (~5 cells).

Main results and the role of chance: 20.0% of blastocysts were affected by segmental aneuploidy (1810/9037). The distribution of chromosomal breakpoints was not entirely random, with a number of hotspots revealed, some of

which correspond to known fragile sites in human genome. Mosaic segmental errors were more common than segmental aneuploidies affecting all of the cells in the sample (1429 versus 507 instances; P < 0.0001), indicating that most of these abnormalities arise after fertilisation. Interestingly, patients with a history of recurrent implantation failure showed an elevated rate of non-mosaic segmental aneuploidy, suggesting that their gametes have an unusually high risk of suffering chromosome breakage during meiosis (16.8% RIF versus 4.8% AMA and 5.9% RM, respectively; P < 0.0001). There was no association between segmental abnormality and female age. Rates of blastocyst segmental aneuploidy were not identical for all clinics, ranging from 2.5%-25.2% of embryos affected (P < 0.0001). In an effort to determine the reason for this variation, culture methods were assessed in detail at ten of the clinics referring samples for PGS. Rates of meiotic segmental aneuploidies were identical across all clinics. However, levels of mosaic (i.e. post fertilisation) segmental abnormalities differed, tending to be higher in clinics utilising continuous culture media as compared to those using sequential (P = 0.019).

Limitations, reasons for caution: The degree of mosaicism may not be representative of the entire embryo in all cases, as it is determined from a small sample of trophectoderm (TE) tissue. Sometimes, mosaicism may be absent from TE sample, but present elsewhere in the embryo.

Wider implications of the findings: The study confirms that segmental aneuploidy is common in blastocysts and typically arises after fertilisation. The results indicate that culture environment modulates the risk of segmental abnormalities occurring, providing an opportunity to optimise embryological methods. Additionally, there is evidence that some patients are predisposed to segmental errors affecting their embryos.

Trial registration number: Not applicable.

O-113　A novel method to calculate the mitochondrial DNA/ nuclear DNA ratio in human blastocysts as a biomarker for human embryo implantation potential

S. Madjunkova[1], R. Antes[1], R. Abramov[1], V. Kuznyetsov[1], E. Fish[1], A. Silver[1], J. Librach[1], C. Librach[1,2,3]

[1]Create Fertility Centre, Preimplantation Genetics, Toronto, Canada
[2]Women's College Hospital, Department of Gynecology-, Toronto, Canada
[3]University of Toronto, Department of Obstetrics and Gynecology and Department of Physiology-, Toronto, Canada

Study question: What is the significance of the human blastocyst mitochondrial DNA/nuclear DNA ratio as an IVF biomarker tested by next-generation sequencing (NGS)?

Summary answer: Mitochondrial-DNA/nuclear-DNA ratio of human blastocyst, adjusted for size/level of chromosomal-aberrations, can be used as a biomarker of implantation potential of euploid embryos in patients >35years.

What is known already: Previous research evaluating levels of mitochondrial DNA and mitochondrial DNA/nuclear DNA ratio (mtDNA/nDNA ratio) of human blastocyst and its clinical significance has shown conflicting results. While some have enthusiastically announced this ratio as promising universal IVF biomarker, there were important arguments against it involving method of testing, study design and accuracy of ratio calculation.

Study design, size, duration: This was a retrospective study where we reanalyzed the PGS data from low pass whole genome sequencing of 1152 blastocysts and developed a mathematical method to accurately calculate mtDNA/nDNA ratio. The studied group also included reanalysis of genomic content and mtDNA/nDNA ratio calculation of 188 blastocyst transfers with pregnancy outcomes.

Participants/materials, setting, methods: Trophectoderm biopsies of D5/D6 blastocysts (n = 1152) from 387 patients were tested with NGS for PGS at Create Fertility Preimplantation Genetic lab. The calculation of mtDNA/nDNA ratio involved quality filtering of mtDNA and nDNA specific reads and included correction factors reflecting the size of nuclear DNA by gender, chromosomal aberration and the level of mosaicism if present.

Main results and the role of chance: Euploid embryos from patients over 35 years of age that implanted (n = 26, 72%) had significantly higher average mtDNA/nDNA ratio than embryos that didn't implant (n = 10, 28%) (0.001227 ± 0.000667 vs 0.0007915 ± 0.000356, p = 0.00172). This difference was not observed in the transferred euploid embryos from patients under 35

years (n = 119). Embryos that were euploid/mosaic in levels less than 40% (n = 32, 17%) had no difference in the levels of mtDNA/nDNA ratio regardless of patient's age and their implantation potential. When comprehensive ratio calculation was applied euploid (n = 574) blastocysts, had significantly lower levels of mtDNA/nDNA ratios (0.00108 ± 0.0007785) compared to aneuploid (n = 260, 0.0014813 ± 0.0018064) p = 0.0008 and mosaic (n = 269, 0.0012918 ± 0.0008516) embryos p = 0.0008. Patient age didn't have significant influence on the mtDNA/nDNA ratio regardless of ploidy.

Limitations, reasons for caution: This study was limited to the samples analyzed in our lab in 2016 and by the number of pregnancy outcomes available until December 2016.

Wider implications of the findings: Overall, our findings provide evidence that accurate calculation of mtDNA/nDNA ratio can be used to prioritize euploid embryos for transfer in patients that are over 35 years of age.

Trial registration number: N/A.

O-114　Quantitative and qualitative changes of mitochondria in human embryos

S. Hashimoto[1], M. Yamanaka[1], T. Yamochi[1], M. Inoue[1], Y. Nakaoka[1], Y. Morimoto[2]

[1]Sunkaky Medical Corporation, IVF Namba Clinic, Osaka, Japan
[2]Sunkaky Medical Corporation, HORAC Grandfront Osaka Clinic, Osaka, Japan

Study question: What roles do mitochondria play in the development of human embryos?

Summary answer: The mitochondrial respiratory function of human embryos developed along with embryonic growth although the copy numbers of mitochondrial DNA (mtDNA) decreased transiently before blastulation.

What is known already: Although the rate of oxygen consumption (OCR) in mice and cattle changes during preimplantation embryogenesis, the number of mtDNA copy remains unchanged in mice but changes in cattle and pigs. However, dynamic aspects of mitochondrial functions and mtDNA copy numbers in human embryos during preimplantation development remains obscure.

Study design, size, duration: Sixteen oocytes and 100 embryos were used to assess mtDNA copy numbers and OCR. Three oocytes and 12 embryos were used to determine cytochrome c oxidase activity. All specimens were obtained between July 2004 and November 2014, and donated from couples after they had given informed consent.

Participants/materials, setting, methods: Mature oocytes and developed embryos to 2, 3-4, and 5–8 cell, morula and blastocyst stages after ICSI were used to assess their OCR in the presence or absence of mitotoxins. The mtDNA copy number was determined using the samples after analysis of OCR. The relationships between developmental stages and OCR, and developmental stages and mtDNA copy number were analyzed. Furthermore, cytochrome c oxidase activity was determined in oocytes, 4, 8, morula and blastocyst stages.

Main results and the role of chance: Mitochondrial OCR (mtOCR) was calculated by subtracting the value obtained in the presence of cyanide from those obtained without any mitochondrial toxins. No difference in mtOCR was found from oocyte to 8 cell stages. However, mtOCR increased rapidly at 9–14 cell and later stages (P < 0.01) compared with those until 8 cell stage. Furthermore, the mtOCR at blastocyst stage were significantly higher than those until 14 cell stage (P < 0.01). The number of mtDNA copy per specimen in embryos decreased transiently (P < 0.01) at 2 cell, 9–14 cell and morula stages compared with oocytes. The number of mtDNA copy significantly increased (P < 0.01) in expanded blastocyst stage compared with those in earlier stages. The numbers of mtDNA copy per cell in embryos decreased gradually (P < 0.01) from oocytes toward morula and blastocyst stages. Taken together, OCRs increased toward the morula stage ahead of an increase of mtDNA at the time of blastulation. The undifferentiated state of inner cell mass appears to be associated with a low OCR. On the other hand, the aerobic metabolism of mitochondria in trophectoderm cells increased.

Limitations, reasons for caution: All samples except for oocytes were used after vitrification and warming following the guidelines of the Japan Society of Obstetrics and Gynecology. To avoid contamination with mtDNA from spermatozoa attached to the zona pellucida, all embryos were obtained by using intra-cytoplasmic sperm injection.

Wider implications of the findings: Modifying the energy sources required for mitochondrial functions would provide an environment with less stressful conditions for the culture of embryos. The present work showing changes in mitochondrial structure, function, and mtDNA copy numbers during preimplantation development would be useful in optimizing culture media for the development of human embryos.

Trial registration number: This study was approved by the IRB of IVF Namba Clinic and the Japan Society of Obstetrics and Gynecology (Registry numbers 135 and 138).

O-115 Single-Cell Analysis of Telomere Length Dynamics and DNA Damage Across Early Human Development Suggest Alternative Lengthening of Telomeres

L.G. Robinson- Jr.[1], **Y. Kramer**[1], **R. Pimentel**[1], **F. Wang**[1], **P. Navarro**[1,2,3], **D.L. Keefe**[1]

[1]New York University Langone Medical Center, Obstetrics and Gynecology, New York, U.S.A.
[2]University of Sao Paulo, Department of Obstetrics and Gynecology, Faculty of Medicine of Ribeirao Preto
[3]FAPESP (Scholarship, Process 2015/21907-0),

Study question: What happens to telomere length during human meiotic maturation and pre-implantation development? What is the impact of DNA damage and telomere attrition on human development?

Summary answer: DNA damage and telomere attrition limit oocyte maturation in vitro. Telomeres are short in oocytes, increase markedly, and develop increased heterogeneity during pre-implantation development.

What is known already: Telomere length reflects aging in many cell types. Sperm, which emerge from spermatogonia throughout the life of the man, have long telomeres. Oocytes from mouse and women maintain short telomeres. Telomerase, the enzyme that lengthens telomeres, is minimally active in mouse and human oocytes and pre-implantation embryos until blastocyst stage. Lacking appreciable telomerase activity, early mouse embryos elongate telomeres via Alternative Lengthening of Telomeres (ALT), which provides robust telomere elongation, but increased genomic instability. We do not know whether ALT occurs during early human development, and if so, when it takes place.

Study design, size, duration: 60 immature germinal vesicle (GV) and metaphase I (M1) human oocytes donated to research from women ages 18–45 were collected and in vitro matured (IVM) for up to 48 hours following the subjects' retrieval. Additionally, 28 cryopreserved human embryos donated to research from 7 couples (age 27–42 years old), at the New York University Langone Fertility Center.

Participants/materials, setting, methods: Immature oocytes were in vitro matured to metaphase II (M2). Frozen embryos between the 2 pronuclear (2PN) and day 3 (8-10-cell) stage were thawed and dissociated into single blastomere, intact blastocysts were processed whole. Telomere length was evaluated using Single Cell Amplification of Telomere Repeats PCR (SCATR-PCR), expressed as a telomere to reference gene ratio (T/R ratio). DNA damage was assessed by immunoflorescent staining. Statistical analysis was performed using one-way ANOVA or T-test where appropriate.

Main results and the role of chance: During oocyte maturation, immunostaining revealed that oocytes which arrested at the GV stage and failed to mature, contained robust and abundant DNA damage signaling on their chromosomes compared with successfully matured M2s (mean total florescent units = 35073.4 ± 10051.8 vs. 843.7 ± 74.9). Telomere length however did not differ significantly between arrested GV and M2 oocytes (mean T/R ratio = 0.074 ± 0.040 vs 0.105 ± 0.067). Telomere length increased significantly ($p < 0.05$) between M2 oocytes and both 2PN embryos (mean T/R ratio = 0.837 ± 0.546) and blastocysts (mean T/R ratio = 0.634 ± 0.260). The most significant elongation ($p < 0.0002$) occurred by day 2 (2–4 cell) (mean T/R ratio = 0.957 ± 767). Between day 2 and day 3 (mean T/R ratio = 0.385 ± 0.418) telomere length decreased. These data suggest early activation of a telomere lengthening mechanism, prior to zygotic genome activation. Additionally, Intra-embryo telomere length increased until its peak day 3 (Coefficient of Variation = 108.51%) and was at its lowest at the blastocyst stage (Coefficient of Variation = 40.97%) when telomerase becomes active. Together these data suggest that an Alternative Lengthening of Telomeres (ALT) mechanism may be responsible for both increases in telomere length and increased heterogeneity among blastomeres within early embryos.

Limitations, reasons for caution: The limited sample size for some of the earliest embryonic stages in addition to the freezing method for the embryos may have affected quality, and an inability to infer developmental ability as the embryos were not cultured to blastocyst.

Wider implications of the findings: Our study is the first to perform a molecular characterization of telomere dynamics and the role of DNA damage in human oocytes and embryos at the single cell level and provides the first evidence that ALT is part of normal embryonic development in humans.

O-116 Submaximal doses of ghrelin do not inhibit gonadotrophin levels but stimulate prolactin secretion in postmenopausal women

C.I. Messini[1], **M. Malandri**[1], **G. Anifandis**[1], **K. Dafopoulos**[1], **P. Georgoulias**[2], **A. Garas**[1], **A. Daponte**[1], **I.E. Messinis**[1]

[1]University of Thessaly- School of Health Sciences- Faculty of Medicine, Department of Obstetrics and Gynaecology, Larissa, Greece
[2]University of Thessaly- School of Health Sciences- Faculty of Medicine, Department of Nuclear Medicine, Larissa, Greece

Study question: Does ghrelin suppress gonadotrophin levels in estrogen-deprived postmenopausal women? Does ghrelin stimulate PRL secretion in postmenopausal women and what is the role of estrogen?

Summary answer: In estrogen-deprived postmenopausal women, ghrelin administration affects neither FSH nor LH levels but stimulates PRL secretion, that is amplified by exogenous estrogen administration

What is known already: Previous studies in normally menstruating women regarding the role of ghrelin in gonadotrophin secretion have shown either no effect or a suppressive action. It has been suggested that the pattern of ghrelin administration (multiple vs single dosage) may have an impact and that there may be a facilitating action of estrogen on ghrelin-induced gonadotrophin suppression. However, the effect of ghrelin on gonadotrophin secretion in estrogen-deprived postmenopausal women has not been previously investigated. It is well known that exogenous ghrelin stimulates the secretion of PRL, but its effect in postmenopausal women has not been studied as yet

Study design, size, duration: Prospective intervention study in 10 volunteer postmenopausal women 52–74 years old (within 2–29 years past menopause) and a BMI of 22.3–34.6 kg/m^2. All women were studied during two 15-day periods of oral estrogen treatment (A and B) a month apart. The study was conducted between September 2015 and May 2016

Participants/materials, setting, methods: Four experiments (Exp) were performed on days 1 (Exp1A, Exp1B) and 15 (Exp15A, Exp15B) of the two study periods (09.30 h). The women received two ghrelin injections iv (0.15 μg/kg at time 0 min and 0.30 μg/kg at 90 min) in Exp1A and Exp15A and

normal saline (2 ml) in Exp1B and Exp15B. Blood samples were taken at -15, 0, 30, 60, 90, 120, 150 and 180 min. Statistical analysis by Student's t-test and one-way ANOVA

Main results and the role of chance: Hormonal levels are presented as mean±SEM. Before the study onset, serum FSH, LH and estradiol levels were 52.2 ± 6.1 IU/l, 31.6 ± 3.8 IU/l and 27.4 ± 2.6 pg/ml, respectively. After estrogen treatment, serum estradiol values increased significantly on day 15 to levels similar to those in the late follicular phase of the normal menstrual cycle (Period A: 146.9 ± 22.6 pg/ml; Period B: 147.5 ± 29.3 pg/ml, P < 0.001). Total plasma ghrelin levels increased significantly after the two injections of ghrelin in both Exp 1 A (from 630 ± 26 pg/ml at 0 min to 5111 ± 135 pg/ml at 30 min and 5190 ± 158 pg/ml at 120 min, P < 0.001) and Exp 15 A (from 699 ± 55 pg/ml at 0 min to 5053 ± 512 pg/ml at 30 min and 5804 ± 274 pg/ml at 120 min, P < 0.001). Following the two injections of ghrelin (Exp 1 A and Exp 15 A), serum FSH and LH levels remained stable, while GH and PRL levels increased significantly with peak values occurring at 30 and 120 min (P < 0.001). In Exp 15 A, serum PRL increment in response to ghrelin (area under the curve) (1st injection: 140.3 ± 42.7 ng/ml/90 min; 2nd injection: 189.4 ± 45.2 ng/ml/90 min) was significantly greater than in Exp 1 A (16.6 ± 36.4 ng/ml/90 min and 41.5 ± 35.9 ng/ml/90 min respectively, P < 0.05)

Limitations, reasons for caution: LH pulsatility was not investigated in this study. Nevertheless, in normally menstruating women an inhibitory effect of ghrelin on FSH and LH levels has been shown previously in daily blood samples

Wider implications of the findings: The present results do not have direct application to practice. However, they are the basis for further research regarding the role of ghrelin in the physiology of the hypothalamo-pituitary axis

Trial registration number: N/A.

O-117 A second dose of kisspeptin safely optimizes oocyte maturation in women undergoing in IVF treatment: a phase 2 randomized controlled trial

A. Abbara[1], S. Clarke[1], R. Islam[2], J. Prague[1], A. Comninos[1], S. Narayanaswamy[1], D. Papadopoulou[1], R. Roberts[1], C. Izzi-Engbeaya[1], R. Ratnasabapathy[1], A. Nesbitt[1], S. Vimalesvaran[1], R. Salim[2], S. Lavery[2], S. Bloom[1], L. Huson[3], G. Trew[2], W. Dhillo[1]

[1]Imperial College London, Section of Investigative Medicine, London, United Kingdom
[2]Imperial College NHS Trust, IVF medicine, London, United Kingdom
[3]Imperial College London, Division of Experimental Medicine, London, United Kingdom

Study question: Determine whether increasing the duration of LH-exposure by administering a second dose of kisspeptin could further optimize oocyte maturation.

Summary answer: Administering a second dose of kisspeptin safely improves oocyte yield in women at high risk of developing OHSS undergoing IVF treatment.

What is known already: In vitro fertilization is an effective therapy for infertility, but can result in the potentially life-threatening complication ovarian hyperstimulation syndrome (OHSS).

We have previously reported that a single dose of kisspeptin results in an LH-surge of ~12-14hrs duration, which safely triggers oocyte maturation in women at high risk of OHSS.

Study design, size, duration: Phase-2 single-blinded randomized placebo-controlled trial of 62 women at high risk of OHSS were recruited between October 2013 and August 2014.

Participants/materials, setting, methods:
Setting: Hammersmith Hospital, London, UK

Protocol: Following a recombinant FSH/GnRH-antagonist IVF protocol, all patients (n = 62) received a subcutaneous injection of kisspeptin-54 (9.6 nmol/kg) 36hrs prior to oocyte retrieval.

Patients were then randomized 1:1 to receive either a second dose of kisspeptin (D; Double, n = 31), or saline (S; Single, n = 31) 10hrs thereafter.

Primary Outcome: Proportion of patients achieving an oocyte yield (percentage of mature oocytes retrieved from follicles ≥14 mm) ≥60%.

Secondary Outcomes: Reproductive hormone levels, Implantation rate, OHSS occurrence.

Main results and the role of chance: A second dose of kisspeptin induced further LH-secretion at 4hrs and 10hrs after injection compared to saline (P < 0.0001). A higher proportion of patients achieved an oocyte yield ≥60% following a second dose of kisspeptin (S:45.2%, D:71.0%; absolute difference +25.8%, CI 2.1–49.5%, P = 0.042). Patients receiving two doses of kisspeptin had a variable LH-response following the second kisspeptin dose, which appeared to be determined by the LH-response following the first kisspeptin injection. Patients who had a lower LH-rise following the first dose of kisspeptin had a more substantial 'rescue' LH-response following the second dose of kisspeptin. The variable LH-response to the second dose of kisspeptin meant that the proportion of patients achieving an oocyte yield ≥60% was improved, but without also increasing the frequency of ovarian over-response and OHSS.

Limitations, reasons for caution: Further studies are warranted to directly compare kisspeptin to more established triggers of oocyte maturation.

Wider implications of the findings: We observe that a second dose of kisspeptin administered 10hrs following the first is a safe option to improve the proportion of patients achieving an oocyte yield of at least 60%, but without also increasing the risk of ovarian over-response and OHSS.

Study question: Is twice daily progesterone 400 mg vaginal pessary non-inferior to daily progesterone 8% gel after 38 days of luteal phase support (LPS) concerning pregnancy rate?

Summary answer: Progesterone 400 mg vaginal pessary is non-inferior to progesterone 8% (90 mg) gel in clinical pregnancy rate after 38 days of luteal phase support.

What is known already: A pharmacokinetic (PK)/pharmacodynamics (PD) trial compared various dosing regimens of progesterone vaginal pessaries to progesterone 8% (90 mg) gel once daily and placebo in 125 healthy female subjects (EudraCT # 2012-001726-95). With respect to endometrial transformation rates, non-inferiority to progesterone gel was demonstrated for twice daily progesterone 200 mg and 400 mg vaginal pessaries. The PK profile after 10 days of multiple dosing with progesterone vaginal pessary 400 mg bid was most stable and steadily reached physiological plasma progesterone concentrations. The frequency for vaginal spotting and bleeding was lowest after 400 mg progesterone pessary.

Study design, size, duration: This was a multi-center, multi-national, open, randomized, two-parallel groups, non-inferiority trial. Patients were stratified according to center and age groups (≤35, >35 years). 812 patients were screened (randomized: 769). Patients were randomized 1:1 to progesterone vaginal pessary or progesterone gel treatment self-administered twice or once daily, respectively, for a period of up to 70 (±3) days, starting in the evening of the oocyte retrieval day.

Participants/materials, setting, methods: Women undergoing fresh embryo transfer after in vitro fertilization or intracytoplasmic sperm injection as part of their regular ART therapy were included. Clinical pregnancy defined as gestational sac with fetal heart movement was assessed by transvaginal

ultrasonography on Day 38 and Day 70. Primary efficacy endpoint was clinical pregnancy on Day 38. Secondary outcomes included β-hCG levels (Day 18, Day 38) and implantation rate (N implanted embryos/N embryos transferred) on Day 38 and Day 70.

Main results and the role of chance: For the primary end-point, non-inferiority of progesterone pessary versus progesterone gel was met in the full analysis set (FAS) but could not be formally shown for the per protocol set (PPS) based on the pre-defined -9% non-inferiority margin (actual value: -9.5%). Pregnancy rates on Day 38 were 38.3% for progesterone pessaries and 39.9% for progesterone gel (FAS). These rates were higher than anticipated in sample size calculations (assumed a reference rate: 30%) leading to an increased variability, thus to wider confidence intervals than expected and explaining the marginal violation of the non-inferiority criterion for the PPS. Pregnancy rates on Day 70 were 34.5% (progesterone pessary) and 37.6% (progesterone gel). In the progesterone pessary group, the pregnancy rate was higher in younger patients (≤35 years: 41.4%; >35 years: 33.8%) and transfer of two or three embryos led to a higher rate (42.1%) compared to single embryo transfer (31.1%). Pregnancy rates on Day 38 were 21.1%, 38.9%, 37.9%, 38.3%, and 42.4% in Belgium, Bulgaria, Czech Republic, Hungary, and Serbia, respectively. Implantation rates for progesterone pessaries compared to progesterone gel on Day 38 were 24.6% and 26.5% and on Day 70, 22.5% and 24.5% respectively. Both treatments were safe and well tolerated.

Limitations, reasons for caution: A logistic regression analysis was applied to investigate potential 'country' effects. The test for any interaction between country and treatment (p = 0.13) indicated a tendency for country specific differences between treatments. However, since this test is not statistically significant, treatment comparisons over all countries are considered valid and reliable.

Wider implications of the findings: Progesterone pessary, shown to be non-inferior to progesterone gel in regards to clinical pregnancy rates in this study, can be regarded as a reasonable alternative to current treatment options for LPS in ART cycles. Additional available options allow an increasing role for patient centered decision making in LPS.

Trial registration number: EudraCT number 2013-001105-81

O-119 Combination tocolytics on the inhibition of OT-induced contractions of human pregnant myometrium in vitro

L. Riaposova[1], S.H. Kim[1], O. Pohl[2], A. Chollet[2], J.P. Gotteland[2], A. Hanyaloglu[3], P. Bennett[1], V. Terzidou[1]

[1]Imperial College London, Surgery and Cancer - Parturition Research Group, London, United Kingdom
[2]ObsEva SA, Chemin des Aulx 12- CH-1228 Plan-les-Ouates, Geneva, Switzerland
[3]Imperial College London, Surgery and Cancer - GPCR Research Group, London, United Kingdom

Study question: Can OBE002, a novel FP receptor antagonist, which inhibits $PGF_{2\alpha}$- and OT-induced myometrial contractions enhance inhibitory effects of existing tocolytics on OT-induced myometrial contractions in-vitro?

Summary answer: The combination of OBE002 with existing tocolytics, atosiban and nifedipine, enhanced their inhibitory effect on OT-induced contractility.

What is known already: Preterm labour (PTL) is a major cause of neonatal morbidity and mortality. Currently, management of PTL aims to reduce uterine contractions. Since most tocolytics have been developed specifically for the inhibition of uterine contractions, tocolytics are not uterospecific and thus have dose-dependent multi-organ side effects. It is suggested that combined use of tocolytics with drugs interfering with different signaling pathways lead to additive inhibitory effects allowing lower doses with reduced side effects and increased efficacy.

Study design, size, duration: The inhibitory effects of OBE002 in combination with either atosiban or nifedipine, in OT-induced myometrial contractions, were investigated in human pregnant myometrial strips For each combination tocolytics experiment, six non-labouring human myometrial biopsies were used from six different patients undergoing elective caesarean section at term. All experiments were performed within 24 hours from tissue collection to ensure myometrial viability and optimal contractility performance.

Participants/materials, setting, methods: Myometrial strips from the same patient were mounted on a DMT Myograph 800 MS. Regular baseline contractions were recorded for 20 mins prior to treatment with OBE002 at 60 and 600 nM alone or with atosiban or nifedipine (6 nM) and effects on spontaneous contractility was measured in the next 10 min. The effect of the tocolytics upon OT stimulation was measured with increasing OT concentrations (1, 10, and 100 nM) at 10 min intervals.

Main results and the role of chance: Atosiban reduced OT-induced myometrial contractility at 6 nM and this effect was enhanced in a dose-dependent manner when combined with OBE002 (p < 0.01 vs Ato 6 nM, ANOVA). Concurrent administration of OBE002 and atosiban, at maximum concentration of 600 nM, reduced the contractility to basal level. Nifedipine and OBE002 alone inhibited the OT-induced contractions, and their inhibitory effects were increased further when the two drugs were used together. The combination of OBE002 and nifedipine was more effective than OBE002 alone (p < 0.01 OBE002 60 nM vs Nif+OBE002 60 nM, ANOVA).

Limitations, reasons for caution: Synergistic effects of OBE002 and atosiban/nifedipine were observed but further dose-response treatments could strengthen our findings. This study was carried out using term, non-labouring samples, but preterm or labouring samples will be useful to be examined in the future.

Wider implications of the findings: Targeting the FP receptors with OBE002 in combination with the existing tocolytics may therefore be a more effective strategy for preventing or delaying preterm delivery.

Trial registration number: N/A.

O-120 Melatonin in assisted reproductive technology: the MIART trial - A pilot double-blind randomised placebo-controlled clinical trial

S. Fernando[1,2], E. Wallace[3,4], L. Rombauts[3,5]

[1]The Ritchie Centre, Obstetrics and Gynecology, Clayton, Australia
[2]Hudson Instituite of Medical Research, Obstetrics and Gynaecology, Clayton, Australia
[3]The Ritchie Centre, Obstetrics and Gynaecology, Clayton, Australia
[4]Hudson Institute of Medical Research, Obstetrics and Gynaecology, Clayton, Australia
[5]Monash IVF, Monash IVF, Clayton, Australia

Study question: Does oral melatonin, when given during ovarian stimulation, improve clinical pregnancy rate after IVF?

Summary answer: When given at the doses tested, melatonin does not improve clinical pregnancy rate after ART.

What is known already: Melatonin is a potent oxygen scavenger and for this reason, it is thought to protect the oocyte and embryo from oxidative damage during the ART process. Previous uncontrolled and non-randomised studies have indicated that melatonin may improve ART outcomes, including the total number and quality of oocytes and embryos as well as pregnancy rate. Based on this, melatonin is currently used by many infertility specialists as an adjunct to ovarian stimulation with the intention of improving IVF success rates.

Study design, size, duration: A pilot double-blind, dose-finding, randomised placebo-controlled clinical trial of 160 women recruited between September 2014 and September 2016.

Participants/materials, setting, methods: Women undergoing their first cycle of IVF or ICSI were randomised to receive one of four different regimes of trial medication (placebo, n = 40; melatonin 2 mg, n = 41; melatonin 4 mg, n = 39; melatonin 8 mg, n = 40) twice per day from Day 2 of their cycle until the night before oocyte retrieval. Primary outcome was clinical pregnancy rate (presence of a live intrauterine fetus at 7-week ultrasound). Secondary outcome measures included oocyte number and maturity and embryo number and quality.

Main results and the role of chance: Compared with placebo, the geometric mean concentrations for melatonin in the highest dose group (8 mg bd) on the day of oocyte retrieval were 2-fold (P < 0.03) and 8-fold (P < 0.001) higher in serum and follicular fluid respectively. Despite these significant changes in serum and follicular fluid concentrations, there was no statistically significant difference in clinical pregnancy rates between the four groups. There were no

statistically significant differences between the groups in total oocyte number, number of MII oocytes or number of fertilised oocytes or in the number or quality of embryos between the groups. There was also no difference in the number of utilised embryos. When comparing placebo with any dose of melatonin, there were no statistically significant differences in the median number of embryos (3.5 vs 3.0, p = 0.85) or good quality embryos (1.5 vs 2.0, p = 0.76). Compared with placebo, when taking any dose of melatonin, there was also no significant difference in cancelled cycle rate (19.3% vs 5.6%, OR 4.07, 95% CI 0.91–18.22, p = 0.07) or clinical pregnancy rate (22.8% vs 16.7%, OR 1.48 95% CI 0.56–3.94, p = 0.43). Miscarriage rate did not differ between groups.

Limitations, reasons for caution: The sample size of this pilot study may be insufficient to detect small differences in clinical pregnancy rate. Because we recruited women with an expected good ovarian response, we cannot conclude that melatonin has no effect on success rates in women with poor ovarian reserve or poor oocyte quality.

Wider implications of the findings: The lack of effect at any dose seen in our study suggests that the use of melatonin with the intention of improving ART success rates should be discontinued until high quality evidence demonstrates its efficacy in other patient populations.

Trial registration number: ACTRN12613001317785.

O-121   Testosterone treatment in women with poor ovarian repsonse: fertility and live birth rates

G. Mskhalaya[1], E. Eltsova[2], M. Malysheva[3], V. Zaletova[4], S. Kalinchenko[5], Y. Tishova[6]

[1]Center for Reproductive Medicine MAMA, Moscow, Russia C.I.S.
[2]Center for Reproductive Medicine MAMA, Andrology and Endocrinology, Moscow, Russia C.I.S.
[3]Center for Reproductive Medicine MAMA, Gynecology, Moscow, Russia C.I.S.
[4]Center for Reproductive Medicine MAM, Gynecology, Moscow, Russia C.I.S.
[5]People's Friendship University of Russia, Endocrinology, Moscow, Russia C.I.S.
[6]People's Friendship University of Russia, Endocrinology, Moscow, Russia C.I.S.

Study question: The main question was to evaluate the efficacy of testosterone treatment before controlled ovarian stimulation (COS) on clinical pregnancy and live birth rate in poor responders undergoing IVF

Summary answer: Testosterone undecanoate treatment may increase pregnancy and live birth rate women with diminished ovarian response undergoing IVF.

What is known already: Many different technologies are used to improve pregnancy and live birth rates in poor responders, but none of them showed any statistically significant increase in these parameters, except androgen treatment. Testosterone treatment showed possible increase in pregnancy rate in women with poor ovarian response.

Study design, size, duration: 149 women with poor ovarian response, defined according to ESHRE consensus/the Bologna criteria of low ovarian response were included. Patients were randomly divided into 2 groups: Testosterone undecanoate (TU) treatment group (98 women) or control group (51 women). For TU group Testosterone undecanoate oral form 40 mg was given daily for at least 40 days (median 54 days) preceding COS for IVF.

Participants/materials, setting, methods: Primary outcome measures were clinical pregnancy (PR) and live birth (LR) rates in different age groups. Statistical research was made using a software package statistics (StatSoft Inc. U.S., version 12). Quantitative data is presented as median and quartile range. When comparing the quantitative data of two independent groups Mann Whitney U-test and Fisher exact two-tailed test were used. Values were considered statistically significant if p less than 0.05

Main results and the role of chance: There were no differences in patients' characteristics between the two groups. There was no significant difference in starting FSH dose or total dose of gonadotropins administered between the groups. There was a significant increase in number of oocytes retrieved 2 [1; 3] vs 1 [1;2] in TU group (p = 0.04). Clinical pregnancy rate (per cycle) was significantly higher in TU group (24.5%) than in control group (7.8%), p = 0.015. Live birth rate was higher in TU group than in control group 17.3% vs 5.9%, respectively, though the difference was not statistically significant (p = 0.07).

The treatment and control groups were divided into 2 subgroups each according to age: 1 subgroup less than 40 years old and 2 subgroup – 40 years

and older. There was a significant increase in clinical pregnancy and live birth rate in TU 1 subgroup (less than 40 years old) compared to the control 1 subgroup: 38% vs 8.7% (p < 0.001) and 29.3% vs 6.5% (p < 0.01), respectively. There was no difference neither in clinical pregnancy nor in live birth rate between TU and control 2 subgroups.

Limitations, reasons for caution: no placebo control

Wider implications of the findings: This is the first study using oral testosterone undecanoate as a possible substance for treatment women with poor ovarian response. The effect observed in women less than 40 years is much higher, women 40 years and older, they may need more prolonged pretreatment with TU for better success rate.

O-122   Quantifying the parameters affecting the success of egg donor program: A predictive model and optimization tool

M. Calonge[1], N. Garrido[2], A. Cobo[3], F. Gonzalez-Valdes[4], D. Morbeck[5], A. Requena[6], C. Troncoso[7]

[1]IVI Santiago, IVF Laboratory, Santiago, Chile
[2]IVI Valencia, Andrology Laboratory and Sperm Bank, Valencia, Spain
[3]IVI Valencia, IVF Laboratory, Valencia, Spain
[4]Pontificia Universidad Catolica de Chile, Engineering, Santiago, Chile
[5]Mayo Clinic, IVF Laboratory, Rochester, U.S.A.
[6]IVI Madrid, Gynecology, Madrid, Spain
[7]IVI Santiago, Gynecology, Santiago, Chile

Study question: Which donor/ recipient parameters are relevant to predict blastocyst formation, implantation and live birth rate in an egg donor program with fresh and vitrified oocytes?

Summary answer: The predictive model included six factors: donor and recipient age, donor's estradiol (E2) at trigger, oocyte retrieval number, oocyte source and morphological embryo category.

What is known already: Currently there are predictive models that analyze clinical and embryo parameters to predict clinical outcomes after IVF, e.g. risk of multiple pregnancies. However, there are no reports of models to determine the optimal number of oocytes needed for successful egg donation with fresh and vitrified oocytes, which is definite by blastocyst formation, implantation and live birth rate. Moreover, survival rates in vitrified oocytes aren´t 100%. Additionally, vitrified oocytes yield less blastocyst formation than cycles using fresh donor oocytes. Thus, the number of vitrified oocytes needed in an oocyte donation cycle is likely higher than a fresh donor cycle.

Study design, size, duration: We performed a retrospective observational study in ovum donation program. The study group is composed by all patients who attended Spain and Portugal IVI Clinics to carry out assisted reproduction treatment with egg donation The data analysis was performed between 2013 and 2015. The study includes 20.551 cycles of oocyte donation. A total number of 263.124 oocytes were analyzed, an amount of 135.253 were fresh and 127.871 were vitrified.

Participants/materials, setting, methods: Econometric modelling was applied to build a model capable of providing an estimate for the appropriate number of oocytes needed in a recipient cycle. The dependent variables were discrete (e.g. vitrified/ fresh) and continuous (e.g. estradiol levels); on continuous variables optimal levels are also calculated. When possible, we used multinomial logit models and otherwise we used generalized lineal models representing a binomial process with a logit link function. Variable significance was analyzed through a t-test.

Main results and the role of chance: With the data analysis, 6 important parameters were determined for development of the model; donor and recipient age, donor's estradiol (E2) at trigger, oocyte retrieval donor number, oocyte source (fresh and vitrified) and morphological embryo category.

According to our data, implantation rate and live birth do not show difference related with oocyte origin when we transferred the same quality blastocyst, but blastocyst formation was less in vitrified oocytes compared to fresh. Using the model, we may calculate the additional number of vitrified oocytes cycles needed to obtain the same number of blastocyst formation. That number varies depending on the clinical characteristics, donors and patients cycle parameters considered by the model.

The impact of oocyte vitrification is illustrated by the following example: while keeping other parameters constant, 8 fresh versus 10 vitrified oocytes are required to obtain the same number of blastocyst. Moreover, when we transfer 1 blastocyst classified with A quality, probability of implantation was 60% and probability of life birth was 48% at age of 40 years old, both independent of oocyte origin. This model allows a user to enter data to calculate the probability of blastocyst formation, implantation and live birth based on number of oocytes.

Limitations, reasons for caution: Not all factors that impact success of IVF were included. In addition, the correlations identified may vary in different populations or countries.

Wider implications of the findings: A predictive model capable of estimating the probability of implantation and live birth would be extremely helpful to improve outcomes and assist clinicians deciding how many oocytes are needed in oocyte donation programs, according to the odds to get a blastocyst and live birth for each mature oocyte.

Trial registration number: 1607-SCL-062-MC

O-123 Perinatal outcomes following gestational surrogacy versus autologous IVF: analysis of 87,815 singleton live births

S.K. Sunkara[1], B. Antonisamy[2], M.S. Kamath[3]

[1]Queen's Hospital, Assisted Conception Unit, Essex, United Kingdom
[2]Christian Medical College, Department of Biostatistics, Vellore, India
[3]Christian Medical College, Reproductive Medicine Unit, Vellore, India

Study question: Does gestational surrogacy affect perinatal outcomes of preterm birth (PTB) and low birth weight (LBW) compared to autologous IVF treatment?

Summary answer: The present study did not demonstrate significant differences in the risks of PTB and LBW between gestational surrogacy and autologous IVF.

What is known already: Gestational surrogacy is when a woman carries and gives birth to a child through IVF for another individual or couple who are the intended parent/s. Since the first birth following gestational surrogacy in 1985, there has been an increasing trend in IVF-surrogacy. However, little information is available regarding obstetric or infant outcomes following surrogacy. There is a higher risk of pregnancy complications following ART compared to spontaneously conceived pregnancies and recent literature has shown oocyte donation pregnancies to be associated with higher risk of adverse obstetric and perinatal outcomes. It is a matter of interest if surrogacy influences perinatal outcomes.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of assisted reproduction treatment (ART) in the UK. The HFEA has collected data prospectively on all ART performed in the UK since 1991. Data from 1996 to 2011 involving a total of 87,815 singleton live births (244 following IVF-surrogacy cycles and 87,571 following stimulated fresh autologous IVF ± ICSI cycles) were analysed.

Participants/materials, setting, methods: Data from all women who underwent IVF-surrogacy or fresh autologous IVF cycles during the study period were analysed to compare perinatal outcomes (PTB, early PTB, LBW, very LBW) following singleton live births. Occurrence of live birth at <37 weeks gestation is defined as PTB and at <32 weeks gestation as early PTB. Birth weight <2500 grams is defined as LBW and <1500 grams as very LBW. Logistic regression analysis was performed adjusting for potential confounders.

Main results and the role of chance: The unadjusted odds were OR 0.89, 95% CI 0.56 to 1.41 for PTB, OR 0.23, 95% CI 0.03 to 1.67 for early PTB, OR 0.87, 95% CI 0.55 to 1.38 for LBW and OR 0.45, 95% CI 0.11 to 1.81 very LBW. After adjusting for potential confounders such as female age category, year of treatment, number of previous IVF cycles, previous live births (yes or

no), cause of infertility (male factor, tubal disease, ovulatory disorder, endometriosis, unexplained, cervical factors), number of embryos transferred and initial singleton or multiple pregnancies that lead to singleton live births, there was no significant increase in the risk of adverse perinatal outcomes following surrogacy: PTB (adjusted odds ratio (a OR) 0.90, 95% CI 0.56 to 1.42), early PTB (a OR 0.23, 95% CI 0.03 to 1.68), LBW (a OR 0.90, 95% CI 0.57 to 1.43) and very LBW (a OR 0. 0.46, 95% CI 0.11 to 1.87).

Limitations, reasons for caution: Although the analysis was adjusted for a number of important confounders, the dataset had no information on confounders such as body mass index and medical history of women during pregnancy to allow adjustment. Given the relatively smaller number of events with IVF-surrogacy cycles, the results need validation by further studies.

Wider implications of the findings: The demonstration that gestational surrogacy is not associated with a significantly higher risk of PTB and LBW compared to autologous IVF provides assurance towards its current expanding application.

Trial registration number: Not applicable.

O-124 Shared motherhood: high delivery rates in a large series of egg donation treatments for lesbian couples using partner-donated eggs

D. Bodri, S. Nair, A. Gill, G. Lamanna, M. Rahmati, M. Arian-Schad, V. Smith, E. Linara, J. Wang, K. Ahuja

London Women's Clinic, Assisted Reproduction, London, United Kingdom

Study question: What are the patient characteristics and overall clinical outcome of a large series of lesbian couples undergoing ROPA (Reception of Oocytes from PArtner) treatment?

Summary answer: For lesbian couples wishing to share biological motherhood ROPA is a highly successful and safe treatment with reassuring obstetrical and perinatal outcome.

What is known already: After its first presentation in the reproductive literature in 2010 (Marina et al, 2010) and following an extensive ethical debate (Dondorp et al, 2010; De Wert et al, 2014) ROPA treatment has become increasingly accepted among ART practitioners and patients. It is currently an established treatment in several European countries (Spain, UK and Belgium, for example) for lesbian couples wishing to share their biological motherhood. Despite this, there is only limited data - a case-series of merely 14 couples - on the overall efficiency of ROPA treatment.

Study design, size, duration: All consecutive lesbian couples (n = 120) having ROPA treatment in a single private HFEA-regulated centre between 2011 and 2016 were included in this retrospective analysis. All fresh and frozen-thawed embryo transfers were followed-up until they achieved live birth (in addition to 19 currently ongoing pregnancies) or until the patients stopped further treatment. In 36% of unsuccessful and 70% of successful patients unused surplus embryos remain in storage.

Participants/materials, setting, methods: 120 lesbian couples underwent 133 treatment cycles (120 first, 10 second and 3 third attempts). There were no significant differences between donors and recipients in age (32.5 ± 4.1 vs 33.4 ± 4.9, p = 0.12) or ovarian reserve markers AMH and AFC; however, recipients were more parous than donors (0.8% vs 15%, p < 0.0001). Most (75%) donors were ≤35 years of age (range: 20–42 years). Recipients received an artificial endometrial preparation with oral oestrogens and vaginal progesterone synchronised with their donor.

Main results and the role of chance: Donors were mostly (82%) stimulated with a GnRH antagonist protocol and triggered with a GnRH agonist yielding an average 11.9 ± 7.1 eggs per cycle (range: 1–34). No moderate/severe OHSS cases were recorded among the oocyte donors. The fertilisation rates per retrieved eggs using donor sperm through IVF (79%) or ICSI (21%) were 66 ± 20% resulting in 7.6 ± 5 fertilised eggs per cycle. Embryos were cultured to blastocyst and cleavage stages in 68% and 31% of cycles, respectively. One treatment cycle (0.8%) was cancelled due to arrested embryo development. In 13 (10%) non-synchronised cycles all embryos were electively frozen. One-hundred-nineteen fresh and 44 frozen-thawed embryo transfers were performed with the replacement of an average 1.4 ± 0.5 embryos mostly (74%) at the blastocyst-stage. The single embryo transfer rate was 60% (98/163). For

the 120 recipient patients the cumulative live birth / ongoing pregnancy rate recorded was at 60%, resulting in 53 live births and 19 ongoing pregnancies (for those conceived in the latter half of 2016). Twinning rate was at 12% (9/72). For singletons premature delivery rate (between 32–36 weeks) and low birth weight (<2.500 g.) rate was 12 % and 13%, respectively. The oldest oocyte donor achieving a live birth was 40 years of age.

Limitations, reasons for caution: No live birth or perinatal data is as yet available for pregnancies conceived in the second half of 2016. Although this series is substantial, it was not large enough to perform a multivariate analysis to determine potential prognostic factors influencing treatment outcome.

Wider implications of the findings: Shared motherhood is the preferred form of ART treatment amongst many lesbian couples. Increasingly the autonomy of ROPA patients is being respected even though complex IVF treatment is performed for (mostly) non-medical indications. To this end, OHSS-free ovarian stimulation with single-blastocyst-transfer provides a uniquely safe and highly efficient treatment modality.

Trial registration number: n/a.

O-125   Oocyte donation in women cured from cancer provide similar live birth rates compared to women without previous history of cancer

M. Zanette[1], D. García[2], R. Vassena[1], A. Rodríguez[1]

[1]Clínica EUGIN, EUGIN, Barcelona, Spain
[2]Fundación EUGIN, EUGIN, Barcelona, Spain

Study question: What are the reproductive outcomes of women cured from cancer undergoing oocyte donation (OD)?

Summary answer: Live birth rate in women treated and cured of cancer following OD is 29.8%.

What is known already: About 5.4% of women worldwide will have cancer by the age of 50. Improvements in oncologic treatments have increased both their long-term survival and quality life; unfortunately, treatments such as chemotherapy (CT) and radiotherapy (RT) can impair fertility by uterine damage and/or diminishing the ovarian reserve in reproductive age women. At present, majority of cancer survivors who wish to become parents will undergo ART, in particular OD. Due to the limited number of the studies available, the current literature provides inconsistent results about reproductive outcomes for these women.

Study design, size, duration: Retrospective cohort study including 172 women cured from cancer, which underwent OD treatment between 2006 and 2015. We describe the reproductive outcomes of their first OD treatment performed at our clinic.

Participants/materials, setting, methods: The study included 172 patients, treated and cured from cancer by one or more of 4 oncological treatments (CT, RT, surgery, bone marrow transplant). All patients started ART after 5 years of follow-up from cancer and with authorization and declaration of cancer-free from their oncologists. All patients were analyzed for common demographic parameters and for reproductive outcomes.

Main results and the role of chance: The average age at OD cycle was 37.2 ± 6.2, all patients were of BMI between 18–25. The majority (166; 96.5%) were Caucasians; 46 were treated for Hodgkin lymphoma (3 also having thyroid, breast cancer or leukemia), 40 lymphoblastic leukemia, 21 borderline ovary cancer, 20 breast cancer, 15 no Hodgkin lymphoma, 7 colon-rectal cancer, 5 bone cancer (1 with ovarian borderline cancer), 4 thyroid cancer, 4 urinary system cancer, 10 others. The majority of patients (64.5%) were given a mixed therapy: 73.3% QT, 51.2% RT, surgery 41.9%, bone marrow transplant 39%. Time between being disease-free and ART was 10.7 years on average. Iatrogenic menopause affected 104 (60.5%) women. In 147 (85.4%) cycles, oocytes were fertilized with partner sperm. ET was performed on day 2-3 in 160 cases (93%). Single ET was performed in 30 (17.4%) cycles, 2 embryos were transferred in 141 (82%) and 3 embryos were transferred once (0.6%). Overall, clinical pregnancy rate as 40.1%, ongoing pregnancy rate 31.4%, and live birth rate 29.8%. When comparing patients who received a bone marrow transplant or not, the differences in reproductive outcomes were not statistically significant (clinical pregnancy: 43.6% vs. 39.1%, ongoing pregnancy 33.3% vs. 30.8%, and live birth 30.1% vs. 28.4%; p>0.05).

Limitations, reasons for caution: The main limitation of this study is its retrospective design, and the fact that patients were recruited along a period of 10 years. During this time, both oncological and ART treatments have undergo significant changes, possibly affecting the generalizability of the presented results.

Wider implications of the findings: According to our results, OD treatments in patients cured of cancer provide satisfactory results, with a live birth rate that is comparable to that reported for women that did not suffer from cancer. Physicians should discuss this option with patients cured of cancer in the context of reproductive counseling.

Trial registration number: NA.

O-126   Impact of the number of retrieved oocytes on cumulative live birthrates after repeated cycles of assisted reproductive technology – A Danish national cohort study

S.S. Malchau[1], A.A. Henningsen[2], A. Loft[3], J. Forman[4], A. Nyboe Andersen[5], A. Pinborg[6]

[1]Copenhagen University Hospital Hvidovre, Dept. of Obstetrics and Gynecology, Hvidovre, Denmark
[2]Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark
[3]Copenhagen University Hospital Rigshospitalet., Fertility Clinic, Copenhagen, Denmark
[4]University of Copenhagen, Dept. of Public Health- Section of Biostatistics, Copenhagen, Denmark
[5]Copenhagen University Hospital Rigshospitalet, Fertility Clinic-, Copenhagen, Denmark
[6]Copenhagen University Hospital Hvidovre, Dept. of Obstetrics and Gynecology-, Hvidovre, Denmark

Study question: Is the number of aspirated oocytes in the first assisted reproductive technology (ART) cycle associated with the cumulative live birthrates (CLBR) in subsequent cycles?

Summary answer: An increasing number of aspirated oocytes was associated with higher CLBR, and lower risk of discontinuing treatment. Initial treatment-response predicts outcome in subsequent cycles.

What is known already: Previous reports have shown a positive association between the number of retrieved oocytes and live birthrate per fresh treatment cycle. This has also been shown for the CLBR in one complete ART-cycle. One complete cycle is defined as one fresh ART-treatment including possible subsequent frozen-thawed transfers (FER). However, it has not been studied whether the number of oocytes in the initial cycle predicts live birthrates in subsequent fresh/complete cycles. Based on HFEA-data, women with 13 oocytes had increased CLBR compared with women with 5 oocytes, but only 40% of the women had more than one fresh cycle.

Study design, size, duration: The Danish National IVF-registry includes all ART treatments in public and private clinics since 1994. Treatment-cycles were cross-linked with the Medical Birth Registry, identifying treatment-related births and spontaneous conception (SC) births. This national cohort study includes all women starting ART treatments with homologous eggs between 2002 and 2011, N = 30,486. Subjects were followed for up to three fresh ART-cycles including subsequent FER-cycles (= three complete cycles), until the first livebirth, or until December 2011.

Participants/materials, setting, methods: The CLBR within 1–3 complete ART-cycles were calculated as the proportion of women with a livebirth, out of all women initiating ART-treatment, including drop-outs (no livebirth or continued treatment within follow-up). The number of retrieved oocytes in the first treatment-cycle was categorized in four groups: 0–3, 4–9, 10–15 and >15. In women with complete follow-up, multivariate logistic regression analysis assessed impact of retrieved oocytes on CLBR, adjusting results for female age and cause of infertility.

Main results and the role of chance: The mean female age at first treatment was 33.1(SD±4.7) years. After one, two and three complete cycles, the observed CLBR after ART-conception was 26.0% [95%CI 25.5–26.5], 40.7% [40.2–41.3], and 48.1% [47.5–48.6], respectively. The CLBR after SC was 4.7% [4.4–4.9], 7.2% [7.0–7.5] and 8.9% [8.6–9.3] after one, two and three complete

cycles. The drop-out rate was 19.9% within three cycles, whereas 15.8% had additional treatments. The CLBR within three cycles, stratified by initial treatment-response were: 0–3 oocytes: 30.5% [29.0–31.9], 4–9 oocytes: 47.0% [46.0–48.0], 10–15 oocytes: 55.8% [54.5–57.2], >15 oocytes: 58.0% [55.8–60.1]. Compared with women with 4–9 oocytes in the first cycle, the adjusted odds ratios (AOR) for livebirth within three complete cycles were 0.5 [0.5–0.6] with 0–3 oocytes, 1.3 [1.2–1.4] with 10–15 oocytes and 1.5 [1.3–1.7] with >15 oocytes. Compared with women with 4–9 oocytes in the first cycle, AOR of livebirth in the 2nd and 3rd cycle were 0.8 [0.8–0.9] with 0–3 oocytes, 1.2 [1.1–1.3] with 10–15 oocytes and 1.4 [1.2–1.6] with >15 oocytes. The risk of discontinuing treatment decreased with increasing number of oocytes. Compared to women with 4–9 oocytes, the AOR for dropping out was 1.7 [1.6–1.9] with 0–3 oocytes, and 0.8 [0.7–0.9] with 10–15 or >15 oocytes.

Limitations, reasons for caution: Although mandatory, there may be treatment-cycles not registered in the IVF-registry.

Wider implications of the findings: The results emphasizes that the ovarian response to stimulation is an important prognostic factor, irrespective of age, for infertile couples entering ART-programs where the success is often based on repetitive cycles and combinations of both fresh and frozen thawed embryo replacements.

Trial registration number: The study was approved by the Danish Data Protection Agency (J.nr. 2012-41-1330).

O-127 Subcutaneous progesterone for endometrial preparation in substituted cycles for oocyte donation recipients: a randomized controlled trial

J. Llacer[1], E.M. Garcia-Hernandez[2], B. Moliner[1], L. Luque[1], J. Ten[1], R. Bernabeu[1]

[1]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain
[2]Instituto Bernabeu, Molecular Biology, Alicante, Spain

Study question: Is there any difference in clinical outcomes between using aqueous formulation of subcutaneous progesterone (SP) or micronized vaginal progesterone (VP) in substituted cycle for fresh embryo transfer in oocyte recipients?

Summary answer: No differences were found between groups in terms of ongoing pregnancy rate at 12 weeks of gestation

What is known already: Luteal phase support has been shown to improve pregnancy rates in women undergoing IVF. Two phase III randomized controlled trials and the subsequent meta-analysis found no differences in clinical outcomes using SP or vaginal progesterone for luteal support in IVF patients after fresh embryo transfers. Another study showed the efficacy of SP for inducing the transformation of the endometrium in substituted cycles. However, to date, clinical outcomes using SP for endometrial preparation have not been studied

Study design, size, duration: Single centre, blinded for the investigator, controlled, prospective, randomized, pilot trial. Over 18 months, 120 oocyte recipients were randomized on the day of egg retrieval of the donor based on a computer-generated randomization list to receive 25 mg daily SP or 200 mg tid daily VP.

Participants/materials, setting, methods: Patients included fulfilled medical and legal criteria for oocyte donation and followed the standard preparation protocol using transdermal estradiol. Randomization took place the day of the oocyte retrieval from the donor and in all the cases the embryo transfer was performed at the blastocyst stage. For the statisical analysis, t-test or anova test were used for continuos variables and Fisher test for categorical variables

Main results and the role of chance: Both groups were homogeneous in terms of age (40.2 years SP; 40.0 years VP p = 0.784), BMI (23.9 Kg/m² SP; 22.8 Kg/m² VP p = 0.074) and duration of infertility (3.8 years SP; 3.1 years VP p = 0.127).

Ongoing pregnancy rate at 12 weeks of gestation was 33.3% in the SP group and 50.0% in the VP group this difference was no significant (p = 0.086). Positive pregnancy test was similar between the groups, 66.07% SP and 64.81 VP (p=1.000). However, we found significant differences in clinical pregnancy rates (36.84% SP; 59.26% VP p = 0.022), implantation rates (32.46% SP; 53.71 VP p = 0.017) and biochemical pregnancy per embryo transfer (26.32% SP; 5.56% VP p = 0.004).

No differences were found in progesterone levels neither the day of the pregnancy test (6.66 ng/ml SP; 9.62 ng/ml VP p = 0.111), at 6 weeks of gestation (21.90 ng/ml SP; 12.98 ng/ml VP p = 0.138) or at 12 weeks of pregnancy (30.85 ng/ml SP; 25.47 ng/ml VP p = 0.387). However, lower levels of progesterone were found in the SP group at the moment of the embryo transfer (5.09 ng/ml SP; 9.59 ng/ml VP p = 0.004).

Limitations, reasons for caution: This is a pilot study and the sample size was not calculated

Wider implications of the findings: Despite ongoing pregnancy rate was not different in the group treated with subcutaneous progesterone biochemical miscarriage was higher so additional studies are needed to demonstrate its utility in substituted cycles.

O-128 Label-free phosphoproteomics reveals a novel calcium signaling pathway activated via kappa-opioid receptor in human spermatozoa

I. Urizar-Arenaza[1], N. Osinalde[2], M. Gianzo[3], R. Matorras[4], A. Exposito[5], J. Irazusta[1], N. Subiran[1], I. Kratchmarova[6]

[3]Unversity of the Basque Country UPV/EHU, Department of Physiology, Leioa, Spain
[4]Cruces University Hospital, Department of Assisted Reproduction, Bilbao, Spain
[5]Cruces University Hospital, Department of Assited Reproduction, Bilbao, Spain
[6]University of Southern Denmark, Department of Biochemistry and Molecular Biology, Odense, Denmark

Study question: Do the signaling pathways underlying G-protein coupled receptors in human spermatozoa differ from those found in somatic cells?

Summary answer: Phosphoproteomic approaches describe a different calcium signaling pathway underlying kappa-opioid receptor (KOR) which lasts in the inhibition of the acrosome reaction in human spermatozoa.

What is known already: The G-protein coupled receptors (GPCR) perceive different molecules from the extracellular environment, activate a broad variety of signaling pathways to finally last in cellular responses and they are the best therapeutic targets for the development of drugs. Some years ago the presence of different GPCRs in human sperm cells was described suggesting that they could participate in the modulation of the sperm fertilizing capacity. Taking into account that human spermatozoa are unable to transcribe and translate proteins, the study of signaling pathways underlying GPCR would be essential to identify different targets which seem to be unique in these cells.

Study design, size, duration: We studied KOR as GPCR model in order to analyze the signaling pathways that differ from the somatic cells. To understand the beginning of the pathway, we stimulated the receptor with U50488, a specific KOR agonist, and phosphorylated proteins were analyzed by LC-MS/MS. Acrosome Reaction was measured by flow cytometry. We used 60 human normozoospermic seminal samples from the Cruces University Hospital, to carry out both phosphoproteomic and functional studies.

Participants/materials, setting, methods: The samples were isolated and capacitated by *swim up*. The control samples were untreated and the rest were stimulated with U50488 for 1 and 60 minutes. To study the beginning of the signaling pathway, the 1 minute treatment samples were divided in 4 biological replicas, processed and analyzed by Q Exactive Mass spectrometer and MaxQuant Software v1.3.0.5. After the 60 minute treatment, the acrosome reaction was conducted by Flow cytometry using the anti-CD46 antibody.

Main results and the role of chance: The phosphoproteomic study shows a decrease in the phosphorylation of four protein targets related to the calcium signaling pathway, after 1 minute of U50488 treatment. Among these potential proteins, CABYR is a Calcium-binding tyrosine phosphorylation-regulated protein, SPANX is a sperm protein associated with the nucleus on X chromosome, PGRMC2 is the Membrane-associated progesterone receptor component 2 and the FAM71B protein, is directly related to the CatSper sperm specific calcium channel. At the same time, CABYR and SPANX, are two testis specific proteins whose expression is limited to the testis and spermatozoa. These results highlights the fact that the U50488 stimulates a novel calcium signalling pathway which differs from those found in somatic cells supporting the idea that GPCR present unique features in their molecular mechanisms. Moreover, this finding could describe the first steps of the signalling pathways activated via the kappa-opioid receptor and which last in an inhibition of the acrosome reaction at one hour, as the functional studies confirm. This outcome is consistent with the idea that the GPCR, participate in the regulation of the acquistion of the fertile capacity in human sperm via cell specific molecular mechanism.

Limitations, reasons for caution: We need further studies to analyze more in deep the molecular mechanisms by which these 4 proteins participate in the inhibition of the acrosome reaction in human spermatozoa.

Wider implications of the findings: A better understanding of the molecular mechanisms that are involved in the physiology of the spermatozoid and differ from the somatic cells could be very helpful to grasp the aetiology of many cases of infertility and to develop new therapeutic targets and strategies.

Trial registration number: CEISH/61/2011.

O-129　Reproductive outcomes of testicular versus ejaculated sperm for intracytoplasmic sperm injection among men with high levels of sperm DNA fragmentation: systematic review and meta-analysis

S. Esteves[1], M. Roque[2], N. Garrido[3]

[1]ANDROFERT, Center for Male Reproduction, Campinas, Brazil
[2]ORIGEN, Center for Reproductive Medicine, Rio de Janeiro, Brazil
[3]IVI Foundation, Andrology, Valencia, Spain

Study question: To assess outcomes of intracytoplasmic sperm injection (ICSI) using testicular compared with ejaculated sperm in men with high sperm DNA fragmentation.

Summary answer: The existing evidence supports the use of testicular sperm in preference over ejaculated sperm for ICSI in men with high sperm DNA fragmentation (SDF).

What is known already: Recent studies have suggested potential benefits of using testicular versus ejaculated sperm for ICSI among couples with repeated ICSI failure. Oxidative-induced SDF during epididymis transit has been postulated to lower ejaculate sperm quality that may negatively impact ICSI outcomes. However, the evidence is not unequivocal, and some studies have found no benefit of testicular versus ejaculated sperm among men with cryptozoospermia. Therefore, we sought to assess the available evidence concerning outcomes of ICSI using testicular versus ejaculated sperm among infertile men with a strong rationale for using testicular sperm, namely, those with confirmed post-testicular sperm DNA fragmentation.

Study design, size, duration: We conducted a systematic search using PubMed, Scielo, and Google Scholar to identify all relevant studies published until December 2016. The search combined terms related to "sperm DNA fragmentation", "sperm DNA damage", "sperm chromatin integrity OR damage", "testicular sperm", "ejaculate", "intracytoplasmic sperm injection", with the filters "human" in any language. For the advanced search, article types selected were: clinical study, comparative study, journal article, meta-analysis, observational study, randomized controlled trial, review, and systematic review.

Participants/materials, setting, methods: Participants were couples undergoing ICSI with the use of ejaculated sperm (Eja-ICSI) or testicular sperm (Testi-ICSI) whose male partners had normo-/oligozoospermia and high SDF. Studies that included men with unexamined SDF were excluded. Subgroup analysis included the comparison among SDF testing methods. The levels of SDF in ejaculated and testicular sperm and live birth rates (LBR) were the primary

outcomes. The secondary outcomes were clinical pregnancy rates (CPR), miscarriage rates, and fertilization rates.

Main results and the role of chance: Our electronic search retrieved 112 articles. After screening titles and abstracts, 11 articles were deemed eligible for full-text evaluation. Among these, we excluded four articles with reasons and included seven studies, involving 507 cycles and 3,840 injected oocytes, for qualitative and quantitative analysis. SDF rates were lower in testicular than in ejaculated sperm (Mean difference [MD] -24.58% [95% CI -32.53%,-16.64%, $P < 0.001$). The live birth rates per embryo transfer were higher when testicular sperm were used for ICSI compared with ejaculated sperm (Odds ratio [OR] 2.35 [95% CI 1.40–3.94; $P < 0.001$). Fertilization rates were not different between the two sperm sources, but the Testi-ICSI group had a trend to lower fertilization rates (OR 0.82 [95% CI 0.58–1.16]. Pooled results showed that CPRs were higher when testicular rather than ejaculated sperm was used for ICSI (OR 2.27 [95% CI 1.48–3.49; $P < 0.001$) whereas miscarriage rates were reduced with the former (OR 0.34 [95% CI 0.15–0.77; $P = 0.01$). Overall, heterogeneity was low but for SDF levels between testicular and ejaculated sperm. Subgroup analysis based on SDF method reduced heterogeneity estimates. Sensitivity analyses did not affect the overall effect size of pooled estimates.

Limitations, reasons for caution: Not all risk factors such as participant age, use of medication, and smoking, which might have affected SDF rates and ICSI outcomes were consistently reported. All included studies were observational. Another limitation refers to the quality of included studies, which also varied.

Wider implications of the findings: Pooled results from evaluated studies suggest that testicular sperm is preferred over ejaculated sperm for ICSI among men with high levels of SDF in the semen. The full clinical implications of using Testi-ICSI for men with high SDF deserves further investigation using randomized controlled trials.

Trial registration number: NA.

O-130　Topographic mapping of sperm chromatin fragmentation within the male reproductive tract and associated reproductive outcomes

A. Melnick, N. Pereira, S. Chow, A. Parrella, S. Cheung, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: To assess sperm chromatin fragmentation (SCF) of sperm isolated from various levels of the male reproductive tract and how it affects reproductive outcomes.

Summary answer: There is an increase in SCF from the testes to the ejaculate, suggesting progressively increasing oxidative stressors through the male reproductive tract.

What is known already: The integrity of DNA in sperm has important fertility-related implications. During the later stages of spermiogenesis, breakage of a sizable amount of single- or double-stranded DNA occurs to allow tight chromatin compaction. Much of this DNA breakage is repaired, although reactive oxygen species (ROS) within the male reproductive tract can cause additional damage. While seminal anti-bodies can protect against damage by ROS in the ejaculate, DNA may still remain considerably fragmented. The topography mapping of SCF is particularly important in men with high SCF in ejaculates, where retrieving spermatozoa from the epididymis or testis may bypass such a chromatinic insult.

Study design, size, duration: Men with high SCF in their ejaculates underwent urologic evaluation and bilateral surgical sampling from vas deferens, epididymis, and testis. SCF of the ejaculated and surgically retrieved sperm samples was assessed by the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay. Clinical outcomes for men undergoing ICSI treatment was recorded and stratified by the sperm source.

Participants/materials, setting, methods: Ejaculated samples were processed in standard fashion for SCF assessment with TUNEL. Surgical samples were minced and prepared for TUNEL, after which they were cryopreserved; these samples were thawed at a later date for ICSI treatment. SCF was measured by TUNEL on specimens isolated from all surgical sites. A commercially available

kit was used for SCF assessment and at least 500 spermatozoa were counted per site under fluorescent microscopy with an adopted threshold of 15%.

Main results and the role of chance: Of the original 86 patients, 73 were treated by ART with an average SCF of 30.8 ± 18.4% (range 7.7–96.0). In 10 men aspiration of the vas deferens resulted in 16.4 ± 8% SCF (range 5.8–30.0) while in 44 men epididymal sampling yielded 15.8 ± 6.8% SCF (range 5.3–34.8) and in 83 the SCF on testicular spermatozoa was 11.3 ± 5.2% (range 2.0–27.0). The SCF progressively decreased as TUNEL was performed proximally from the ejaculate toward the vas deferens ($P = 0.05$), the epididymis ($P = 0.01$), and testis ($P = 0.01$). ART outcome with ICSI utilizing these surgical sources yielded a clinical pregnancy of 29.8%, while with the ejaculated counterpart only 16%. Based on these preliminary findings, a subgroup of patients (n = 19) with SCF of 40.1 ± 18% bypassed the prerequisite cycle with ejaculated spermatozoa. By opting to directly undergo TESE with ICSI, a clinical pregnancy rate of 36.0% per cycle was achieved that translated to 62% per couple treated.

Limitations, reasons for caution: Surgical sampling of the vas deferens, epididymis, and testis in men with high SCF in their ejaculates should only be performed after extensive and individualized counseling. Moreover, such an approach is preliminary and requires further evidence, given that some men may not achieve a pregnancy even with surgically retrieved sperm.

Wider implications of the findings: The topographic mapping of SCF evidenced that oxidative stressors progressively compromise DNA integrity toward the ejaculate. Thus, men with high SCF in their ejaculates who are unable to achieve a pregnancy may benefit from undergoing surgical retrieval of sperm for diagnostic and therapeutic purposes.

Trial registration number: Not applicable.

O-131   ORP: a reliable and reproducible method of evaluating oxidative stress - a multicenter study

A. Agarwal[1], A. Mohamed[2], E. Haitham[2], M. Ahmad[2], S. Alsaid[2]

[1]The Cleveland Clinic Foundation, American Center for Reproductive Medicine-Department of Urology- Cleveland Clinic, Cleveland- Ohio, U.S.A.
[2]Hamad General Hospital, Urology Department, Doha, Qatar

Study question: To investigate the reproducibility and reliability of ORP measurement as an indicator for semen quality across different fertility centers.

Summary answer: ORP is a reproducible and reliable method to differentiate fertile from infertile semen samples.

What is known already: Seminal oxidative stress (OS) is well reported to affect male fertility status. The discrepancy in the measurement of OS has hindered its clinical use as a quality indicator for semen. Few studies measured reactive oxygen species alone while others measured only reductants leading to lack of standardization of results. Oxidation reduction potential (ORP) is a better representative for OS as it provides an overall measure of the activity of both oxidants and reductants. Very recently, ORP assessment by MiOXSYS has been introduced as a measure of OS with high specificity in differentiating fertile from infertile semen samples.

Study design, size, duration: This is a multicenter retrospective study comparing data from semen analysis and ORP measurement between two andrology laboratories in two different demographic areas (USA and Qatar) over a period of 1 year (2015 – 2016).

Participants/materials, setting, methods: The same protocol was followed by both laboratories. Semen analysis was performed according to WHO, Fifth Edition. ORP was measured using MiOXSYS. Each data set contains infertile patients' group and normal fertile donors group. Data was analyzed separately from each laboratory. The data from both laboratories was then combined and analyzed. To compare between two groups a Student's t-test was used. Receiver operator characteristic (ROC) analyses were used to determine cutoff values for sORP.

Main results and the role of chance: The first data set from USA contains 194 patients and 51 fertile donors, while the second data set from Qatar contains 400 patients and 50 fertile donors. In both data sets and in combined data, infertile group had significantly lower sperm concentration, total and progressive motility and normal morphology as well as higher ORP level when compared to fertile men (P < 0.05).

When comparing data from both centers, the infertile group showed significant difference between both data sets regarding progressive motility and morphology (P < 0.001). Also, the percentage of patients with abnormal semen

volume, sperm count, total and progressive motility were significantly different between both data sets (P < 0.05). sORP level showed no significant difference between both data sets (P < 0.08)

ROC analysis indicated that sORP cut-off value of 1.42 mV/10^6/mL in USA group and in Doha group can accurately differentiate fertile from infertile semen groups. When combining both data together the cut-off value for sORP was again found to be 1.42 mV/10^6/mL.

Limitations, reasons for caution: The retrospective design of the study. However all data was available and both centers followed the same protocol.

Wider implications of the findings: Although other semen parameters showed significant differences between the two centers, sORP remained consistent in both data sets individually or in combined data. This proves its reproducibility and reliability. sORP is a measure of semen quality which adds more weight to semen testing in identifying fertile from infertile semen samples.

Trial registration number: N/A.

O-132   Four-dimensional analysis of sperm flagellar waveform as an extension for CASA

M. Muschol[1], C. Wenders[1], D.F. Babcock[2], G. Wennemuth[1]

[1]University Clinic, Anatomy, Essen, Germany
[2]University of Washington, Physiology and Biophysics, Seattle, U.S.A.

Study question: Analysis of sperm movement in 4D in order to gather information about trajectories, chiralities, rolling and beating pattern for understanding the journey to the oocyte.

Summary answer: 4D analysis of sperm movement revealed a wide variety of swimming behaviors used as an answer to environmental circumstances on the oocytal track.

What is known already: Most past studies were only able to draw on 2D methods like CASA (computer assisted sperm analysis) to investigate swimming behavior and flagellar waveform of sperm. In general, they used projections onto the XY plane provided by conventional microscopic imaging in combination with stop-motion imaging. Previous results show that sperm with a linear trajectory rotate around their long axis at a time span correlated to beat frequency. A lack of rotating leads to a circular trajectory. Furthermore, flagellar excursions in the XY plane were described.

Study design, size, duration: Murine, bovine and human sperm were examined in 4D with reference to trajectories, chiralities, rolling behavior, beating pattern and flagellar waveform. A comparison was made between free swimming, adherent and circling sperm as well as a comparison between digital holographic microscopy (DHM) and CASA.

Participants/materials, setting, methods: Murine sperm from NMRI mice (Charles River Labs), bovine ejaculated sperm from a Holstein Friesian bull (HB-No 678525, Rinder-Union West eG) and human sperm from 5 healthy donors (collected under approved ethical protocols) were allowed to swim into physiological buffer at 37 °C. They were used for both, CASA and high speed digital holographic microscopy to record flagellar waveforms and sperm swimming paths in 4 dimensions.

Main results and the role of chance: DHM allows 4D tracking of the head of free-swimming sperm. With distinguishable left and right surfaces of the sperm head, we were able to monitor rolling of sperm around their long axis with correlating changes between left-face- and right-face-downmost configurations. DHM also allows 4D tracking of the flagellum. We were able to identify flagellar excursions into the Z plane as large as the excursions into the XY plane that are travelling down periodically the flagellum as sinusoid waves during each beat cycle. These waves correlate with rolling and beat frequency. The chirality of rolling is always alternating between clockwise and counterclockwise for a roll-counter-roll cycle. Without rolling, sperm obtain a circular trajectory with a planar movement revealed by DHM. Up to now, the current method to analyze sperm is CASA. We performed a comparative measurement between CASA and DHM to demonstrate the benefit of high speed holographic imaging as an extension to the 2D measurements.

Limitations, reasons for caution: Experiments were performed in vitro which means that not all in vivo questions could be answered.

Wider implications of the findings: Our findings will change the concept of sperm movement fundamentally: They indicate a chiral memory in form of a hypothetical elastic linkage within the flagellar machinery which stores torque of

a roll for the following counter-roll. Our CASA measurements demonstrate a powerful extension for CASA with clinical relevance.

Trial registration number: none.

O-133　Oxidation reduction potential and sperm DNA fragmentation levels in sperm morphologic anomalies

A. Majzoub[1], M. Arafa[1], H. Elbardisi[1], S. Al said[1], A. Agarwal[2], K. Al Rumaihi[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar
[2]Cleveland Clinic Foundation, Urology, Cleveland, U.S.A.

Study question: Is there a significant correlation between sperm morphology and structural anomalies and the measures of oxidative stress (OS) and sperm DNA fragmentation (SDF) in seminal plasma?

Summary answer: The degree of abnormality in sperm morphology and anatomic structure has a significant positive correlation with seminal OS and SDF measures.

What is known already: Controversy surrounds the significance of abnormal sperm morphology evaluated with routine semen analysis in predicting male fertility potential. Advanced sperm function assays are ancillary tests utilized to improve the diagnostic accuracy of semen parameters during male fertility evaluation. OS, the state of imbalance between oxidants and reductants, has been recognized to have detrimental effects on spermatogenesis through aggravating sperm apoptosis, lipid peroxidation and DNA fragmentation. Oxidation reduction potential (ORP) is a novel method that assesses the balance between oxidants and reductants, thereby reliably measuring OS in biologic samples.

Study design, size, duration: This is a cross sectional study of 1162 patients presenting to the male infertility unit of a tertiary medical center over a period of 12 months. After the collection of demographic and clinical data, patients were asked to provide a semen sample for analysis after ≥ 2 days of sexual abstinence.

Participants/materials, setting, methods: Semen samples were analyzed according to the 5th Edition WHO manual. Morphology was evaluated by a single experienced technician based on sperm stained using the Diff-Quik protocol. The percentage of abnormality in sperm head, neck or tail was recorded in each semen sample. SDF was tested using the sperm chromatin dispersion assay, while seminal ORP levels were assessed using the MiOXSYS system. Pearson's correlation was used to assess the relationship between study variables.

Main results and the role of chance: Patients mean age $\pm$ standard error of mean was 35.9 ± 0.2 years. Infertility was primary in 69.6% and secondary in 30.4% of patients. After a mean abstinence time of 3.7 ± 0.04 days, semen analysis results revealed a sperm concentration of 32.7 ± 0.78 million/ml, total motility of $50.1 \pm 0.57\%$ and normal morphology of $5.7 \pm 0.22\%$. Sperm with abnormal head, neck and tail were observed in $53.8 \pm 0.35\%$, $23.7 \pm 0.25\%$ and $17.1 \pm 0.24\%$ of patients, respectively. An inverse relationship existed between the percentage of normal sperm forms and measures of ORP and SDF (Table 1). A significant positive linear correlation existed only between the % of abnormal sperm heads and levels of ORP (r 0.34, CI 0.24 – 0.38, p < 0.001) and SDF (r 0.73, CI 0.49 – 0.96, p < 0.001).

Table 1 ORP and SDF levels in different %s of normal sperm forms.

	% normal sperm forms					
	0% (n = 56)	1% (n = 140)	2% (n = 181)	3% (n = 187)	≥ 4% (n = 598)	p value
ORP (mv/10⁶/ml)	13.12 ± 1.8	12.04 ± 1.2	7.3 ± 0.7	4.9 ± 0.5	1.9 ± 0.2	<0.001
SDF (%)	56 ± 8.2	38.5 ± 3.7	31.5 ± 2.7	26.5 ± 2.16	22.6 ± 1.04	<0.001

Limitations, reasons for caution: Results were obtained from semen samples of patients presenting with primary or secondary infertility and hence were not compared with a control group or with men of proven fertility

Wider implications of the findings: Studying the correlation between sperm morphology indices and advanced sperm function tests is important as this would help in resting the controversy surrounding its clinical implication on fertility potential. It may also provide insights for developing novel sperm selection techniques that can be utilized during assisted reproduction.

Trial registration number: Not applicable

O-134　What factors affect mental health in women with endometriosis? Towards the development of a comprehensive explanatory model

F. Facchin[1], G. Barbara[2], E. Saita[3], E. Somigliana[4], D. Dridi[4], D. Alberico[4], L. Buggio[4], P. Vercellini[4]

[1]Catholic University of Milan, Department of Psychology, Milano, Italy
[2]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Obstetrics and Gynecology and Service for Sexual and Domestic Violence SVSeD, Milan, Italy
[3]Catholic University of Milan, Department of Psychology, Milan, Italy
[4]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Obstetrics and Gynecology, Milan, Italy

Study question: What specific factors affect the mental health of women with endometriosis?

Summary answer: The psychological health of women with endometriosis can be affected by age, intimate relationship status, time from diagnosis, pelvic pain, and self-concept.

What is known already: Although it is well known that endometriosis as a chronic disease has a negative impact on mental health and quality of life, recent studies have shown that women's experience of endometriosis is characterized by remarkable variability in psychological outcomes. Such variability is partly explained by the presence of pelvic pain, which is associated with impaired mental health and whose severity can be influenced by personality. However, endometriosis is a multidimensional disease that involves a complex interaction of multiple variables (including individual characteristics such as self-concept) and further research is necessary to identify what specific factors may affect women's mental health.

Study design, size, duration: A total of 187 consecutive endometriosis patients were included in this cross-sectional study conducted between 2015 and 2017 at an Italian academic department of obstetrics and gynaecology located in Northern Italy.

Participants/materials, setting, methods: Participants were 187 endometriosis patients (mean age: 36.8 ± 7.1 years). Demographic and endometriosis-related information (i.e. surgical and hormonal treatment, pelvic pain severity [dysmenorrhea, dyspareunia, chronic pelvic pain, dyschezia], time from diagnosis) was collected. Self-concept was assessed using three validated measures evaluating self-esteem (Rosemberg Self-Esteem Scale), emotional self-efficacy (Emotional Self-Efficacy Scale), and body image (Body Esteem Scale). Mental health was assessed using the Hospital Anxiety and Depression Scale (HADS) and the Ruminative Response Scale (RRS).

Main results and the role of chance: A multivariable approach (i.e. hierarchical multiple regression) was used to examine the psychological impact of three sets of putative predictors identified on the basis of the extant literature: Set 1 – demographic factors (age and intimate relationship status); Set 2 – endometriosis-related factors (hormonal treatment; surgical interventions; current infertility; time from diagnosis; global pelvic pain severity); Set 3 – global self-concept (a single factor, derived from principal component analysis [KMO test = .64, Bartlett's test of sphericity = 91.65, ps < .001], summarizing the information of the three self-concept scales to avoid multicollinearity problems). Significance tests were performed at $P < .05$. A shorter time from

diagnosis was associated with greater anxiety (HADS-A: β = -.256; p = .001) and rumination (RRS: β = -.189; p = .014). Pelvic pain severity affected all psychological variables ($ps < .01$). Younger women displayed higher levels of depression (HADS-D: β = -.207; p = .003). Being in a stable relationship (coded 1 ['yes'] or 0 ['no']) was associated with decreased rumination (RRS: β = -.231; $p < .001$). Greater self-concept led to better psychological outcomes in all dependent variables ($ps < .001$).

Limitations, reasons for caution: A comprehensive model explaining how endometriosis can negatively affect mental health should test the impact of cultural differences, gender believes, and the quality of couple relationships. These variables were not included in our model and our sample was entirely composed of Caucasian women. These should be acknowledged as important limitations.

Wider implications of the findings: Although most endometriosis research focused on the role of pelvic pain, other factors should be considered to explain the psychological impact of the disease. Newly diagnosed younger women, especially with low self-esteem, may present higher levels of distress, which indicates the importance of timely psychological intervention aimed at empowering patients.

Trial registration number: Not applicable.

O-135 Endometriosis and women's sexual functioning: a systematic review of the available evidence

G. Barbara[1], F. Facchin[2], L. Buggio[1], M.P. Frattaruolo[1], N. Berlanda[1], P. Vercellini[3]

[1]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Obstetrics and Gynecology, Milan, Italy
[2]Catholic University, Department of Psychology, Milan, Italy
[3]University of Milan and Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Department of Women's and Children Health, Milan, Italy

Study question: What is the impact of endometriosis and its pharmacological and surgical treatments on female sexual functioning (FSF)?

Summary answer: Endometriosis has a negative impact on multiple domains of sexual functioning. Medical interventions can lead to medium-/long-term improvement, but not necessarily to a definitive resolution.

What is known already: Endometriosis is associated with an increased risk of dyspareunia, witch often coexists with other forms of sexual dysfunctions, such as hypoactive sexual desire, low lubrication and arousal, and orgasm disorders. This is often due to women's fear and anticipation of pain, which represents one of the most powerful inhibitor of the sexual response cycle. As endometriosis affects about 5–10% of women of reproductive age, a large proportion of young women in their most sexually active period of life could present sexual dysfunctions caused by the disease, which may interfere with physical and psychological quality of life and with conception.

Study design, size, duration: We conducted a systematic review of studies on the association between endometriosis and FSF. According to the PRISMA guidelines, we evaluated articles published between 2000 and 2016 on the correlation between: 1) the mere fact of having endometriosis and the presence of related female sexual dysfunctions; 2) the association between surgical and/or pharmacological treatments for endometriosis and related effects on FSF.

Participants/materials, setting, methods: Observational and retrospective studies on the impact of endometriosis and its treatments on FSF based on adequate description of participants, setting, medical intervention, and sexual outcomes were included. In order to investigate all aspects of FSF, we included only studies in which sexual outcomes were evaluated with a comprehensive sexual questionnaire, focusing not only on dyspareunia, but also on all the other aspects of FSF. Exclusion criteria were: qualitative research, case-report, commentaries or review articles

Main results and the role of chance: 31 studies were included in this systematic review and divided in 3 categories: no-intervention studies (n = 9), investigating the association between endometriosis and FSF; surgical intervention studies (n = 17), examining postoperative sexual outcomes of surgery for endometriosis; pharmacological intervention studies (n = 5), evaluating the effects of pharmacological endometriosis treatments on FSF. The clinical

scenario described by the "no-intervention studies" was that around 70% of women with endometriosis suffer from sexual dysfunction (pain at intercourse, low satisfaction, lack of desire, low arousal, orgasm difficulties), with a negative impact on women's psychological well-being and intimate relationships. The "surgical intervention studies" showed that surgery for endometriosis may lead to improved sexual functioning, although the extent and the length of these positive effects were often poorly defined. Most articles had an exclusive focus on deep infiltrating endometriosis and radical laparoscopic surgery. Although several studies considered a post-operative pharmacological adjuvant therapy, surgery and hormonal treatment were directly compared in one study only. The paucity of "pharmacological intervention studies" might seem surprising. However, almost all of this kind of studies focused exclusively on deep dyspareunia, without considering the global female sexual functioning. Overall, pharmacological treatment leads to a medium-long term amelioration of FSF.

Limitations, reasons for caution: The heterogeneity of population, instruments, and sexual outcomes considered in the different studies did not allow to pool data and accurately estimate the sexual effects of the different intervention programs for amelioration of FSF in women suffering from endometriosis.

Wider implications of the findings: Since FSF is a multidimensional phenomenon deriving from the interaction of multiple physical, psychosocial, and emotional factors, we think that the best treatment program for women affected by endometriosis related sexual dysfunctions can be provided by multidisciplinary teams composed of gynaecologists, sexologists, and psychotherapists.

Trial registration number: not applicable.

O-136 Endometriosis - How male partners experience sexuality

S. Haemmerli[1], A. Kohl Schwartz[2], D. Fink[3], P. Imesch[4], M. Wölfler[5], S. Von Orelli[6], B. Leeners[1]

[1]University Hospital Zurich, Reproductive Endocrinology, Zurich, Switzerland
[2]University Hospital Bern, Gnyecological Endocrinology and Reproductive Medicine, Bern, Switzerland
[3]University Hospital Zurich, Clinic for Gnyecology, Zurich, Switzerland
[4]University Hospital Zurich, Clinic for Gynecology, Zurich, Switzerland
[5]University Hospital Graz, Obstetrics and Gynecology, Graz, Austria
[6]Triemli Hospital Aachen, Obstetrics and Gynecology, Zurich, Switzerland

Study question: How do male partners experience sexuality in partnership with women suffering from endometriosis?

Summary answer: Partners of endometriosis patients are less satisfied with their sexual relationship and their sexual problems interfere with relationship happiness.

What is known already: Sexuality is strongly associated with wellbeing, partnership satisfaction and the long-term development of couples' relationship. Endometriosis-associated pain, dyspareunia and fatigue influence couples' sexuality, but little is known about the male perspective in affected couples.

Study design, size, duration: A multi-center case-control study was performed between 2010 and 2015 in Switzerland, Germany and Austria. 236 partners of endometriosis patients and 236 partners of age-matched control women without endometriosis with a similar ethnic background.

Participants/materials, setting, methods: Participants were asked to answer a modified form of the Brief Index on Sexual Functioning (BISF) and the Global Sexual Functioning (GSF) questionnaire. The questionnaire was analyzed with SPSS (IBM Corp. Released 2010. IBM SPSS Statistics for Windows, Version 22.0. Armonk, NY: IBM Corp).

Main results and the role of chance: Partners of endometriosis patients were less satisfied (p = 0.002) with their sexual relationship and their sexual problems interfered stronger with relationship happiness (p = 0.001) than in partners of control women. The wish for sexual activity (p = 0.387) and sexual desire (p = 0.919) was similar in both groups. Frequencies of sexual intercourse (p < 0.001) and other sexual activities were significantly higher in the control group.

Limitations, reasons for caution: Women asked their partners to participate in this study which might reflect a more satisfied study sample compared to the general population.

Wider implications of the findings: Symptoms of endometriosis are related to a reduced satisfaction with sexual relationships and the associated relationship happiness in male partners. Therefore, counselling should include potential effects of endometriosis on sexual activity and partners should be invited to participate in aiming to find solutions for a fulfilling sexual and partner relationship.

Trial registration number: NCT 02511626.

O-137   Determinants of patients' experiences with patient-centeredness in endometriosis care

A. Schreurs[1], W. Nelen[2], W. Kuchenbecker[3], P. Van de Ven[4], L. Van der Houwen[5], E. Dancet[6], S. Apers[6], C. Lambalk[5], V. Mijatovic[5]

[1]VU University Medical Centre Amsterdam, gynecology, Amsterdam, The Netherlands
[2]Radboud university medical center, gynecology, Nijmegen, The Netherlands
[3]Isala, gynecology, Zwolle, The Netherlands
[4]VU University Medical center, epidemiology and biostatistics, Amsterdam, The Netherlands
[5]VU University Medical center, gynecology, Amsterdam, The Netherlands
[6]University Hospitals Leuven, gynecology, Leuven, Belgium

Study question: Which demographic and medical characteristics of woman are associated with their assessment of patient-centeredness in endometriosis care?

Summary answer: A lower educational level, dyspareunia and membership of a patient-organization were found to be independently associated with patient-centeredness as experienced by women in endometriosis care.

What is known already: Patient-centered care (PCC) is one of the six dimensions of quality of care. Indeed, focusing on improving patients' experiences with patient-centered care is necessary to improve quality of care. The patient-centeredness of endometriosis care can be measured with the validated and reliable Endocare Questionnaire (ECQ), generating patient-centeredness scores (PCS). Those PCS can subsequently facilitate the development of care improvement projects. A previous study found that a lower educational level was correlated with a higher overall PCS in patients from solely two tertiary clinics.

Study design, size, duration: A cross-sectional study was conducted in surgically diagnosed patients with endometriosis. A total of 401 patients were eligible and received the ECQ in 2015 and 2016 and, if needed, two reminders were sent.

Participants/materials, setting, methods: All patients were selected from a Dutch tertiary and a Dutch secondary clinic. All 401 patients underwent endometriosis surgery between 2013 and 2014. Univariate and multivariate regression analyses with a forward elimination procedure were conducted to identify variables associated with PCC.

Main results and the role of chance: The overall response rate was 56.9%. In total, data from 209 patients was eligible for analysis. Univariate analyses showed 'educational level', 'membership of a patient organization', 'child wish in the future', 'subfertility', 'dysmenorrhea', 'dyspareunia', 'chronic pelvic pain' and 'the degree of which disease is suppressed' as potential determinants of PCC (all p < 0.2). 'The degree of which disease is suppressed' was excluded from multivariate analysis due to the low response rate (n = 90).

After adjustment for clinic, multivariate analysis showed a lower educational level (B=0.551, p = 0.027), presence of dyspareunia (B=0.790, p = 0.001) and a being member of a patient organization (B=1,670, p < 0.001) to be independently associated with higher overall PCS (R^2=0.21).

Limitations, reasons for caution: Since endometriosis is a chronic disease and care is very dynamic, one cross-sectional study will not comprehend the possible change in patients' experiences to its fullest. A larger sample size would be valuable for identifying determinants of the overall PCS.

Wider implications of the findings: The afore-mentioned determinants of PCC are of value for studies benchmarking clinics for their patient-centeredness. In addition, they help clinicians to determine how to tailor their care to their individual patients.

Trial registration number: not applicable.

O-138   Reproductive outcome in severe endometriosis in different age groups with abnormal intra-follicular markers: A prospective observational study in IVF cycles

S. Sharma[1], S. Bathwal[1], A. Singh[2], R. Chattopadhyay[1], S.K. Goswami[1], S. Ghosh[1], I. Saha[1], B. Chakravarty[1]

[1]Institute of Reproductive Medicine, ART, Kolkata, India
[2]Indian Institute of Technology- Kharagpur, School of Medical Science and Technology, Kharagpur, India

Study question: Does severe endometriosis in younger age with abnormal cytokines affect reproductive outcome in women undergoing in- vitro fertilization (IVF)?

Summary answer: Younger women with severe endometriosis had similar reproductive outcome as tubal factor infertility irrespective of lower oocyte/ embryo yield and abnormal intra-follicular cytokines/angiogenic factors.

What is known already: Endometriosis, a chronic inflammatory state, can impair reproductive outcome for reasons incompletely known. Women with endometriosis have high levels of macrophages, pro-inflammatory cytokines and angiogenic factors in peritoneal fluid when compared to fertile controls. It is also reported that altered intra-follicular cytokines and angiogenic factors (interleukin-8, interleukin-12, adrenomedullin) may adversely affect the oocyte and embryo quality. A recent systematic review and meta-analysis suggested that severe endometriosis is associated with low IVF success. Various studies have suggested that this is due to both diminished number and quality of oocytes.

Study design, size, duration: This prospective observational study included 652 infertile women who underwent IVF at a tertiary infertility centre during the period January 2012 to December 2015. Subjects were divided into two groups- study group/group A (n = 294) consisted of women with severe endometriosis (ASRM stage III/IV) and control group/group B (n = 358) had women with tubal factor as sole cause of infertility. All subjects belonged to age group of 25–40 years.

Participants/materials, setting, methods: Follicular fluid samples were collected during oocyte retrieval. ELISA was used to measure cytokines and angiogenic factors. The groups were sub-stratified based on age (group A:A1 (<35), A2(≥35) and group B:B1(<35), B2(≥35)). Number of Metaphase II oocytes, grade I/II embryos, pregnancy rate and miscarriage rate per number of pregnancies were compared. Significance of differences were evaluated by Chi-square test and multivariate analysis was applied for follicular fluid markers and its relation to oocyte and embryo quality.

Main results and the role of chance: Endometriosis group had a reduced pregnancy rate in comparison with tubal group (27.21% vs 34.08%, p < 0.06), though not statistically significant. Majority of the women in endometriosis group were <35 years (68%) compared to 57.3% in tubal group. Pregnancy and miscarriage rates were comparable between A1 and B1 [(31.84% vs 36.58%, NS) and (18.75% vs 16%, NS) respectively]. In contrast, when A2 was compared to B2, pregnancy rate was significantly lower in A2 (17.2% vs 30.7%, P < 0.02) but miscarriage rate was similar. A significant elevation of cytokines (IL-1β, TNF-α, IL-2, IL-4, IL-6, IL-8, IL-10, IL-12, IFN-γ) and angiogenic molecules (vascular endothelial growth factor, adrenomedullin, angiogenin) was found in endometriosis group compared to tubal group (P < 0.001). Number of Metaphase II oocytes and grade I/II embryos were significantly lower in group A1 versus B1 (6.63 ± 3.28 vs 7.66 ± 3.68; p < 0.003 and 3.38 ± 1.8 vs 4.02 ± 1.54; p < 0.001). Similar results were observed in group A2 versus B2 [Metaphase II oocytes (4.63 ± 2.33 vs 5.69 ± 1.39; p < 0.001) and grade I/II embryos (2.6 ± 1.28 vs 3.55 ± 0.98; p < 0.001)]. IL-8, IL-12 and adrenomedullin were identified as most important markers in follicular fluid that negatively affects oocyte and embryo quality (p < 0.001).

Limitations, reasons for caution: The present study does not necessarily impart evidence towards a direct correlation between elevated intra-follicular biomarkers and pregnancy outcome since more than one embryo is usually transferred per IVF cycle. A relatively smaller sample size of women with endometriosis ≥35 years perhaps reduces the potentiality of this observation.

Wider implications of the findings: In our study, women > 35 years with severe endometriosis have poorer IVF outcome compared to younger women.

Since the diagnosis of endometriosis is often late, earliest opportunity should be sought to reduce its adverse effect on reproductive outcome. This can be avoided by early resortment to ART and fertility preservation.

Trial registration number: Not applicable.

O-139   Endometriosis-related infertility: severe pelvic pain is associated with more severe disease

T. Thubert[1], P. Santulli[1], M.C. Lamau[1], L. Marcellin[1], M. Bourdon[1], C. Maignien[1], V. Gayet[1], K. Pocate-Cheriet[2], C. CHAPRON[1]

[1]Université Paris Descartes- Faculté de Médecine- Assistance Publique—Hôpitaux de Paris AP- HP- Paris- France, Service de Gynécologie Obstétrique II and Reproductive Médicine Professor Chapron-, Paris, France
[2]Université Paris Descartes- Faculté de Médecine- Assistance Publique—Hôpitaux de Paris AP- HP- Paris- France, Service d'Histologie-Embryologie-Biologie de la Reproduction, Paris, France

Study question: What is the significance of severe preoperative painful symptoms for patients presenting with endometriosis-related infertility?

Summary answer: In case of endometriosis-related infertility, severe pelvic pain is significantly associated with more severe endometriosis with deeply infiltrating lesions.

What is known already: Endometriosis is associated with infertility. In the setting of infertility the management of endometriosis is actually still debated. The extent of the disease plays an important role in the decision process between surgery or ART. The impact of painful symptoms in case of endometriosis related infertility is debated without reaching a consensus.

Study design, size, duration: This was an observational, cross-sectional study using data prospectively collected in all non-pregnant patients aged between 18 and 42 years, who were surgically explored for benign gynaecological conditions at our institution between January 2004 and December 2016. For each patient, a standardized questionnaire was completed during a face-to-face interview conducted by the surgeon during the month preceding surgery. Complete surgical excision of was performed for each patient.

Participants/materials, setting, methods: Surgery was performed in 1374 histologically proven endometriosis affected women. 505 women had endometriosis-related infertility. Of them, 167/505 patients had severe pain. Pain was considered as severe when visual analogue scale (VAS) was ≥ 7. Prospective preoperative assessment of type and severity of pain symptoms (VAS) was compared with preoperative and operative findings. Correlations were sought with univariate analysis to determine characteristics of infertile severe painful patients compared to non painful patients

Main results and the role of chance: Among infertile women suffering from endometriosis, patients who had severe pain had significantly more history of scholar absenteeism (60.2% vs. 15.6%, p < 0.001), more previous prescription of contraceptive pills because of severe primary dysmenorrhea (26.3% vs. 11.9%, p = 0.004) and more previous history of surgery for endometriosis (47.0% vs. 14.4%, p < 0.001) than infertile women without severe pelvic pain. Phenotype of endometriosis was significantly different between both group with higher rAFS total score in the painful group (39.2 ± 33.7 vs. 17.9 ± 24.5, p < 0.001). According to the surgical phenotype of endometriosis, infertile painful women had more frequently deeply infiltrating lesion than non painful women (57.9% vs 17.3%, p < 0.001). However, there was no more endometrioma in the painful group (16.6% vs 22.2%, p < 0.001). Deeply infiltrating lesion were more often localized in the intestine (64.8% vs 2.4%, p < 0.001) or in the vagina (48.5% vs 27.6%, p < 0.001) in the painful patients.

Limitations, reasons for caution: We cannot exclude that infertile women with a diminished ovarian reserve, as assessed during their infertility work-up, were referred less frequently to surgery and might therefore be underrepresented. In addition we cannot exclude that our group of women present other causes of infertility.

Wider implications of the findings: In case of severe pain, infertility among endometriosis women was significantly associated with deeply infiltrating lesions. In this situation, the practitioner should perform an appropriate preoperative imaging work-up in order to plan the correct strategy of patient management (surgery or assisted medical reproduction).

Abstract text

Study question: In 2013, what was: global utilization of ART as measured by number and type of cycles; effectiveness as measured by clinical pregnancy, miscarriage and live birth rates; safety as measured by multiple births and other complications, and; the status of extensive additions and revisions to the ICMART-WHO 2009 glossary?

Summary answer: Globally, ART utilization continues to increase but with wide variation in utilization, effectiveness and safety. Participation in data collection is gradually improving through regional as well as national registries. The International Glossary on Infertility and Fertility Care, a partnership effort led by ICMART, provides significantly enhanced standardization of concepts, processes, procedures, and clinical events for data collection and research essential for precise and harmonized global communication.

What is known already: ICMART began ART global data collection in 1991. Utilization, effectiveness and safety have continuously improved with more cycles, higher pregnancy rates and lower rates of multiple births. This last outcome has been coupled with a proportional increase in the number of frozen embryo transfer (FET) cycles; however, wide variations exist globally. Over 6.5 million ART babies have been born. ICMART has helped develop African registries in association with ANARA. Data collection and quality remain challenging. The 2009 glossary has been widely utilized.

Study design, size, duration: Countries and regions annually collect ART data, some prospectively and others retrospectively. ICMART retrospectively requested these data from all known global sources for 2013, analyzed them and presents preliminary results. The 2009 Glossary revision involved a 3-year interactive consultative and consensus process with subject experts, then reassessment over one year together with international and regional societies and patient representatives.

Participants/materials, setting, methods: The European IVF Monitoring Consortium (EIM), SART, Latin American Network of Assisted Reproduction (REDLARA), Australian/ New Zealand Registry, ANARA and other countries,

totaling approximately 60, contributed national data through standard ICMART forms. Data were reviewed, corrected, analyzed and summarized by ICMART working with the University of Uppsala, Sweden using standard statistical tests. ICMART led the glossary revision with experts and its society partners, ASRM, ESHRE, IFFS, March of Dimes, AFS, GIERAF, ASPIRE, MEFS, REDLARA, and FIGO.

Main results and the role of chance: Data collection and analysis are ongoing. Preliminary results are presented at ESHRE. The number of ART cycles continues to increase, but utilization is still very influenced by affordable access to ART which is related to insurance or public funding. Regional differences persist in the age of the population treated, number of embryos transferred, rate of multiple births, and other factors.

Additionally, the revised 2009 glossary, now named The International Glossary, has been expanded to 283 terms with definitions covering: Clinical terminologies, Outcome terminologies, Epidemiology and public health, Laboratory including andrology, and Embryology. Some 2009 definitions have been modified or expanded.

The role of chance is minimal.

Limitations, reasons for caution: Global ART results are limited to reporting countries and clinics representing approximately 2/3 of global cycles. Many countries have limited data validation and ICMART can perform only minimal verification of submitted data. The International Glossary definitions are based on a detailed and pre-determined consensus process that was sometimes challenging across many disciplines and different stakeholders.

Wider implications of the findings: It is accepted that measurement of human activities improves quality and outcomes. ICMART World Reports standardize data, track trends, enable comparisons, stimulate questions and improve ART quality in clinics, countries, regions and globally. Additionally, better understanding of ART increases societal acceptance and eventually creates broader support for ART research and clinical access. The International Glossary on Infertility and Fertility Care represents a unique global partnership outcome and provides a terminology platform that will harmonize clinical data reporting, research and communication.

O-142   The International Glossary on Infertility and Fertility Care: Led by ICMART in Partnership with ASRM, ESHRE, IFFS, March of Dimes, AFS, GIERAF, ASPIRE, MEFS, REDLARA, FIGO

Abstract text

Study question: To generate a consensus and evidence-driven set of terms and definitions to be used globally in order to ensure consistency when reporting on infertility issues and fertility care interventions, as well as to harmonize communication among the medical and scientific communities, policy-makers, and lay public including individuals and couples experiencing fertility problems.

Summary answer: A set of 283 consensus-based and evidence-driven terminologies used in infertility and fertility care has been generated through an inclusive consensus-based process with multiple stakeholders.

What is known already: In 2006 ICMART published a first glossary of 53 terms and definitions. In 2009 ICMART together with WHO published a revised version expanded to 87 terms, which defined infertility as a disease of the reproductive system, and increased standardization of fertility treatment terminology. Since 2009, limitations were identified in several areas and enhancements were suggested for the glossary, especially concerning male factor, demography, epidemiology and public health issues.

Study design, size, duration: Twenty-five professionals, from all parts of the world, representing their expertise in a variety of sub-specialties, were organized into five working groups: clinical definitions; outcome measurements; embryology laboratory; clinical and laboratory andrology; and epidemiology and public health. Assessment for revisions, as well as expansion on topics not covered by the previous glossary, were undertaken. A larger group of independent experts and representatives from collaborating organizations further discussed and assisted in refining all terms and definitions.

Participants, setting, methods: Members of the working groups and glossary coordinators interacted through electronic mail and face-to-face in international/ regional conferences. Two formal meetings were held in Geneva, Switzerland, with a final consensus meeting including independent experts, as well as observers and representatives of international/regional scientific and patient organizations.

Main results and the role of chance: A consensus-based and evidence-driven set of 283 terminologies used in infertility and fertility care was generated to harmonize communication among health professionals, scientists, and the lay public, patients and policy makers. Definitions such as "fertility care" and "fertility awareness" together with many other terminologies used in epidemiology and public health as well as in Embryology and andrology have been introduced in the glossary for the first time. Furthermore, the definition of "infertility" was expanded in order to cover a wider spectrum of conditions affecting the capacity of individuals and couples to reproduce. The core of the definition of Infertility remains as a disease characterized by the failure to establish a clinical pregnancy after 12 months of regular, unprotected sexual intercourse; however, it also acknowledge that the failure to become pregnant is not always the result of a disease, and therefore introduces the concept of an "impairment of a person's capacity to reproduce" which can lead to a disability as an impairment of function.

Limitations, reasons for caution: All stakeholders agreed to the vast majority of terminologies included in this glossary. In cases where disagreements were not resolved, the final decision was reached after a vote, defined before the meeting as consensus if passed with 75%. Over the following months an external expert group, which included representatives from non-governmental organizations, reviewed and provided final feedback on the glossary.

Wider implications of the findings: Some terminologies have different definitions, depending on the area of medicine, e.g. demographic or clinical as well as geographic differences. These differences were taken into account and this glossary represents a multinational effort to harmonize terminologies that should be used worldwide.

INVITED SESSION

SESSION 39: DNA REPAIR IN OOCYTES AS A KEY DETERMINANT OF REPRODUCTIVE FAILURE

| Tuesday 4 July 2017 | Room B | 11:45–12:45 |

O-143   Role of DNA Repair and BRCA Gene Function in Oocyte Aging and Reproduction

K.H. Oktay

New York Medical College, Division of Reproductive Medicine & Infertility- and Laboratory of Molecular Reproduction & Fertility Preservation, Valhalla- N.Y., U.S.A.

Abstract text

Emanating from our first observations of reduced ovarian reserve in women with BRCA mutations, we have previously shown that oocyte DNA DSB repair declines with age, resulting in increased accumulation of DNA DSB and increased oocyte apoptosis. Furthermore, ovarian aging was accelerated in BRCA1 mutant mice and the overexpression of BRCA1 in mouse oocytes rendered these oocytes more sensitive to genotoxic stress. Based on these revelations, we hypothesized that declining DNA DSB repair may be a fundamental mechanism in oocyte aging. Multiple recent prospective studies have now confirmed that the serum AMH levels are lower in BRCA mutation carriers compared to controls and those carriers may experience early menopause. Large GWAS studies also identified BRCA and DNA repair genes in general, among the most significant determinants of age at natural menopause. While the impact of BRCA mutations on fertility is unclear in younger women, these differences may have impact on fecundity in later reproductive years. Further, BRCA gene and DNA repair pathways may also be involved in the maintenance of meiotic spindle and hence any deterioration may have adverse consequences for oocyte quality. Because of the elimination of women with most severe BRCA dysfunction from the reproductive pool via risk reducing salpingo-oophorectomy or cancer-treatment-induced ovarian failure, the women who are available for most studies likely represent the tip of the iceberg. This also explains why some small and retrospective studies may not easily identify BRCA-mutation-related ovarian compromise. Given the strong concordance of laboratory and clinical studies and confirmation across numerous trials, BRCA-related DNA Repair and its dysfunction appears to be a critical component of oocyte aging.

O-144   Meiosis-quality assurances and their failures

R. Jessberger

Technische Universität Dresden, Medical Faculty Carl Gustav Carus, Dresden, Germany

Abstract text
Meiosis – Quality Assurances and Their Failures

The faithful transmission of genetic information between generations is essential for human health. Safeguarding mechanisms act at various stages of gem cell development, including in female and male meiosis. Yet, the quality assurance processes that ought to ensure proper meiotic chromosome structure and dynamics are not error-free. In meiotic prophase I the completion of repair of programmed DNA double-strand breaks and the proper synapsis of homologous chromosomes are monitored. Spermatocytes that fail in these processes are efficiently eliminated through an X/Y chromosome-based mechanism, which is lacking in oocytes. The dictyate stage at the end of prophase I in which oocyte remain arrested for a very long period poses a particular challenge to chromosomal integrity. The well-known increase in aneuploidy with increasing age of oocytes poses the most severe problem to faithful inheritance. In recent years, the gradual loss of cohesin, the protein complex responsible for sister chromatid cohesion, was found in a number of mouse models to prominently contribute to loss of chiasmata in metaphase I and to dissociation of sister chromatids in metaphase II. The role of cohesin and its decay, as well as the potential impact of cohesin regulatory factors during oocyte ageing will be discussed.

INVITED SESSION

SESSION 40: PROGESTERONE SUPPORT - EXAMINING THE EVIDENCE

Tuesday 4 July 2017   Room W+X   11:45–12:45

O-145   Progesterone support in ART

P. Humaidan

The Fertility Clinic - Skive Regional Hospital Faculty of Health- Aarhus Universi, Skive, Denmark

Abstract text

The luteal phase of all stimulated IVF/ICSI cycles is abnormal. The main reason for the luteal phase defect (LPD) is the multi-follicular development achieved during ovarian stimulation, leading to supra-physiological levels of steroids (progesterone and estradiol) secreted by a high number of corpora lutea during the early luteal phase, which directly inhibit the release of LH from the pituitary via feedback actions at the hypothalamic-pituary axis level. This reduction in circulating endogenous LH has a detrimental effect on the early-mid luteal phase, as LH plays a crucial role for the steroidogenic activity of the corpus luteum in terms of progesterone production. Thus, luteal phase support with progesterone remains mandatory in fresh transfer cycles after ovarian stimulation for IVF/ICSI treatment. Moreover, with the introduction of new embryo culture systems and in particular vitrification of supernumerary embryos, the live birth rate after frozen-thaw embryo transfer is now similar to, and in many cases superior to that of fresh embryo transfer. This has created a paradigm shift in stimulation policies, in which GnRHa is used for ovulation trigger, followed by segmentation and subsequent transfer in either an HRT frozen-thaw cycle or a natural cycle. For scheduling purposes many centers favor the HRT cycle. Although, poorly defined, until recently a "standard" luteal phase progesterone support was considered sufficient for all patients undergoing fresh as well as frozen-thaw embryo transfer; however, recent scientific evidence questions this policy. During the last decade personalization - or individualization became the "mantra" of ovarian stimulation, and the concept subsequently moved on to the choice of ovulation trigger. Indeed, near future suggests personalization of the luteal phase support as well. This will demand monitoring of the mid-luteal phase in terms of serum progesterone, as the mid-luteal progesterone level seems to play a pivotal role for reproductive success in ART.

O-146   Progesterone in early pregnancy

Y. Cheong

University of Southampton Academic Unit of Human Health and Development, Faculty of Medicine Consultant in Obstetrics and Gynaecology Subspecialist in Reproductive Medicine and Surgery, Southampton, United Kingdom

Abstract text

Much scientific progress has been made since progesterone was first isolated in 1930 s from the corpus luteum. We now know that progesterone is a 21-carbon atoms sex steroid, as opposed to androgens (19-cardon atoms) and estrogens (18-carbon atoms). Progestogen is a class of steroid hormones, which binds to, and activates the progesterone receptor and includes the natural hormone progesterone and synthetic forms (progestin). Progesterone and progestin are structural but not functional analogues. Progesterone is produced from cholesterol and acts as precursors to all other endogenous steroids including androgen, oestrogen, glucocorticoid, mineralocorticoid and neurosteroid. Hence, whilst progesterone is central to many aspects of reproduction through nuclear and extra-nuclear receptor mechanisms, it is also crucial in many non-reproductive processes on bones, central nervous system and metabolism.

In early pregnancy, progesterone is produced by the corpus luteum until the placenta takes over at around the 7th week of gestation. A defective luteal phase, where there is insufficient progesterone exposure to maintain a normal secretary endometrium to facilitate normal embryo implantation and growth has long been proposed as a possible cause of subfertility and miscarriage. However, until now, there is yet no consensus on the diagnosis of this condition. Clinical treatment strategies with progesterone supplementation to improve pregnancy outcomes face the conundrum of having to evaluate the treatment of a disease that cannot be accurately diagnosed. Results from studies on the supplement of progesterone to improve pregnancy outcomes remain conflicting. It is, however, clear that progesterone use during early pregnancy is non beneficial in women with unexplained recurrent miscarriage.

In assisted conception with ovarian stimulation, it is recognized that luteal phase support is required due to the presence of a dysfunctional luteal phase although the mechanisms behind this is still not completely clear. Studies have highlighted the presence of non-synchronized delay in endometrium development in approximately 25% of women undergoing assisted reproduction (IVF). Re-synchronisation of the implantation window, by way of personalized progesterone therapy, segmentation of luteal phase and/or realigning the circadian clock may be potential strategies to improve the outcomes of early pregnancy

SESSION 41: PARAMEDICAL SESSION - PLANNING A FAMILY

Tuesday 4 July 2017　　　　　　Room C　　　　　　11:45–12:45

O-147　Contraceptive counseling is a golden opportunity to talk about fertility and reproductive health

Y. Skogsdal[1], H. Fadl[2], J. Karlsson[3], Y. Cao[4], T. Tydén[5]

[1]Orebro University, Faculty of Medicine and Health, Orebro, Sweden
[2]Orebro University Hospital, Department of Obstetrics and Gynaecology, Orebro, Sweden
[3]Orebro University, University Health Care Research Center- Faculty of Medicine and Health, Orebro, Sweden
[4]4Clinical Epidemiology and Biostatistics, School of Medical Sciences, Örebro University

Unit of Biostatistics, Institute of Environmental Medicine, Karolinska Institutet
[5]Uppsala University, The Medical Faculty, Uppsala, Sweden

Study question: Can information about fertility and the use of a Reproductive Life Plan in contraceptive counseling increase women's knowledge about fertility and reproductive Health?

Summary answer: Information about fertility and factors affecting reproductive health was appreciated of the majority of women and increased their knowledge of fertility and reproductive Health.

What is known already: Traditionally counseling about contraceptive methods has emphasis on the efficacy and safety. Other aspects of reproductive health such as reproductive capacity are not routinely discussed and consequently women lack an important piece of information for their own understanding of fertility and reproductive health. The Center for Disease Control and prevention (CDC) recommends a tool called Reproductive Life Plan (RLP). It is a plan for having children or not and how to achieve these goals. Healthcare professionals should encourage their patients to consider an RLP, but few studies have evaluated the effectiveness of using the RLP in clinical settings.

Study design, size, duration: A randomized controlled trial was conducted between 2015 and 2016. Women (n = 6354), who attended 86 midwives at 28 clinics for contraceptive counseling, were assessed for eligibility. Main outcome measures were knowledge of fertility and reproductive Health.

Participants/materials, setting, methods: Participants (n = 1946) were randomly assigned to control group (CG, n = 970) or intervention group (IG, n = 976). Before the counseling they answered a baseline questionnaire. Both groups received standard counseling, and the IG also received the RLP-based intervention including questions on the RLP, oral information about fertility and reproductive health and a specially designed brochure about fertility. Two months later a questionnaire was mailed for follow-up.

Main results and the role of chance: The two groups were comparable regarding background factors. Women in the IG increased their knowledge significantly (p < 0.05) in all questions about fertility; age and fertility, chances of getting pregnant at time of ovulation, fecundity of an ovum and chances of having a child with help of IVF. The IG also increased their knowledge of factors impacting reproductive health such as stop using tobacco, to refrain from alcohol, to be of normal weight and to start with folic acid before a pregnancy.

Women in IG who did not plan any more children, used more long acting reversible contraception than women in CG, 56.5% vs. 44.6%. We found no difference between IG and CG at what age women wished to have their first (28 years) and last (34 years) child.

At baseline, 42 % planned to do lifestyle changes before a pregnancy. The corresponding figure after the intervention was 78 %.

We evaluated the experience of the intervention: 75 % had read the brochure, 60 % were very or fairly positive to the RLP discussion, 76 % felt that RLP discussion should be a routine during visits to the midwife or other health professional.

Limitations, reasons for caution: The follow-up was only two months. We have no information on whether the increased knowledge will turn into a behavioral change before a future pregnancy. The study included only Swedish-speaking women who were between 20 to 40 years old.

Wider implications of the findings: Most women appreciated the intervention and we therefore suggest that the RLP-concept with increased information about fertility can be used in contraceptive counseling. The screening question; Do you wish to have (more) children in the future turned out to be relevant in contraceptive counseling.

Trial registration number: ISRCTN 32759.

O-148　Hope for the best …. But prepare for the worst

S. Bailey[1,2], C. Bailey[3], Y. Cheong[4], E. Kitson-Reynolds[1], N.S. Macklon[5,6]

[1]University of Southampton, Health Sciences, Southampton, United Kingdom
[2]University Hospital Southampton NHS Foundation Trust, Research and Development, Southampton, United Kingdom
[3]University of Nottingham, Health Sciences, Nottingham, United Kingdom
[4]University of Southampton, Human Development and Health- Faculty of Medicine, Southampton, United Kingdom
[5]University of Southampton, Obstetrics and Gynaecology, Southampton, United Kingdom
[6]University of Copenhagen, Obstetrics and Gynaecology, Copenhagen, Denmark

Study question: How do women experience the waiting period (the first twelve weeks) of a new pregnancy following recurrent miscarriage?

Summary answer: Women prepare for the worst, fully expecting another miscarriage to occur. Extreme levels of anxiety are accompanied by feelings of guilt, loneliness and frustration.

What is known already: Recurrent miscarriage is an extremely distressing condition and can be both physically and emotionally traumatising. Studies investigating miscarriage and its effects on emotional morbidity indicate that increased levels of anxiety are often experienced by women with a history of reproductive loss during subsequent pregnancies and that the experience of recurrent miscarriage frequently results in a period of 'marked stress reaction' when the woman becomes pregnant again, whilst they wait for confirmation by ultrasound scan that their pregnancy is ongoing and viable. Some women will elect not to conceive at all rather than face this period of troubling uncertainty.

Study design, size, duration: A qualitative process evaluation employed semi-structured interviews to investigate women's subjective experiences of study methods and explored in-depth women's initial experience of pregnancy following repeated miscarriages. This was nested within a two-centre RCT feasibility study of a novel self-help intervention aimed at improving psychological well-being during the waiting period of a new pregnancy following recurrent miscarriage. Recruitment (n = 75 feasibility RCT, n = 14 qualitative component) took place over a two-year period.

Participants/materials, setting, methods: Participants were recruited from the Recurrent Miscarriage Clinics in two major hospitals in the United Kingdom. Participants were randomised and either received the intervention and weekly questionnaires to assess their psychological well-being up until twelve weeks of their new pregnancy, or simply completed the same weekly questionnaires. Study participants accepted an invitation to participate in semi-structured interviews. Qualitative data was analysed using a thematic network approach and data saturation was achieved after 14 interviews.

Main results and the role of chance: This abstract presents the findings from the qualitative component of the study. Thematic network analysis identified 6 main organising themes:

'Preparing for the worst'
Women reported that they 'prepare for the worst,' fully expecting a further miscarriage to occur. There is a reluctance to emotionally invest in their new pregnancy, taking one day at a time and avoiding looking forward to a successful pregnancy outcome.

Uncertainty and emotional turmoil
Women continually ruminate between the potential outcomes of their new pregnancy. Levels of anxiety and worry are extreme, affecting all aspects of their lives.

Checking for symptoms of ongoing pregnancy

This was often excessive and included compulsive checking for vaginal bleeding and monitoring of pregnancy symptoms. Fluctuating symptoms caused increased distress.

Social isolation and loneliness

Social isolation was seen as a method of controlling the potential threat of social interaction with other pregnant women.

Guilt

Participants reported a 'constant guilt'. They were to blame for their miscarriages and they were letting their partner and family down at their 'failure' to have a successful pregnancy.

Professional care

Women expressed the importance of supportive care and understanding health professionals. This made a positive difference to the negative emotions they were experiencing.

Limitations, reasons for caution: While every effort was made to support the recruitment of a diverse sample to the feasibility study, the UK setting may limit extrapolation to other national and cultural contexts. The purposive sampling strategy enabled an inclusive approach to data collection from the ethnicities represented in the main study sample.

Wider implications of the findings: This study investigated an issue which causes distress and anxiety to women affected by recurrent miscarriage. It adds valuable information to the body of evidence regarding the understanding of the initial experience of pregnancy following recurrent miscarriage and highlights the unmet needs of this vulnerable patient population.

Trial registration number: This study is registered with the ISCTRN registry. The registration number is: ISRCTN43571276.

O-149   Have we left family out of family planning?

B. Grace[1], **J. Shawe**[2], **J. Stephenson**[3]

[1]UCL Institute for Women's Health, Sexual and Reproductive Health, University College London Medical School Building- 74 Huntley Street- London WC1E 6 AU, United Kingdom

[2]School of Health Sciences, Faculty of Health & Medical Sciences, University of Surrey- Guildford- Surrey- GU2 7XH, United Kingdom

[3]UCL Institute for Women's Health, Sexual & Reproductive Health, University College London- Medical School Building- 74 Huntley Street- London WC1E 6 AU, United Kingdom

Study question: What are the current experiences of women and men of reproductive age and healthcare professionals regarding fertility and family planning education in the UK?

Summary answer: There is bias in reproductive health education towards preventing pregnancies. New terminology is needed to encourage more balanced messages encompassing planning to have a family.

What is known already: Although the term family planning implies planning to have a family, it is typically understood to mean birth control, use of contraception or prevention of pregnancy. According to Oxford dictionaries, family planning can be defined as 'the practice of controlling the number of children one has and the intervals between their births, particularly by means of contraception or voluntary sterilisation"[1]. There is currently no widely accepted equivalent terminology for planning to have children. In our study, we introduced the concept of 'family-building" as an alternative terminology for construction or formation of a family and investigated participants' experiences.

Study design, size, duration: We carried out 34 qualitative in-depth interviews with 13 women, 13 men and 8 healthcare professionals. Interviewees were purposively sampled to include men and women from the reproductive age range (18–45 years), ethnicity and education background. Interviews were conducted between October 2016 and January 2017.

Participants/materials, setting, methods: The study was a qualitative component of a wider mixed methods study. Participants were sampled from a UK cross-sectional survey on Fertility Awareness with 1080 participants who agreed to a follow-up interview. Survey participants were recruited nationwide via online newspaper and social media adverts. Healthcare professionals included doctors and nurses. Healthcare professionals were recruited from RCN, RCGP, RCP, doctors.org.uk. Data was transcribed and analysed via thematic analysis. Favourable ethical opinion was given by UCL.

Main results and the role of chance: Participants stated that the term'family planning' meant the avoidance of pregnancy but could not state similar terminology for planning a family. We introduced the concept of family-building to elicit views.

We found recurring themes towards postponement family-building for various socioeconomic reasons. However respondents reported little or no school education on preparation for family-building later in life. Topics such as age-related fertility decline and assisted reproductive therapy were not covered. There was no other source of formal education on family-building in the continuum until men and women were ready to start families, often with inaccurate expectations and fertility issues. Many would like family-building education in work-settings.

Interviewees were also unsure of how to access reliable information. Access e.g. GP appointment was reported as one of the main barriers to seeking information from healthcare professionals. Men reported that they were unlikely to visit walk-in family-planning clinics; and for women who find it easier, focus is on the use of contraception. Information on family-building was seldom provided.

Healthcare professionals were also more likely to view family-planning in the context of pregnancy-prevention. They highlighted knowledge gaps amongst patients and themselves but were uncertain about where the responsibility lies for improving education.

Limitations, reasons for caution: Although we gathered rich data, interviewees were self-selected and results principally reflect views of those who we willing to participate. Due to the online recruitment method, there is a bias towards more educated respondents with online access.

Wider implications of the findings: Emphasis on pregnancy-prevention means that relatively little attention's being drawn to issues associated with postponement of childbirth and impact of infertility. There remains an important need for advocacy to improve access to contraception as part of family-planning education, but should be balanced by messages about fertility, healthy pregnancy and family-building.

Trial registration number: Not applicable.

O-150   The organisation of patient recruitment in directly competing IVF studies to optimise recruitment rate and patient satisfaction

S. Wellstead[1], **J. Forbes**[1], **Y.C. Cheong**[2,3], **N.S. Macklon**[2,3]

[1]University Hospital Southampton NHS foundation Trust, Princess Anne Hospital Reproductive health research team, Southampton, United Kingdom

[2]University of Southampton, Unit of human development and health- faculty of medicine, Southampton, United Kingdom

[3]University Hospital Southampton NHS foundation Trust, Complete fertility centre-Department of Obstetrics and Gynaecology, Southampton, United Kingdom

Study question: How should recruitment to intervention studies be managed to optimise numbers and reduce conflict when competing trials have similar eligibility criteria?

Summary answer: Presenting patients with the study most appropriate for them when multiple complex IVF studies are being carried out in one unit, reduces patient disengagement.

What is known already: Research active fertility units often have more than one intervention study ongoing. The challenge is to ensure that all trials are recruited to successfully and within the target period. Failure to do so risks being unable to answer the research question, impacts on the reputation of the unit and has financial consequences for the researchers and sponsors. Previous studies report that placing the choice with patients can be overwhelming, and result in disengagement from research. The optimal strategy for addressing this issue remains unclear.

Study design, size, duration: This retrospective study over a three month period analysed the engagement of patients with the research team and recruitment rates, when more than three complex studies was discussed concurrently during the initial consultation with patients.

Participants/materials, setting, methods: Women referred to the research nurse by their clinician, were approached to discuss the studies in which they were eligible to participate. As the number of studies increased, a drop in recruitment was observed, we considered alternative approaches to disclosing all studies.

Main results and the role of chance: Having competing complex IVF studies had a negative impact on patient engagement with the research team. We examined strategies for managing competing studies when introducing them to patients, including 'disclosure of all trials' to all eligible patients, or randomly dividing the population and presenting them with only one study. As a team, we reflected on the ethical implications of withholding a study from a patient and the positive and negative impacts this could have on both the patient and the trial. This posed the dilemma of who is responsible for deciding which studies were offered to which patients. We therefore introduced a flow diagram for the research team. This clarified which studies patients were eligible for, and then the expected period of time until their treatment would commence. Patients were then approached and presented with the most appropriate study for them and their circumstances thus avoiding overwhelming them and hence patient disengagement. Following the implementation of this decision making model, engagement (defined by continued ongoing dialogue) with the research team improved greatly to 87.5% over the subsequent two months, compared to 69% before.

Limitations, reasons for caution: This was a retrospective observational study and was not powered for patient engagement before and after the decision making model was implemented.

Wider implications of the findings: The management of multiple studies within a limited population has a potentially significant impact on recruitment. Caution should be taken when interpreting the data but the concepts reported may be of assistance when multiple trials are competing for recruitment from one patient population.

Trial registration number: Not applicable

INVITED SESSION

SESSION 42: MHR SYMPOSIUM - TRANSGENERATIONAL PROGRAMMING VIA THE PATERNAL GENOME

Tuesday 4 July 2017　　　　　Plenary 2　　　　　14:00–15:00

O-151　High-dose folic acid supplementation alters the human sperm methylome and is influenced by the MTHFR C677T polymorphism

J. Trasler

McGill University Health Center, Developmental Genetics Laboratory- E.M.0.2236- Montreal Children's Hospital and Research InstituteBlock E- Room E.M.0.2236, Montreal, Canada

Abstract text

Male and female germ cells show distinct differences in the timing of epigenetic patterning, including that of DNA methylation. Such sex-specific differences suggest that males and females will be susceptible to the induction of epigenetic defects in their germ cells at different times in their lives, with the possibility of passing such defects on to their offspring. In the male, the major period of DNA methylation acquisition occurs before birth in male germ cells of the fetal testis. Postnatally, the patterns must be maintained in the male germ line stem cells and a small amount of additional methylation occurs as germ cells develop from spermatogonia to spermatocytes. Folate in the diet is an important source of methyl groups for DNA methylation. Folate deficiency, either due to diet or folate pathway enzyme defects, and folate supplementation are important clinical situations in which methyl donors required for DNA methylation are either lower or higher than normal. High dose folic acid supplementation (4.0–5.0 mg/day) is prescribed to women at high risk for neural tube defects and pregnancy complications, such as preeclampsia, and in the treatment of men with infertility. The potential adverse effects of high dose folic acid on the sperm epigenome have not been examined. We hypothesize that folate status will perturb DNA methylation in male germ cells that are exposed at the key prenatal and postnatal times (susceptibility windows) when DNA methylation patterning occurs. In mouse and human models, we are using array and next generation sequencing based assays to identify DNA methylation alterations in sperm associated with altered folate

status. In the mouse we have administered folic acid supplemented diets to model prenatal and postnatal exposures and have found evidence of intergenerational adverse reproductive effects and sperm DNA methylation defects. In men with no history of infertility, low doses of folic acid (0.4 mg/day) given for 3 months did not result in alterations in sperm DNA methylation. In contrast, in men with idiopathic infertility receiving supplements of 5.0 mg/day of folic acid for 6 months, DNA methylation at imprinted loci remained unchanged; however, there was unexpected loss of methylation across the sperm epigenome, effects that were exacerbated in men homozygous for a common polymorphism in the folate pathway enzyme methylenetetrahydrofolate reductase (MTHFR). In summary, both the mouse and human data indicate that clinically relevant high dose folic acid supplements can impact the sperm epigenome. In addition, the mouse studies suggest that DNA methylation defects in male germ cells associated with folic acid supplementation may be heritable and have adverse effects on future generations. (Supported by CIHR).

O-152　Transgenerational epigenetic programming via sperm microRNA recapitulates effects of paternal stress

T. Bale[1], J. Chan[2]

[1]*University of Pennsylvania, Biomedical Sciences, Philadelphia- PA, U.S.A.*
[2]*University of Pennsylvania, Biomedical Sciences, Philadelphia, U.S.A.*

Abstract text

Neurodevelopmental disorders including autism and schizophrenia have been highly associated with parental factors, including lifetime stress experience. We have developed a mouse model of paternal stress in which adult male mice exposed to chronic stress prior to breeding produce offspring with hypothalamic-pituitary-adrenal (HPA) stress axis dysregulation. Paternal sperm was examined for changes in miRNA content where 9 specific miRNAs were identified as significantly increased in the sperm from previously stressed fathers. To test the relevance and potential mRNA targets of these miRNAs following fertilization, we synthesized and injected the 9 miRNAs into single cell zygotes and found that the resulting offspring phenotype completely recapitulated that found from paternal stress sires. In addition, we have now completed single cell amplification from injected zygotes using Fluidigm technology and determined the maternal stored mRNAs that were targets of these sperm miRNAs. Gene set enrichment analysis of the offspring hypothalamus demonstrated broad changes in transcription, largely increasing gene repression in the brains from stressed dads. We hypothesize that the epididymal epithelial cells in the caput of the epididymis that secrete miRNA-containing exosomes are involved in the this sperm reprogramming. Our current studies are studying these cells in vitro and in vivo, to determine how stress interacts with the exosome processing machinery and changes in the miRNA content. We are targeting these cells in an attempt to rescue this paternal transmission and offspring phenotype. Overall, these results demonstrate that paternal experience across the lifespan can induce long-term germ cell epigenetic reprogramming and impact offspring hypothalamic regulation, and may therefore offer novel insight into factors influencing neuropsychiatric disease risk. Identification of the specific miRNAs in germ cells that are altered long-term following stress experience may point to unique biomarkers that could identify at-risk populations.

INVITED SESSION

SESSION 43: ENDOMETRIOSIS MANAGEMENT - LESS OF THE PAST, MORE OF THE FUTURE

Tuesday 4 July 2017　　　　　Room A　　　　　14:00–15:00

O-153　A vision of the future direction of surgery for endometriosis

T.C. Li

Prince of Wales Hospital, Department of Obstetrics & Gynaecology - Chinese University of HK, Shatin, Hong Kong

Abstract text

Endometriosis is a common gynaecological condition resulting in reproductive failure or pelvic pain. Surgery has played an important role in the management of the condition. In endometrioma, the key question is how to preserve ovarian function if surgery is indeed indicated. The various strategies to be discussed will include a flexible approach to cystectomy or cystotomy and ablation, as well as reduction of mechanical and vascular injury. Specifically, the preliminary experience of the use of an haemostatic agent, floseal, based on an ongoing RCT will be highlighted. In adenomyosis and adenomyoma, there is a limited role of surgery but recent development in hysteroscopic approach to the management of cystic adenomyoma and its advantages will be outlined. In Stage I/II endometriosis, the choice between ablation and excision will be discussed with emphasis on how to select suitable cases for the two techniques. In stage III/IV disease and deep infiltrating endometriosis (DIE), the ongoing debate of treatment by accredited surgeons in specialized center and its alternatives will be revisited. In the future, surgery will continue to play an important role; there will be some refinement of surgical techniques but important advances in treatment including prevention of postoperative recurrence will follow breakthrough in understanding the genomics & cell biology of different sub-types of endometriosis and the development of specific medical or adjuvant "target" therapies.

O-154   Future perspectives on the medical management of endometriosis

E. Somigliana

Fondazione Ospedale Maggiore Policlinico U.O. Centro Sterilita, Obstetrics-Gynecology and Neonatology, Milano, Italy

Abstract text

During the last decades, endometriosis management have been inspired by the observation of the natural history of the disease. Endometriosis is exceedingly rare before menarche, it transiently improves during pregnancy and it resolves after menopause. Accordingly, progestins, estroprogestins and GnRH analogues have all been demonstrated to markedly improve pain and prevent recurrences. However, once these agents are discontinued, symptoms tend to resume and protection against recurrences vanishes.

Surgical excision of lesions is sometimes demanding and risky but significantly improves symptoms. However, it is poorly effective on adhesions and, again, does not protect from recurrences. A crucial point here is that surgery can remove the lesions but cannot remove the causes of the disease, leaving women exposed to recurrences.

On these bases, researchers have struggled to find out the holy gray for the definite cure of the disease. These efforts have been up to now disappointing. Interfering with the molecular pathway of endometriotic lesions was systematically shown to have concomitant repercussions also on ovulatory mechanisms or on the eutopic endometrium, thus limiting their clinical interest. Overall, we failed to identify agents that are superior to the already available classical hormonal treatments.

Research must continue. No-one knows the long term future of the treatments of endometriosis. However, despite recognizing this difficulty, pessimism is not justified. To date, we cannot cure women with endometriosis but we can effectively treat them. We should re-think the treatment of of the disease in a more pragmatic and woman-centered manner. The future (the present) is a personalized and more conscious management. Physicians and patients should be aware of the relevant beneficial effects of currently available therapies and concomitantly also accept and deal with their limitations. Progestins, estroprogestins, GnRH analogues, surgery and IVF represent an outstanding armamentarium provided that they are used within a personalized medicine that puts women, their symptoms, their fears and their whishes in the Center. Physicians are called to establish a in-depth relationship with the patients, based on honest and detailed information in order to tailor the best treatment for every woman. The future is improving the satisfaction of the women with the available instruments rather than seeking for the holy gray. And we can do it.

Abstract text

Pre-implantation genetic testing for aneuploidy (PGS or PGT-A) is an early form of prenatal diagnosis. The embryos obtained during an *in vitro* fertilization cycle (IVF) are tested with the goal to identify those that are affected by chromosomal aneuploidies. As for pre-implantation genetic testing for monogenic disease (PGD or PGT-M), this strategy has the principal objective to avoid the instauration of a pregnancy with an affected embryo. To date there are not yet a clear consensus about the population of patients that would benefit from PGT-A approach. The main indications suggested in the literature are: advanced maternal age, history of recurrent miscarriages and/or repeated IVF failures. However, other indications have been proposed over time including: previous genetically abnormal pregnancy, poor embryo quality, previous radiotherapy and single embryo transfer policy. Chromosomal aneuploidies are indeed the main reason for implantation failure and pregnancy loss, and their prevalence in the embryos is strongly related to female age. In theory, all patients undergoing an IVF cycles have a potential risk to produce aneuploid embryos and could thus benefit from this test. The debate about the usefulness of PGT-A has started after the clinical failure of its first version based on cleavage stage biopsy and 9 chromosome-FISH analysis. Today, PGT-A is performed by comprehensive chromosome screening (CCS) techniques on trophectoderm (TE) biopsies. To understand the potentiality of the technology as performed now, 3 aspects have to be considered: invasivity of the biopsy, accuracy of the test and clinical efficiency in terms of sustained pregnancy rate per transfer and miscarriage rate. Unlike blastomere biopsy, TE biopsy is a safe and extensively validated approach with low biological and technical margin of error. The prevalence of mosaic diploid/aneuploid embryos is estimated to be low at the blastocyst stage, between 0 and 16 %. All CCS technologies adapted to, or designed to conduct PGT-A are highly concordant. The false positive error rate is estimated to be around 0.5% while a clinically recognizable error rate per transferred blastocyst of 0.2 %. Moreover, RCTs, observational and prospective studies were able to show that in both young and advanced maternal age populations, PGD-T resulted in a higher delivery rate per embryo transferred. To this regard, in particular, it was shown that single euploid blastocyst transfer equals double untested embryo transfer in terms of live birth rate, but with significantly better obstetrical outcomes. These data collectively represent a considerable body of evidence in favour of PGT-A clinical efficiency. An analysis of the cost-effectiveness of PGT-A is however still missing. Ideally, it should also take into account pre-natal test cost and obstetrical and neonatal costs. In conclusion, there is a sufficient body of evidence to support the clinical application of CCS-based PGT-A on TE biopsies. The main limiting factor is the need for a high-standard laboratory to conduct blastocyst culture, biopsy, vitrification, and genetic test and, in turn, the cost of the procedure.

O-156   Con

S. Repping, S. Mastenbroek

Center for Reproductive Medicine, Center for Reproductive Medicine, Amsterdam, The Netherlands

Abstract text

The aim of preimplantation genetic screening (PGS) is to select out embryos that are aneuploid. The reason to do so has generally been to increase the chance of live birth in couples undergoing IVF/ICSI. However, data that supports the notion that PGS increases live birth rates is lacking. In fact, PGS using day 3 biopsy and FISH results in a significant reduction in live birth rates. For novel technologies using day 5 biopsy and array based or NGS analysis, well designed trials are largely lacking. Simple reasoning demonstrates that no selection method will ever increase cumulative live birth rates per started cycle and the scientific consensus is that it does not. At best, PGS could perhaps reduce time to pregnancy or reduce the number of miscarriages but at what cost? And how should we inform patients about these (un)certainties and how are they informed?

INVITED SESSION

SESSION 45: PATIENT SESSION: PUSHING THINGS FORWARD: ACCELERATING CHANGE - PATIENT ASSOCIATION ROLE IN MAR

| Tuesday 4 July 2017 | Room W+X | 14:00–15:00 |

O-157   25 million people matter. Patients' network as a driving force in Europe

S. Rautakallio-Hokkanen

Lapsettomien yhdistys Simpukka ry, Infertility Association, Tampere, Finland

Abstract text

Infertility is a very personal and intimate issue. There is a need to talk to someone who shares your thoughts and knows what your going through. This is where patient associations have their role. There are cultural and legislational differences in Europe, but the main idea of patient associations everywhere is still the same: to support, to understand, to listen and to reach out a helping hand. National associations are very important when there is a need to discuss infertility related issues with authorities, lawmakers and health care professionals in their own countries.

But when it comes to patients' rights on European level, it's very hard to influence or make things move forward from national level. Fertility Europe is an umbrella association for European infertility associations. It was founded in 2009 with 9 members and has since then reached most of the European countries. With 23 member associations from 21 countries Fertility Europe has a significant role in joining over 25 million people facing infertility in Europe. What can an umbrella association do for its members? What has Fertility already done to promote the rights of infertile patients? What does it mean that #InfertilityMattersEU?

O-158   Questions? Questions! How can patients contribute to improvement of fertility care?

J. Knijnenburg

Groesbeek, The Netherlands,

Abstract text

The basis of science is a curiosity, that leads to questions for which scientists seek and find answers with some hard work. Guidelines summarize the best answers on these scientific questions in order to implement a good standard of care. That's all in the world of the scientist and professional caregivers. And it's all about groups and not about individuals.

Patients come to you for answers on their personal questions. But how do they know that they are in the right place, handled with the right care? And how do you know that you give them the care that suits them in their personal lives?

Patient organization Freya has developed several tools in order to try and bring caregivers and patients together in their mutual quest for the best fertility care. We use different questionnaires to measure the quality of care from a patients' perspective, to compare the care actually given to the guidelines and try to make fertility care more transparent. Furthermore, we encourage patients to ask more questions in the consulting room so they get the individual answers they seek.

O-159   Reproductive health education of adolescents as a tool for early prevention of infertility

I. Popova

Zachatie Association Member of Fertility Europe, Sofia, Bulgaria

Abstract text

Zachatie Association is the patient organization of people with reproductive health issues in Bulgaria. Established in 2004, the NGO is entirely volunteer structure and some of its main goals are to promote public debate on infertility in Bulgaria; to assist the implementation of national strategy for reproductive health; to initiate and support changes in legislation, related to reproductive health and infertility treatment; to provide information and support on prevention and treatment of infertility-inducing diseases.

Zachatie Association supports the vision of the International Federation of Gynecology and Obstetrics (FIGO), that „*prevention reduces or sometimes avoids the harm of infertility for some of the population at risk, even if some of those affected later have access to treatment. Prevention generally involves not only access to health-care but also to health education.*"

In our understanding, the education about the human reproductive health should start at early age – namely at puberty – in order to have a maximum preventive effect. The main issues we focus on are as follows:

(1) Education about functioning of the human reproductive system;
(2) Education about sex and birth control;
(3) Education about healthy lifestyle and possible risk factors for the reproductive health.

Zachatie Association considers the government-provided mandatory education in high schools as not adequate and sufficient in that matter. Therefore, as a socially responsible organization, the Association has decided to launch its own educational and awareness campaign among the teenagers of the country, in favour of public health.

The awareness campaign, called "**Stay in the Loop: Your Reproductive Health**" is aimed mostly at school boys and girls aged 13–17. The campaign was launched in 2011 and is still going on.

This presentation will describe into details the main goals, aspects, tools and outcomes of the reproductive health awareness campaign for teenagers in Bulgaria, as well as our conclusions and vision for potential future development of the project on European scale. Our hope is that this campaign will serve as an example for the government and that reproductive health education will be considered part of the mandatory high school education in the future. It is our strong belief, that reproductive health education will lead to prevention of some forms of infertility in the future and to economic benefits for the society in the long run.

O-160   MAR in Croatia: Retrospective and Prospective. The role of patients' organisation in positive change of MAR practices

I. Lodder Rozic

Zagreb, Croatia,

Abstract text

On the July, 17 2009 Croatian government pass one of the most restrictive law on the assisted reproduction and infertility treatments. Among other, it limited number of fertilized oocytes to three (3) within a cycle, banned cryopreservation of embryos and MAR was made available for married couples only. As consequence of such political act, patients went through numerous unnecessary

ART treatments, number of high-risk multiple pregnancies increased and more couples opted for cross-border treatments.

Although NGO Roda (Stark) dealt with the issues of (in)fertility since 2003, this law shifted focus from patient information and support to advocacy for the best medical practices, becoming virtually the only voice of reason. This presentation will give an overview of actions and campaigns for change and public awareness.

After almost three years of struggle and with a governmental change, on July 13, 2012 new MAR law came into force. Even so, current legislative still tried to conciliate opposite personal and political views on the expense of medical standards and minority groups. So, five years later, where are we?

SESSION 46: FRONTIERS OF EMBRYOLOGY

Tuesday 4 July 2017　　　　Plenary 1　　　　15:15–16:30

O-161　Establishment of appropriate methods for human oocyte-activation by PLCZ1 cRNA (PLCZ) injection

T. Yamaguchi[1], A. Tanaka[1], M. Nagayoshi[1], T. Ichiyama[1], M. Ohno[1], K. Kuroda[2], M. Ito[3]

[1]Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan
[2]Juntendo University School of Medicine, Department of Obstetrics and Gynecology, Tokyo, Japan
[3]Hamamatsu University School of Medicine, Department of Infectious Diseases, Hamamatsu, Japan

Study question: Is PLCZ injection into human oocyte a better method for oocyte-activation compared to other methods like Electrical stimulation or Ionomycin?

Summary answer: We found the optimal concentrations of PLCZ to activate oocytes physiologically, with a similar pattern of Ca^{2+} oscillations to that of in vitro fertilization oocytes.

What is known already: At fertilization, mammalian oocytes show repetitive transient Ca^{2+} transients each of which is due to Ca^{2+} release from the endoplasmic reticulum through Inositol 1,4,5-trisphosphate(IP_3) receptors. During fertilization, the so called sperm factor, is released into the oocyte and induces series of Ca^{2+} spikes that are required for oocyte activation. They are called Ca^{2+} oscillations. IP_3-producing enzyme phospholipase C zeta (PLCZ1) is a strong candidate to be the sperm factor.

Study design, size, duration: We performed this retrospective study to investigate the usefulness of PLCZ injection into human oocyte. 94 fresh M-II oocytes from 34 patients were used to find optimal concentration to activate human oocytes and 67 oocytes from 29 patients were used to compare with the other oocyte activation methods from January 2013 to December 2015.

Participants/materials, setting, methods: Optimal RNA concentration for oocyte activation was examined by injection with various concentrations of PLCZ into human oocytes from IVF patients who had consented to this experiments. After injection, the rate of PN formation was checked and the intracellular Ca^{2+} concentration of injected oocytes was monitored by Fluo8H AM fluorescent Ca^{2+} indicator.

Main results and the role of chance: Optimal concentration of PLCZ1 to activate human oocytes was 100 ng/μl in the examination using 94 fresh M-II oocytes (Table 1).

The pattern of Ca^{2+} oscillations by PLCZ injection was similar to the pattern of Ca^{2+} oscillations seen in the in vitro fertilized oocytes (Table 2).

	Oocytes (n)	Day 1	Day3 (>= 7 cell)
1PN+ First polar body number (%)	Cleaved embryos number (%)		
Ionomycin	15	66.7 (10/15)	40.0 (4/10)
PLCZ1	35	65.7 (23/35)	60.1 (14/23)
Electrical stimulation	17	52.9 (9/17)	44.4 (4/9)

In comparison with the other oocyte activation methods, cleavage rate was the highest in the oocytes activated by PLCZ. However it showed no significant differences in pregnancy rates.

Limitations, reasons for caution: Birth of healthy offspring and reproduction of healthy second generation from mouse oocytes activated by PLCZ was reported in 2008. However healthy human births have not been reported after using this method. The safety of PLCZ injection to human health should be further examined for future clinical applications.

Wider implications of the findings: First it will rescue the unfertilized oocytes after ICSI due to insufficient oocyte activation, which accounts for approximately 40% of all unfertilized oocytes. Secondly, this new oocyte activating method which is more physiologically oocyte activation will be beneficial for improving clinical outcome of ROSI.

Trial registration number: UMIN Clinical Trials Registry: UMIN000020860.

O-162　Using artificial intelligence to improve blastocyst morphology evaluation

ABSTRACT UNDER PRESS EMBARGO

Concentration of PLCZ (ng/μl)	0.01 (n = 13)	0.05 (n = 14)	0.1 (n = 4)	1 (n = 6)	5 (n = 25)	10 (n = 11)	100 (n = 18)	1000 (n = 3)
Day 1	Second polar body (%)	23.1	14.3	0	0	16.0	9.1	66.7	66.7
1PN (%)	23.1	14.3	0	0	8.0	9.1	66.7	66.7

Participants/materials, setting, methods: In a clinical IVF setting, we compared oocyte number and recorded the development of supernumerary embryos collected from women receiving agonist protocol (n = 81 women, 401 embryos) and those from women receiving an antagonist (n = 87 women, 378 embryos). The non-invasive consumption/release of glucose, pyruvate, lactate and amino acids were measured on spent droplets of culture medium from day 5 to 7. Total triglyceride levels within individual embryos were also determined on day 7 of development.

Main results and the role of chance: Antagonist cycles led to significantly fewer oocytes per patient, higher rates of blastocyst formation on day 5 (p < 0.01) and lower implantation rates in treatment cycles, despite there being no differences in patient demographics including female age, AMH levels, BMI, cycle number and cause of infertility. Of those embryos donated to research, blastocyst rates were again significantly higher (42.6% compared to 31.2% on day 7) in the antagonist and these embryos had less endogenous triglyceride on day 7 (7.41 ng compared to 9.96 ng for the agonist group, p < 0.01). Glucose, pyruvate and amino-acid metabolism of day 7 blastocysts was not influenced by stimulation regimen, however lactate production was significantly higher in the antagonist group (122.97 & 100.42 pmol/embryo/hr respectively p = 0.01). The excess lactate production indicates that glucose is diverted into aerobic glycolysis, which may allow faster incorporation of carbon into biomass, facilitating rapid cell division. This may explain the higher rates of blastocyst development, however it could be speculated that, precocious development may be detrimental for implantation, hence the lower pregnancy rates in fresh cycles. Although statistical power has been achieved for metabolic primary end points, this is a retrospective study and further studies would be required to validate implantation findings.

Limitations, reasons for caution: The analysis has been performed on supernumerary embryos, originating from a single IVF unit and not selected for use in treatment. Endometrial interactions would also require further consideration.

Wider implications of the findings: The data indicate that ovarian stimulation is associated with distinct phenotypic changes in the embryo during the preimplantation period, highlighting the potential legacy of the ovarian conditions under which the oocyte has matured and influence on embryo developmental viability and potential likelihood of successful implantation.

Trial registration number: not applicable.

O-163 The effect of gonadotropin releasing hormone (GnRH) agonist and antagonists stimulation protocols on the viability and metabolism of human oocytes and early embryos

C. Leary[1], R. Sturmey[2]

[1]East Riding Fertility Services, The Hull IVF Unit, Hull, United Kingdom
[2]The Hull York Medical School, Centre for Cardiovascular and Metabolic Research, Hull, United Kingdom

Study question: Does ovarian stimulation protocol influence oocyte viability and subsequent in-vitro embryo development and metabolic regulation?

Summary answer: GnRH antagonist protocol was associated with higher blastocyst rates, yet these blastocysts had a distinct metabolic phenotype and were less likely to implant.

What is known already: Ovarian stimulation influences IVF success. GnRH agonist and antagonists protocols are both used. Comparative studies have focused primarily on clinical pregnancy rates and ovarian response, yet the impact on on oocyte and embryo viability has received little attention.

Attempts to investigate the effects of exogenous gonadotrophins on embryo development in rodent models have indicated delayed development to the blastocysts. Whilst this is important for embryo selection blastocyst development rates are a limited measure of embryo competence. The study of embryo metabolism provides a quantifiable, objective measure of how ovarian stimulation could influence oocyte and subsequent embryo metabolic physiology and viability.

Study design, size, duration: We conducted a retrospective study to compare the impact of GnRH agonist and antagonist protocol on embryo development to blastocyst. In addition, we have measured non-invasively the metabolic activity of 779 IVF/ICSI embryos from 168 consecutive women who donated their surplus embryos to research, and have related the data retrospectively to their cycle outcome.

O-164 Noninvasive fluorescence lifetime imaging microscopy to detect metabolic differences in mouse embryos: safety and live birth analysis

T. Sanchez[1], D. Sakkas[2], E. Seidler[2,3], M. Venturas[1], D. Needleman[1]

[1]Harvard University, Molecular and Cell Biology, Cambridge- MA, U.S.A.
[2]Boston IVF, Reproductive Endocrinology and Infertility, Waltham- MA, U.S.A.
[3]Harvard Medical School, Beth Israel Deaconess Medical Center, Boston- MA, U.S.A.

Study question: Can noninvasive fluorescence lifetime imaging microscopy (FLIM) be used safely and does it detect different metabolic profiles in mouse embryos of the same morphology?

Summary answer: Metabolic imaging can sensitively detect differences in mouse embryo metabolism and does not decrease live birth rates when compared to non-exposed controls.

What is known already: Metabolic function changes as embryos develop, with both varying degrees of ATP synthesis and turnover at different developmental stages. As NADH and FAD+ are both autofluorescent and integral to cellular respiration, monitoring their fluorescence yields valuable information for characterizing cellular metabolism. Superior to intensity-only (single parameter) measurements, FLIM generates three additional parameters that are sensitive to metabolic shifts. As with other noninvasive assessment methods such as time lapse, FLIM does not require the introduction of additional markers or dyes. Thus, FLIM holds great potential as a new embryo assessment tool; however, its safety for embryos has yet to be validated.

Study design, size, duration: Control and FLIM illuminated blastocysts were transferred in groups of twelve to pseudopregnant females. In total, 96 illuminated embryos and 84 control embryos were transferred to 8 and 7 pseudopregnant females, respectively. At birth, the pups were counted and weighed

to assess for any adverse effect of FLIM exposure. In addition, averaged FLIM data for 93 embryos was analyzed to evaluate for natural variation between embryos and reproducibility of the measurements.

Participants/materials, setting, methods: Mouse embryos were obtained from a commercial source. Embryos were cultured from the 2-cell until the blastocyst stage using a closed microscope chamber, with and without exposure to FLIM illumination. Comprehensive metabolic measurements (NADH and FAD+) were taken every two hours during the course of mouse embryo development using the on-stage incubation system. Control embryos were cultured in the same chamber but were not illuminated.

Main results and the role of chance: FLIM-based metabolic imaging was not detrimental to both live birth rate and pup weight when compared to control. The mean (+SD) number of pups per mouse for control and illuminated groups was 4.6 + 3.1 and 4.5 + 1.7, respectively. The pup weights (g) were 1.89 + 0.27 (Control) and 1.92 + 0.40 (FLIM), respectively. When we collated the metabolic FLIM signatures over the course of mouse embryo development from the 2-cell to the blastocyst stage we found that embryos exhibited distinct and consistent metabolic changes over the course of their development. In particular, NADH levels peaked around compaction and decreased significantly during blastocyst formation, likely corresponding with an associated change in energy demands. Additionally, we observed significant variation between embryos, compared to the error on our measurement, further indicating the potential of this technique to sensitively detect differences in metabolic state. Finally, we found a high degree of reproducibility from different days in the measurements. The ability to identify each embryo's distinct metabolic profile regardless of similar morphology validates the concept of using FLIM to generate a unique metabolic signature.

Limitations, reasons for caution: Although these findings represent an innovative mechanism of embryo evaluation, a defined standard for interpreting metabolic FLIM parameters remains to be developed. The hardiness of the mouse model may represent that caution is still needed if this method is to be used for testing human embryos.

Wider implications of the findings: This work represents a novel tool for assessing the metabolic health of embryos. Preliminary results indicate promise for both safety and its use as a potential embryo selection tool. Future in-clinic measurements on human embryo samples are planned and will investigate possible correlations between metabolic signatures and final pregnancy outcomes.

Trial registration number: Not applicable.

O-165 Non-invasive prediction of blastocyst implantation and live birth by day three embryo culture medium lipid fingerprinting

A. Setti[1], D.P.A.F. Braga[2], D.A. Montanni[3], E.C. Cabral[4], M.N. Eberlin[5], E.G. Lo Turco[3], E. Borges Jr.[2]

[1]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assitida, Scientific Research, São Paulo, Brazil
[2]Fertility Medical Group, Scientific Research, São Paulo, Brazil
[3]Universidade Federal de São Paulo, Disciplina de Urologia, São Paulo, Brazil
[4]UNICAMP, Centro Pluridisciplinar de Pesquisas Químicas- Biológicas e Agrícolas – CPQBA, Campinas, Brazil
[5]UNICAMP, Laboratório ThoMSon de Espectrometria de Massas – Instituto de Química, Campinas, Brazil

Study question: Is the embryo culture media lipid fingerprinting, by mass spectrometry (MS), able to identify blastocyst with increased potential to implant and lead to live births?

Summary answer: The culture media lipidomics is a promising approach to identity blastocyst able to implantation and lead to live births.

What is known already: *In vitro* fertilization (IVF) success have been remarkably improved in the last decades. However, its efficiency, measured as the live birth rate, is still below 50%. Improvements to IVF depend on the ability to select the most viable embryos for transfer. Non-invasive approaches to access embryo development have been proposed, and it includes embryo metabolome and, more specifically, embryo lipidome. Modern approaches for lipidomic analysis are dominated by MS, which afford the study of intact lipid molecular species from very small amounts of samples. Therefore the embryo culture media lipidomics may be a promising tool to access embryo viability.

Study design, size, duration: For this case-control study 33 samples of embryo culture media were collected on day three for 22 patients undergoing intracytoplasmic sperm injection (ICSI) and day five embryo transfers. Samples were split into groups according to the implantation: Positive-Implantation-Group (n = 19) or Negative-Implantation-Group (n = 14). The study included exclusively samples from high-quality transferred blastocysts and the Positive-Implantation-Group included exclusively samples from patients with 100% implantation diagnosis. Subsequently to the implantation confirmation, culture medium samples were analyzed by MS.

Participants/materials, setting, methods: Samples were collected between January/2015 and November/2015 in a private university-affiliated IVF center. The lipids from culture medium were individually extracted using the Bligh and Dyer method. Mass spectra were obtained with a direct infusion of both the negative and positive ion modes into a Q-Tof mass spectrometer. Obtained data was analyzed by Principal Component Analysis (PCA) and Partial Least Square Discrimination Analysis (PLS-DA), combined with variable influence in the projection (VIP) scores.

Main results and the role of chance: All blastocysts from the Positive-Implantation-Group lead to live births. Concerning the PCA analysis, an increase difference was noted for lipidic characteristics between the Negative- and Positive-Implantation-Group, when compared with the negative mode.

Moreover, we could note a better clustering in negative implantation group for both, positive and negative modes. The PLS-DA showed satisfactory separations between the Positive- and Negative-Implantation-Groups for both, positive and negative modes.

The VIP plot of the PLS-DA provided a list of four ions, in the positive mode, with an area under the curve (AUC) of 73.5% and six ions, in the negative model, with and AUC of 72.0%. For both positive and negative modes, possible biomarkers for the negative implantation were identified by the lipidmaps: phosphoethanolamine, dicarboxylic acids, glycerophosphoglycerol, glycerophosphocholine, glicerophosphoinositol, phosphoethanolamine and unsaturated fat acids. The other ions were not identified. These lipids are involved in the GPI anchor biosynthesis and synthesis of glycerophospholipids and phosphate inositol.

Limitations, reasons for caution: For this study MS/MS, to confirm the presence of the lipids identified here, was not performed. In addition, the identification of the viable embryo may not guarantee the positive implantation and live birth outcome, since, besides proper embryo development, embryo implantation also depends on the acquisition of a receptive endometrium.

Wider implications of the findings: Mass spectrometry fingerprinting is a useful predictive tool for blastocysts that fail to implant, and therefore this technique could be incorporated in the laboratory routine, adjunct to morphology evaluation to identify embryos that should not be transferred.

Trial registration number: None.

SELECTED ORAL COMMUNICATIONS
SESSION 47: WHAT IS NEW IN AMH?

Tuesday 4 July 2017	Plenary 2	15:15–16:30

O-166 Intercyclic variation in AMH levels; challenges of using single-sample measurements for clinical predictions

L. Bungum[1], J. Tagevi[2], N. Tørring[3], C.Y. Andersen[4], N. Macklon[5], M. Bungum[6], A. Giwercman[6], S. Skouby[7]

[1]Skåne University Hospital Malmö, Reproduktionsmedicinsk Center/FertilitetscentrumIngång 71- Plan 6, Malmö, Sweden

[3]Aarhus University Hospital, Clinical Biology, Aarhus, Denmark
[4]University Hospital of Copenhagen, Laboratory of Reproductive Biology, Copenhagen, Denmark
[5]University of Copenhagen and Southampton, Sjælland University Hospital, Roskilde, Denmark
[6]Skåne University Hospital, Reproductive Medicine Center, Malmø, Sweden

[7]University of Copenhagen Hospital, Gynecology and Obstetrics, Copenhagen, Denmark

Study question: To quantity the extent of long-term variability in Anti Müllerian Hormone (AMH) levels and potential differences between analytical assays

Summary answer: Long-term AMH measurements reveal a significant variation, probably caused by biological variation in the number of AMH-producing follicles

What is known already: AMH measurement has become increasingly used in fertility evaluation and prediction of response to ovarian stimulation and its interpretation may have major implications for clinicians' recommendations and patients' choice of treatment. While recognized clinical biomarkers are expected to express a low degree of variation, both biological and analytical variability exists. For AMH, reported intra- and intercyclic variability may be based on the dynamics in folliculogenesis with follicle activation and atresia providing a variable number of AMH-producing follicles at any time. Additionally, various assays will deliver diverse results depending on which molecular form of AMH being measured.

Study design, size, duration: Prospective cohort study covering three spontaneous menstrual cycles in ovulatory women

Participants/materials, setting, methods: A total of 27 healthy women, all non-smoking and with a regular menstrual cycle, volunteered to participate in the study. All study participants had blood drawn day 5-10-15-20-25 (30) in three consecutive cycles. All samples were analyzed using two platforms; the Immunotech EIA AMH/MIS manual kits from Beckman Coulter, Inc. and the automated Roche Elecsys Cobas e601. The difference in coefficiant of variation between assays was tested in a paired t-test.

Main results and the role of chance: The average number of consecutive AMH recordings per study subject (over three menstrual cycles) were 14.7 exposing a substantial degree of variation. The lowest differences in AMH recordings in one study subject were in absolute and relative form (%): Beckman Coulter 3.9 pmol/l (60%), Cobas 4.4 pmol/l (37.3%), and the corresponding maximum values were; Beckman Coulter 33.0 pmol/l (446%) and Cobas 31.4 pmol/l (274 %). There was no statistically significant difference in the coefficient of variation between assay platforms, neither by cycle, nor menstrual day

Limitations, reasons for caution: Number of participants limited

Wider implications of the findings: The findings question whether a single AMH measurement is sufficient for decision-making in assisted reproductive technologies.

Trial registration number: Lund Ethical review Board, Sweden Dnr. 539/2008.

O-167 High AMH in ovulatory women predicts high cumulative pregnancy rate after spontaneous conception

A.S. Korsholm[1], K. Birch Petersen[1], J.G. Bentzen[1], L.M. Hilsted[2], A. Nyboe Andersen[1], H.W. Hvidman[1]

[1]Rigshospitalet, The Fertility Clinic, Copenhagen Ø, Denmark
[2]Rigshospitalet, Department of Clinical Biochemistry, Copenhagen Ø, Denmark

Study question: Can AMH predict cumulative pregnancy rates and TTP in women attempting to conceive spontaneously and what is the lower AMH threshold compatible with spontaneous conception?

Summary answer: High AMH was associated with higher cumulative pregnancy rate compared with intermediate/low AMH. Spontaneous conceptions occurred with AMH levels down to 1.2 pmol/L.

What is known already: AMH is a quantitative marker of ovarian reserve and is successfully used in ART to predict ovarian response. However, AMH is a weak predictor of pregnancy after IVF-treatment. Few publications have investigated AMH in relation to spontaneous conceptions and the results are inconsistent possibly because some studies included only women that did conceive and thus had proven fertility; a few others used selected groups of patients/women.

Study design, size, duration: A cohort study of 260 women aged 25–42 years included at The University Hospital of Copenhagen, Rigshospitalet during 2008–2014. All included women initiated an attempt to conceive spontaneously or had an unplanned conception within two years after inclusion.

Participants/materials, setting, methods: The participants originated from two subcohorts: A) women aged 25–42 years consulting the Fertility Assessment and Counselling Clinic and B) health care workers aged 25–41 years employed at Rigshospitalet. Users of oral contraceptives at inclusion were excluded. All had AMH (Elecsys), ovarian sonography and extensive reproductive history. Follow-up on pregnancy attempts was collected through questionnaire.

Main results and the role of chance: Participants were stratified in low AMH (1st quintile): <9.5 pmol/L, intermediate AMH (2nd – 4th quintiles): 9.5 – 33 pmol/L, and high AMH (5th quintile): >33 pmol/L. Cumulative pregnancy rates within two years increased with increasing AMH: 60.1% (low) versus 70.0% (intermediate) versus 78.3% (high AMH) (p = 0.03). Pregnancy rates were reduced in women with high AMH and cycle length >35 days (pregnancy rate: 37.5%) compared with women with high AMH and regular cycles (pregnancy rate: 84.1%, p = 0.01). The incidence of unplanned pregnancies increased with AMH: low: 6.7%, intermediate: 20.4%, high AMH: 27.5%. In a univariate analyses the oldest quintile (>36.7 years) had longest TTP (p = 0.03). AMH was the only independent predictor of TTP in a multivariate analyses adjusted for female age, cycle regularity and previous conception. TTP was shorter among women with high AMH compared with intermediate or low AMH (HR: 0.63 and 0.55, p≤0.01). Trend test of AMH groups confirmed the stepwise trend (p = 0.01). Five of nine women with AMH value <3 pmol/L became spontaneously pregnant (TTP range 26–523 days). Spontaneous pregnancies were observed in women with AMH down to 1.2 pmol/L; three women had AMH below this value and none conceived spontaneously (attempted pregnancy for 104–327 days).

Limitations, reasons for caution: Sperm analyses were unavailable.

Wider implications of the findings: Spontaneous conceptions occur over a wide range of AMH values but high AMH suggesting a low "biological age" was associated with high natural fecundity in ovulatory women. Nonetheless, TTP differ substantially within similar AMH levels and AMH therefore has limited value in prediction of TTP.

Trial registration number: Data collection was approved by the Ethical Committee of the Capital Region of Denmark (H-B-2007–129 and H-1-2011-081).

O-168 The impact of serum anti-Müllerian hormone (AMH) levels on clinical outcome of individualised follitropin delta dosing and conventional follitropin alfa dosing in controlled ovarian stimulation

A. La Marca[1], S. Nelson[2], M. Göthberg[3], B. Mannaerts[4], J.C. Arce[5], &. ESTHER-1[6]

[1]University of Modena and Reggio Emilia and Clinica Eugin, Mother-Infant Department, Modena, Italy

[5]Ferring Pharmaceuticals, US Development, Parsippany, U.S.A.
[6]on behalf of the ESTHER-1 trial group, Evidence-based Stimulation Trial with Human rFSH in Europe and Rest of World, Copenhagen, Denmark

Study question: To evaluate ongoing pregnancy rate and the risk of early ovarian hyperstimulation syndrome (OHSS) in relation to serum AMH levels, following treatment with individualised follitropin delta or conventional follitropin alfa.

Summary answer: Individualised follitropin delta prevented ongoing pregnancy rates from declining in patients with high AMH and reduced the risk of early OHSS.

What is known already: In response to gonadotropin stimulation, there is a direct association between serum AMH and the number of oocytes retrieved, as well as between the number of oocytes retrieved and the risk for OHSS. An individualised dosing regimen of follitropin delta (FE 999049), targeting an adequate number of oocytes retrieved, significantly reduced the incidences of preventive interventions for early OHSS and preventive interventions and/or

OHSS, while maintaining non-inferior ongoing pregnancy rates compared to conventional follitropin alfa treatment (Nyboe Andersen and Nelson et al, Fertil Steril, 2016).

Study design, size, duration: Randomised, assessor-blind, controlled trial including 1326 patients undergoing their first IVF/ICSI cycle. Patients were randomised 1:1 to individualised follitropin delta (fixed daily dose based on patient's AMH and body weight) or conventional follitropin alfa (starting dose 150 IU/day, with potential adjustments from day 6). Preventive interventions for early OHSS included cycle cancellation ($\geq$25 follicles $\geq$12 mm), GnRH agonist triggering (25–35 follicles $\geq$12 mm, no fresh blastocyst transfer) and/or dopamine agonist administration ($\geq$20 follicles $\geq$12 mm).

Participants/materials, setting, methods: Retrospective comparative analyses of ongoing pregnancy rates, early OHSS, preventive interventions for early OHSS and total FSH dose in subgroups defined by AMH cut-off levels of $\geq$5, $\geq$10, $\geq$15, $\geq$20, $\geq$25, $\geq$30 and $\geq$35 pmol/L, including 92%, 73%, 55%, 39%, 27%, 20% and 13% of the trial population, respectively. AMH was measured by Elecsys® AMH (Roche Diagnostics).

Main results and the role of chance: In the subgroup with AMH $\geq$5 pmol/L the ongoing pregnancy rate was 31.4% (193/615) following individualised follitropin delta dosing and 32.0% (194/607) following conventional follitropin alfa dosing. In both treatment groups, the ongoing pregnancy rate was stable with increasing AMH cut-offs up to the subgroup with AMH $\geq$20 pmol/L. Above this threshold, the ongoing pregnancy rate remained stable with individualised follitropin delta dosing, whereas conventional follitropin alfa dosing was associated with a decline in the ongoing pregnancy rate. This discordance was most striking for women with an AMH $\geq$35 pmol/L, where the ongoing pregnancy rate was 31.4% (27/86) for follitropin delta and 23.8% (20/84) for follitropin alfa. Early OHSS and preventive interventions for early OHSS increased with increasing serum AMH. In the subgroup with AMH $\geq$35 pmol/L, the incidence of early OHSS was 4.7% and 11.9% with follitropin delta and follitropin alfa, respectively, and the incidence of preventive interventions was 4.7% and 23.8%, respectively. The total follitropin delta dose declined with increasing AMH from 87.5 μg (AMH $\geq$5 pmol/L) to 63.7 μg (AMH $\geq$35 pmol/L), whereas the total follitropin alfa dose was AMH independent.

Limitations, reasons for caution: In this retrospective analysis the number of patients with high AMH ($\geq$35 pmol/L) was limited.

Wider implications of the findings: In potential high responders, individualised follitropin delta dosing may improve ongoing pregnancy rates per started cycle and at the same time improve the safety of ovarian stimulation, in terms of lower incidences of OHSS and preventive interventions for OHSS.

Trial registration number: NCT01956110.

O-169   Towards the development of a WHO International Standard for immunoassays of Mullerian Inhibiting Substance/Anti Mullerian Hormone (MIS/AMH)

J. Ferguson[1], **D. Pepin**[2], **P. Donahoe**[2], **C. Burns**[1]

[1]National Institute for Biological Standards and Control, Biotherapeutics Division - Endocrinology Section, Potters Bar, United Kingdom
[2]Massachusetts General Hospital, Pediatric Surgical Research Laboratories, Boston, U.S.A.

Study question: Is formulated, lyophilised, recombinant human MIS/AMH suitable for the preparation of a WHO International Standard to calibrate AMH immunoassays?

Summary answer: A trial preparation exhibited a linear, parallel dose-response in the immunoassays tested. Between-method content estimates by commercially-available immunoassays varied with a GCV% of 26.67%.

What is known already: WHO has recognised the requirement for an International Standard to calibrate immunoassays of MIS/AMH. This requires sufficient MIS/AMH for the production of 2000–3000 ampoules, a stable, immunoreactive formulation and a strategy to define the content in mass units. Historical calibration exercises including the use of bovine, recombinant or native MIS/AMH calibrators and the calibration of new assays by serum value transfer present challenges both in the value assignment and in the eventual introduction of a reference material. The nature and extent of these challenges were explored by the measurement of a trial, lyophilised preparation, coded SS-581, by seven immunoassay methods.

Study design, size, duration: Five laboratories, provided with ampoules of SS-581, were asked to measure the MIS/AMH content in terms of their kit/method calibrators using the immunoassay methods currently in use in their laboratory and measuring a minimum of five concentrations in the linear part of the dose-response curve. In addition, participants were asked to measure concomitantly, a panel of six serum samples, coded S1 to S6, which contained between 0.1–13.0 ng/mL MIS/AMH.

Participants/materials, setting, methods: Trial ampoules coded SS-581 were prepared by lyophilisation of a 0.5 ml/ampoule volume of a formulation containing 0.24 % (w/v) bovine casein, 0.50 % (w/v) trehalose and nominally 1 μg/ml MIS/AMH. Human serum samples were obtained from a commercial source, aliquoted and stored at -80°C. Estimates of AMH content were determined in terms of kit calibrators by fitting a parallel-line model comparing log assay response to log concentration using CombiStats (Version 5.0, EDQM/ Council of Europe).

Main results and the role of chance: Five laboratories returned data from seven methods coded A-G. In all methods, the recombinant, human MIS/AMH was recognised and the dose-response was parallel to kit standards, allowing estimation of MIS/AMH content. In terms of kit standards, the MIS/AMH content of SS-581 was variable with a GCV% of 39.95 % across all assay methods although it must be noted that this decreased to 29.08% for automated immunoassay platforms only and to 26.67% for the four commercially-available methods. Three assays are reported to use the same monoclonal antibodies (F2B 12/H and F2B 7/A). The variability of the estimates made by these methods was 29.8% (GCV), suggesting that epitope recognition may not be the sole contributor to the observed variation and that calibration, assay format and the kinetics of antibody-binding may also influence the AMH concentrations obtained. Variability in the reported AMH content of the serum samples ranged from 14.90 – 22.35 % (GCV) with the exclusion of serum S3 which had an MIS/ AMH concentration near the lower limit of detection.

Limitations, reasons for caution: Three of the methods in the study were not commercially available at the time of the study.

It is not possible to draw conclusions regarding the commutability of a reference material prepared from human, recombinant MIS/AMH as considerably more serum samples would be measured in a full commutability assessment.

Wider implications of the findings: Lyophilised, recombinant MIS/AMH is suitable for the preparation of an International Standard. However, the introduction of such a reference material will require careful consideration. Furthermore, assignment of a mass value to the standard requires orthogonal physico-chemical data from SI-traceable reference methods, which will be challenging for a large, dimeric glycoprotein.

O-170   Applying data-driven approaches to develop a novel ovarian reserve score that leverages underlying relationships between distinct markers of ovarian reserve

K. Hunter Cohn[1], **C. Glazner**[1], **L. Tan**[1], **E. Widra**[2], **M. Leondires**[3], **B. Miller**[4], **C. Benadiva**[5], **J. Nulsen**[5], **G. Letterie**[6], **A. Copperman**[7], **P. Yurttas Beim**[1]

[4]Reproductive Medicine Associates of Michigan, Fertility Center, Troy, U.S.A.
[5]The Center for Advanced Reproductive Services, Fertility Center, Farmington, U.S.A.
[6]Seattle Reproductive Medicine, Fertility Center, Seattle, U.S.A.
[7]Reproductive Medicine Associates of New York, Fertility Center, New York, U.S.A.

Study question: The objective of the study was to apply data-driven approaches to develop an ovarian reserve score leveraging underlying relationships between distinct markers of ovarian reserve.

Summary answer: A machine-learning approach identified distinct factors corresponding to follicular and pituitary components of ovarian reserve, which were algorithmically combined into a composite ovarian reserve score.

What is known already: Ovarian reserve is often estimated by indirect markers such as anti-Müllerian hormone (AMH) levels, basal antral follicle count (BAFC), or baseline levels of pituitary hormones, such as follicle-stimulating

hormone (FSH) and luteinizing hormone (LH). These biomarkers are known to be interdependent and yet are still typically individually assessed as part of a standard diagnostic evaluation and optimization of ovarian stimulation protocols. Machine learning methodologies allow for combination of information from multiple correlated variables into summary (factor) scores, and hence reduce the impact of measurement error and improves results from prediction and correlation analyses.

Study design, size, duration: We conducted a multi-centre retrospective study of fresh IVF cycles at 13 clinics in the United States (2009–2015). After excluding cycles in which cleavage stage embryos were transferred or preimplantation genetic screening was performed, this analysis included a total of 31,263 cycles from 26,929 patients.

Participants/materials, setting, methods: Exploratory factor analysis (EFA) is used to group correlated variables that measure the same factor. We used EFA to determine the total number of distinct factors that AMH, BAFC, and basal levels of LH, FSH, and estradiol (E_2), E_2 at surge, total and metaphase II (MII) oocytes retrieved, and number of 2 pronuclear (2PN) and clinically usable embryos measure. Structural equation modeling (SEM) was used to explore relationships between the factors uncovered by EFA.

Main results and the role of chance: EFA/SEM analyses revealed that ovarian reserve was defined by two distinct factors: one measured to a similar degree by BAFC and AMH (Factor 1) and the other by FSH and the LH to FSH ratio (Factor 2). Interestingly, the two distinct factors that were automatically identified by the algorithms correspond to two biologically meaningful subgroups: ovarian follicle measures (Factor 1) and pituitary hormone-related measures (Factor 2). E_2 at surge, the number of total and MII oocytes retrieved, and the number of 2PN and usable embryos were all found to measure the same factor (ovarian response).

The ovarian reserve score decreased with maternal age and basal E_2 (both $p < 0.001$), but age had a larger impact. Higher ovarian reserve scores were correlated with lower total gonadotropin dose (GND, $p < 0.001$) and higher ovarian response ($p < 0.001$). Higher GND doses were correlated with higher ovarian response ($p < 0.001$). A correlation analysis revealed that the ovarian reserve score ($R^2=0.55$) was more than twice as powerful in explaining variation in ovarian response than any of the individual metrics alone: AMH ($R^2=0.24$), BAFC ($R^2=0.22$), basal FSH ($R^2=0.06$), the ratio between basal levels of LH and FSH ($R^2=0.06$), basal E_2 ($R^2=0.007$), or maternal age ($R^2=0.07$).

Limitations, reasons for caution: Our analysis included measurements performed at multiple laboratories. Our study was performed on retrospective data from the United States, and future studies are needed to investigate whether findings could extend to European practice patterns.

Wider implications of the findings: Although AMH, BAFC, and FSH measurements reflect different physiological components of ovarian reserve, this data-driven analysis revealed underlying relationships among them. We developed an ovarian reserve score based on these factors that reduced the impact of measurement error and offered better predictive accuracy than univariate measures alone.

O-171   Ovarian stimulation with Corifollitropin alpha (CFA) for 7 days leads to reduced progesterone levels on the day of trigger and to higher ongoing pregnancy rates

H.M. Fatemi[1], I. Missiou[2], J. Long[3], B. Lawrenz[4]

[1]IVI, Middle east, Abu Dhabi, United Arab Emirates
[2]msd, EUCAN MSD, Athens, Greece
[3]Merck Sharp & Dohme Corp., Whitehouse Station, NJ- USA, U.S.A.
[4]ivi, ART, Abu Dhabi, United Arab Emirates

Study question: Does hormonal stimulation with CFA-only result in lower progesterone levels and higher ongoing pregnancy rates (OPR) compared to CFA plus recFSH?

Summary answer: Stimulation with CFA-only leads to lower progesterone levels on the day of hCG-trigger and to higher ongoing pregnancy rates, compared to stimulation with additional recFSH.

What is known already: Premature progesterone rise during the late follicular phase of stimulation for IVF has a negative impact on the reproductive outcome of IVF / ICSI-cycles. Until now, the mechanism, by which elevated progesterone levels reduce pregnancy rates, is still not fully understood. Progesterone elevation has an impact on the endometrial receptivity by inducing endometrial advancement and therefore leading to asynchrony between the endometrium and the developing embryo. Recent studies suggest, that the cause of premature progesterone rise in ovarian stimulation for assisted reproductive techniques might be enhanced FSH stimulation.

Study design, size, duration: Post-hoc subgroup data-analysis of the previously published Ensure trial, which was a randomized, double-blind, double-dummy equivalence trial to compare the efficacy of 100 µg CFA with daily 150 IU recFSH for ovarian stimulation in patients ≤ 60 kg. Analysed were the data comparing CFA as a sole stimulation medication versus CFA and additional recFSH after day 8 of stimulation, comparing the incidence of elevated progesterone on the day of hCG-trigger and ongoing pregnancy rate.

Participants/materials, setting, methods: The ENSURE study included women aged 18–36 years, weighing ≤ 60 kg, a body mass index of 18–32 kg/m2, a menstrual cycle-length (24–35 days), access to ejaculatory spermatozoa and an indication for ovarian stimulation for IVF or ICSI. The Ensure study was a multicentre, multinational trial involving 14 centres in Europe and five centres in Asia.

Main results and the role of chance: The study included 396 patients. 268 patients underwent ovarian stimulation with 100 µg CFA and 128 patients with recFSH. Out of the 268 patients from the CFA-arm, 35 patients (13.1%) received the hCG-trigger after stimulation with CFA-only. 233 patients (86.9%) did not meet the criteria for final oocyte maturation on day 7 and needed therefore additional recFSH from day 8 onwards.

Of the 233 patients with additional recFSH after day 8, a total of 90 patients (38.6%) had progesterone levels of > 0.8 ng/ml, whereas in the group of the 35 patients, receiving CFA as sole medication, only 1 patient (2.8%) had a progesterone level of > 0.8 ng/ml (p < 0.0001).

The incidence for progesterone elevation in the CFA plus daily recFSH-group was 38.6% (90/233) for progesterone levels > 0.8 ng/ml, 7.3% (17/233) for > 1.5 ng/ml and 2.6% (6/233) for > 1.9 ng/ml respectively.

The OPR was 31.4% (11/35) for patients with CFA-only and 24.5% (57/233) for patients with additional recFSH after day 8 (p = 0.378). The OPR in patients with CFA and recFSH was 18.9%, 5.9% and 0% in the groups of progesterone levels > 0.8 ng/ml, > 1.5 ng/ml and 1.9 ng/ml respectively(P < 0.0001).

Limitations, reasons for caution: The limitations of the data are the post hoc analysis of an earlier conducted prospective randomized controlled trial and the relatively small sample size of the patients who met the criteria of final oocyte maturation on day 8. Those points could limit the meaningfulness of the findings.

Wider implications of the findings: The pharmacokinetic profile of CFA mimicks a step-down-protocol. Reduction of FSH-dosage towards the end of the cycle releases stimulation pressure on the growing follicle. This results in lower incidence of premature progesterone rise and higher ongoing pregnancy rates.

Trial registration number: NCT 00702845.

O-172   Time interval between hCG administration and oocyte retrieval significantly influences IVF-ET results

T. Tadros, L. Chenoz, M. Poulain, E. Adda-Herzog, J.M. Ayoubi, R. Fanchin

Foch Hospital, reproductive medicine unit, Suresnes, France

Study question: Do slight variations in the interval between hCG and oocyte retrieval (hCG-OR interval) influence IVF-ET results?

Summary answer: Roughly within a 34–39 hour frame, our data indicated that the shorter hCG-OR interval, the poorer IVF-ET results.

What is known already: For decades, in controlled ovarian hyperstimulation (COH) cycles for IVF-ET, hCG-OR interval has been pragmatically set around 36 hours to mimic the physiological events occurring during the menstrual cycle. Yet, little attention has been paid, both in the literature and in the daily practice of IVF-ET clinics, on the possible impact of slight variations of such an arbitrary schedule on IVF-ET results. Indeed, the actual degree of flexibility offered to clinicians to properly schedule oocyte retrieval and the ideal hCG-OR interval remain to be set.

Study design, size, duration: We studied 616 COH cycles for IVF-ET. All patients received hCG (10,000 IU, IM) according to usual criteria of follicle maturation.

Participants/materials, setting, methods: Patients were sorted into 6 groups according to whether hCG-OR interval was 34.0–35.0 hours (n = 48), 35.1–35.4 hours (n = 89), 35.5–35.9 hours (n = 186), 36.0–36.4 hours (n = 180), 36.5–36.9 hours (n = 69), and 37.0–39.0 hours (n = 44).

Main results and the role of chance: As shown in the Table, whereas patients and COH characteristics were similar in all groups, we observed a remarkable stepwise increase in the number of mature oocytes and embryos obtained together with an increase in pregnancy rates from the 34.0–35.0 hours to the 37.0–39.0 hours groups. Incidentally, the prevalence of negative OR was comparable over the 6 groups.

	34.0–35.0 h	35.1–35.4 h	35.5–35.9 h	36.0–36.4 h	36.5–36.9 h	37.0–39.0 h	P
Ages (ys)	35.0 ± 0.7	35.0 ± 0.5	35.2 ± 0.3	34.5 ± 0.3	35.8 ± 0.5	35.7 ± 0.7	0.33
Serum AMH (ng/mL)	3.2 ± 0.4	4.3 ± 0.5	4.0 ± 0.2	3.9 ± 0.2	3.3 ± 0.5	3.9 ± 0.6	0.31
No. ≥ 16 mm follicles	6.0 ± 0.4	6.5 ± 0.2	6.1 ± 0.2	6.5 ± 0.2	6.0 ± 0.3	6.0 ± 0.4	0.62
No. mature oocytes	6.8 ± 0.5	8.5 ± 0.5	8.5 ± 0.3	9.5 ± 0.3	9.3 ± 0.6	9.6 ± 0.6	<0.007
No. cleavage embryos	4.7 ± 0.4	6.1 ± 0.4	6.3 ± 0.3	7.0 ± 0.3	6.7 ± 0.5	7.6 ± 0.6	<0.002
Ongoing pregn. rate (%)	25.0	21.3	33.9	41.7	46.4	50.0	<0.001

Limitations, reasons for caution: The present study could not address the question of the influence of larger hCG-OR intervals (>39 hours) neither discriminating possible outcome differences inside the 37.0–39.0 hours group due to limited sample size. Further prospective studies, including larger populations, are needed to confirm and expand present findings.

Wider implications of the findings: Our data indicate that the mere adjustment of the hCG-OR interval can lead to a noticeable improvement in IVF-ET output. Whether present results may be extrapolated or not to cases in which GnRH agonist is used instead of hCG to prime OR should be addressed in future studies.

Trial registration number: Not Applicable.

O-173   The negative effect of progesterone levels on hCG administration (Phcg) on live-birth rate (LBR) is not restricted to values above 1.5 ng/ml in IVF/ICSI cycles

P. Arvis[1], P. Lehert[2], A. Guivarc'h[1], F. Jaffre[1]

[1]Clinique la Sagesse, AMP, Rennes, France
[2]Faculty of Medicine-, the University of Melbourne, Melbourne 3010- Victoria-, Australia

Study question: Is the negative effect of progesterone level limited to values above 1.5 ng/ml with a threshold effect, or already relevant for lower values?

Summary answer: The effect of P_{hcg} on LBR is non-linear, optimum at 0.80 ng/l and sharply decreasing for both lower and higher values. The 1.5 ng/ml threshold is arbitrary

What is known already: High P_{hcg} was commonly shown associated with lower LBR following IVF/ICSI cycles, irrespective of the use of analogue, antagonist, or type of gonadotropins for ovarian stimulation. As number of oocytes and estradiol level on the day of hCG administration are positively associated with progesterone levels, wether this negative effect persists after adjusting for ovarian response is still under debate. However, these effects were based in dichotomizing P_{hcg} following cut-off values, with the most known being 1.5 ng/ml. Models based on the continuous P_{hcg} value was never tested, thus linearity of the P_{hcg} effect and the validity of this threshold remain debatable

Study design, size, duration: Non-interventional, retrospective, observational, single-centre cohort study. No inclusion or exclusion criteria were applied. A sample size of 4300 cycles was calculated to provide a power of 90% to detect an odds ratio (OR) as large as .6 per Log(Pb) at p<.001 level (type I correction for multiple testing). Due to the expected correlation between cycles on the same patient, the analysis was conducted on last recent 5447 IVF/ICSI cycles performed on 2192 patients during 2009–2015

Participants/materials, setting, methods: Patients (median age 34y [IQ = 31–37]) underwent ovarian stimulation, with either GnRH long agonist, short, or antagonist protocol, and HP-hMG or rFSH, alone or combined with rLH, was used. We conducted a non linear mixed model featuring logistic regression assessing LBR as the dependent variable. The non linear effect of the log-transformed P_{hcg} was tested by polynomial regression, patient as random factor, patient mix, number of oocytes, time and total FSH dose used as fixed covariates

Main results and the role of chance: We found a highly significant non-linear effect featured by a linear (odds ratio OR = .58 per Log(P_{hcg}) ng/ml, 95% CI [.39-.85], p = .006) and quadratic (OR = .04, [.01,.13],p<.001) components, resulting in an optimal LB value at P_{hcg} = .8 ng/ml [.71-.86] sharply decreasing for both lower values and higher values. A significant effect was found in using the current threshold >1.5 ng/ml (OR = .32 [.21,.49], p<.001), however this threshold was not justified by a discontinuity and only 5.9% of sample were concerned. According to our model, a mean LB decrease of 34% (OR=.66, .56-.77) was found for patients out of the [.5,1.1] ng/ml P_{hcg} interval (33.8% of the sample). Sensitivity analyses successfully tested the robustness of our model: (a) P_{hcg} effect remains highly significant without adjusting on covariates; (b) The decreasing linear effect of P_{hcg} adjusting for the number of oocytes suggested in previous studies was found with a lower determination (OR = .83/log(Pf ng/ml), 95%CI [.66, .92]; (c) Results remain virtually unchanged in removing the number of occytes from the model; (d) P_{hcg} effects is independent of the number of oocytes (interaction test, OR=.98 per oocyte.ng/Ml, p=.67)

Limitations, reasons for caution: Data from a single-center study: the exact identification of the optimum value and its confidence interval may vary with different progesterone assay kits. In routine practice, P_{hcg} measurement is an important but very late information, raising the question as to whether earlier progesterone determination may also predict LBR

Wider implications of the findings: We demonstrate a non-linear effect indicating an optimal value and decreasing effect for both lower and higher values. The currently admitted threshold of 1.5 ng/ml is arbitrary and poorly sensitive. As this model is independent of retrieved oocytes number, it may represent a guidance in decision-making for cancellation or freeze-all policy

Trial registration number: unnecessary.

O-174   Cumulative ongoing pregnancy and live birth rates following repeated controlled ovarian stimulation (COS) cycles using individualised follitropin delta dosing compared to conventional follitropin alfa dosing

J. Havelock[1], E. Bosch[2], F. Sánchez Martin[3], B. Mirner Klein[4], B. Mannaerts[5], J.C. Arce[6], &. ESTHER-1 and ESTHER-2[7]

[6]Ferring Pharmaceuticals, US Development, Parsippany, U.S.A.
[7]on behalf of the ESTHER-1 and ESTHER-2 trial group, Evidence-based Stimulation Trial with Human rFSH in Europe and Rest of World, Copenhagen, Denmark

Study question: To evaluate the clinical outcome of individualised follitropin delta per treatment cycle and the cumulative ongoing pregnancy and live birth rates following fresh blastocyst transfers after 3 treatment cycles.

Summary answer: The cumulative ongoing pregnancy and live birth rates after 3 treatment cycles were similar between individualised follitropin delta and conventional follitropin alfa treatment.

What is known already: An individualised dosing regimen of follitropin delta (FE 999049) resulted in non-inferior ongoing pregnancy and ongoing implantation rates, and significantly reduced the incidences of preventive interventions for early ovarian hyperstimulation syndrome (OHSS) and preventive interventions and/or OHSS, compared to conventional follitropin alfa treatment (Nyboe Andersen and Nelson et al, Fertil Steril, 2016). There were no reports of neutralising anti-FSH antibodies, neither after the first cycle nor following repeated cycles (Buur Rasmussen et al, Hum Reprod, 2016).

Study design, size, duration: Patients undergoing their first IVF/ICSI cycle were randomised to follitropin delta (n = 665) or follitropin alfa (n = 661). Patients who did not achieve ongoing pregnancy could continue with the same treatment in up to two repeated cycles. In cycle 2 and 3, 252 vs 261 and 95 vs 93 patients were included in the follitropin delta and follitropin alfa groups, respectively. Only blastocyst transfers were performed, but cryopreserved cycles were allowed between or after the fresh cycles.

Participants/materials, setting, methods: In the first cycle, follitropin delta was dosed based on the patient's anti-Müllerian hormone (AMH), measured by Elecsys® AMH (Roche Diagnostics), and body weight, while the follitropin alfa starting dose was 150 IU/day (11 µg). In subsequent cycles the starting doses were adjusted based on ovarian response in the previous cycle. In all cycles, the follitropin delta dose was fixed throughout stimulation, whereas the follitropin alfa dose could be adjusted from day 6 of stimulation.

Main results and the role of chance: The ongoing pregnancy rate with follitropin delta and follitropin alfa, respectively, was 30.7% vs 31.6% in cycle 1, 27.8% vs 25.7% in cycle 2, and 27.4% vs 28.0% in cycle 3. Excluding cryopreserved cycles, the cumulative ongoing pregnancy rate after 3 treatment cycles was 45.1% (300/665) with follitropin delta and 45.7% (302/661) with follitropin alfa, and the cumulative live birth rate was 43.9% (292/665) and 44.5% (294/661), respectively. The mean number of oocytes retrieved and good quality blastocysts was similar between the two treatment groups in each cycle. The average duration of stimulation was consistently 9 days regardless treatment group or cycle. The mean total dose in cycle 1 was 90.0 vs 103.7 µg (p < 0.001) with follitropin delta and follitropin alfa, respectively, 107.7 vs 121.7 µg (p < 0.001) in cycle 2, and 130.0 vs 132.7 µg in cycle 3.

Limitations, reasons for caution: Patients had the option to have one or more cryopreserved blastocyst transfers after each treatment cycle. The follow-up of these pregnancies is still ongoing and therefore not included in these data analyses.

Wider implications of the findings: Repeated cycles of follitropin delta treatment results in the same ongoing pregnancy and live birth rates as follitropin alfa treatment but the individualised follitropin delta dosing algorithm provides a safer treatment option.

Trial registration number: NCT01956110, NCT01956123.

O-175 Cumulative live birth rates following the first ovarian stimulation for IVF/ICSI. A European multicenter analysis of ~15.000 women using individual patient data

N.P. Polyzos[1], P. Drakopoulos[2], J. Parra[3], A. Pellicer[4], H. Tournaye[2], E. Bosch[4], J. Garcia-Velasco[5]

[1]Dexeus University Hospital, Reproductive Medicine, Barcelona, Spain
[2]UZ Brussel, Center for Reproductive Medicine, Brussels, Belgium
[3]Vrije Universiteit Brussel, Medical Statistics, Brussels, Belgium
[4]Instituto Valenciano de Infertilidad, IVI Valencia, Valencia, Spain
[5]Instituto Valenciano de Infertilidad, IVI Madrid, Madrid, Spain

Study question: What is the impact of ovarian response on fresh and cumulative live birth rates (LBR) in women undergoing their first ovarian stimulation cycle?

Summary answer: Although LBRs reach a plateau and subsequently decline when 20 oocytes are retrieved, cumulative LBRs steadily increase with the number of oocytes, exceeding 70%.

What is known already: Despite that controlled ovarian stimulation (COS) has been a milestone in modern ART, several studies supported that it may negatively affect oocyte quality and/or endometrial receptivity. Large registry analyses demonstrated that the highest LBR is associated with an oocyte yield of 10–15, beyond which success rates decline. Still, this was based only on fresh IVF cycle outcome. Taking into account the advancements in cryopreservation techniques and the increasing use of the 'freeze-all' policy, we set to evaluate the most meaningful outcome for patients, the cumulative LBR following the transfer of all fresh and frozen-thawed embryos, after their first ovarian stimulation.

Study design, size, duration: This is the largest multi-center analysis using individual patient data, conducted in 15 tertiary referral Hospitals in Europe. The study included women undergoing their t first ovarian stimulation cycle for IVF/ICSI in an antagonist protocol from 2009 to 2014. All patients were followed up for at least 2 years until using all their fresh and frozen embryos.

Participants/materials, setting, methods: A logistic model was fitted to predict live birth using fractional polynomials to handle the number of oocytes retrieved as a continuous independent variable. The prediction model, allowed the estimation of the probability of live birth in the fresh cycle, and also the cumulative live birth according to the number of oocytes retrieved. Cumulative live birth was defined as the delivery of the first liveborn after the transfer of fresh or all available frozen-thawed embryos.

Main results and the role of chance: In total, 14469 patients were analysed. The median number of eggs retrieved per cycle was 9 [inter-quartile range (IQR) 6–14]. Cumulative live birth rates steadily increased with the number of oocytes, reaching even 70% when >or=25 oocytes were retrieved. Interestingly, no plateau in cumulative live birth rates was observed but a moderate increase of 5.1% in average was detected beyond 27 oocytes. Regarding the fresh cycle outcome, the optimal number of oocytes was 13, as the likelihood of live birth was 36.5% when 13 eggs were harvested. Although no significant decrease was detected up the number of 20 oocytes, a drop in fresh live birth rates was identified thereafter. The drop in live birth rates could be attributed to the progressive increase in freeze-all cycle rate with the number of oocytes retrieved, exceeding 20% in patients with > 20 oocytes retrieved.

Limitations, reasons for caution: This is a cohort analysis based on retrospective data collection. Despite our robust methodological approach, the presence of biases related to retrospective design cannot be excluded.

Wider implications of the findings: This is the largest multicenter study, with individual patient data, evaluating for the first time the impact of ovarian response on cumulative LBR. The significant progressive increase of cumulative LBR with the number of oocytes, exceeding 70%, suggests that COS is unlikely to have a detrimental effect on oocyte/embryo quality.

O-176 Inherited diseases in donor conceived individuals -what can be expected

L. Bruhn Madsen, G. Koustas, O. Schou

Cryos International, Aarhus, Denmark

Study question: In gamete donor programs thorough efforts are made to avoid inherited diseases; but what can realistically be expected concerning inherited diseases in donor-conceived offspring?

Summary answer: Evidence is provided, that risks of transmitting genetic diseases to donor offspring cannot be avoided. Therefore, informing all parties about this risk is extremely crucial.

What is known already: All humans carry several genetic diseases and are predisposed for various genetic conditions. Gamete donors at sperm and egg banks are currently assessed prior to acceptance by a thorough evaluation of donors personal and family medical history to screen for the risk of potential inherited diseases. However, only some inherited diseases can be elucidated, due to temporal factors, reduced penetrance or variable expressivity. Moreover, it is common for gamete donor banks to perform karyotyping and to screen for a variable number autosomal recessive diseases, using carrier screening to identify and reduce the incidence of a limited number of recessive diseases.

Study design, size, duration: During recent years, there has been a significant increase in the number of reported conditions on gamete donors even though donor screening programs are more thorough than ever. A retrospective review of reported conditions at the sperm and egg bank Cryos International has been carried out on all reported conditions in restricted donors from 2010–2016, representing a total of 124 sperm donors, corresponding to approximately 20% of the total donor cohort at the bank.

Participants/materials, setting, methods: All data were collected from reported conditions in either donor conceived offspring, supplemental tests performed on donors or new diagnoses reported in the gamete donors or in their family. Reports of conditions have been received and collected using standardized procedures throughout the time period in order to notify relevant parties upon specific concerns with respect to elevated genetic risk in offspring.

Main results and the role of chance: 124 donors were assigned a condition based on suspected or established diagnosis of the donor, his family members or in donor-conceived offspring.

32% of the conditions could be attributed to various or suspected recessive diseases and 78% of these were caused by reports from donor-conceived individuals. The remaining cases were discovered mainly due to additional carrier screening introduced, on previously accepted donors.

An autosomal dominant disease was assigned to 7 of the restricted donors despite thorough screening of the medical history at the time of acceptance, but could in some cases be explained by variable expression or penetrance. In a case of branchial fistula further questions to donor's medical history confirmed the finding in the offspring.

48% were assigned a condition due to an increased likelihood for a multifactorial disorder (MD). Congenital heart defects, and autism spectrum disorders, accounted for 21% and 25% of these, reflecting the general population frequency, as these are the most frequent congenital abnormalities. In some cases, it is not evidenced if the MD is associated to the donor since multiple factors are playing a role including preterm delivery, multifetal pregnancies, and advanced maternal age.

Limitations, reasons for caution: Quantification of reported conditions might be biased due to incomplete reporting, i.e. lack of reported conditions, or report of live births. Moreover, some recipients might over attribute medical concerns in a child to inherited factors from the donor.

Wider implications of the findings: This study contributes to the discussion among health care providers, authorities, and recipients to provide clear expectations towards the use of gamete donors as it is impossible to screen out genetic disorders and predispositions for genetic diseases, since all individuals are carriers of mutations for various diseases.

Trial registration number: Not applicable.

O-177   The role of sialyl-Lewis(x)-binding protein and sialidase in spermatozoa-zona pellucida Interaction in humans

Y. Wang[1], C. Lee[1], K. Lam[2], S. Mei[1], W. Yeung[2], E. Ng[2], P. Chiu[1]

[1]The University of Hong Kong, Department of Obstetrics & Gynaecology, Hong Kong, Hong Kong
[2]Queen Mary Hospital, Department of Obstetrics & Gynaecology, Hong Kong, Hong Kong

Study question: Are sperm Sialyl-Lewis(x) (SLeX)-binding protein and sialidase involved in human spermatozoa-zona pellucida (ZP) interaction?

Summary answer: SLeX-binding protein mediates the initial spermatozoa–ZP binding and the sperm sialidase desialylates the ZP glycans for further spermatozoa-ZP interaction and induction of acrosome reaction.

What is known already: Human fertilization begins when a spermatozoon binds to ZP, which induces acrosome reaction of ZP-bound spermatozoon. Defective spermatozoa-ZP binding leads to subfertility and it is an important cause of reduced fertilization rates in assisted reproduction. By using ultrasensitive mass spectrometry, we are the first to identify SLeX sequence as the most abundant terminal sequence on the glycans of human ZP and it is also the major carbohydrate ligand for human sperm-ZP binding. Molecules carrying SLeX can suppress spermatozoa-ZP binding but do not affect acrosome reaction, showing that other molecules are involved in the induction of acrosome reaction during spermatozoa-ZP interaction.

Study design, size, duration: The cellular localization of sperm SLeX-binding protein and sialidase were studied. The roles of SLeX-binding protein and sialidase on sperm functions and their association with capacitation were assessed.

Participants/materials, setting, methods: Spermatozoa were obtained from semen samples from normozoospermic men. Human oocytes were obtained from an assisted reproduction program. Affinity chromatography followed by mass spectrometric analysis was used to identify the SLeX-binding proteins on spermatozoa. The localization/expression of sperm SLeX-binding protein and sialidase were studied by immunostaining and Western blotting. Their functional roles were determined by functional blocking antibody, pharmaceutical inhibitors or competitive substrate. Sperm functions were assessed by standard assays.

Main results and the role of chance: C1orf56 was identified to be one of the SLeX-binding proteins in the membrane protein extracts of capacitated spermatozoa. The acrosomal region (a region known to bind ZP) of spermatozoa possessed C1orf56, sialidase-1 and -3 immunoreactivities and their intensities increased after capacitation in vitro, suggesting translocation of these molecules during capacitation. Blocking the functions of C1orf56 and sialidase-1/3 inhibited spermatozoa-ZP binding and ZP-induced acrosome reaction, but did not affect sperm viability, motility and spontaneous acrosome reaction. The role of sperm sialidase on sperm-ZP interaction was further demonstrated by the increased sperm binding capacity and acrosome reaction-inducing ability of the human ZP after exogenous sialidase treatment.

Limitations, reasons for caution: The functional relationship between sperm SLeX-binding protein and sialidase on spermatozoa-ZP interaction have not been depicted.

Wider implications of the findings: The results provide direct evidence that human spermatozoa-ZP interaction involves different proteins assembled during capacitation. The results also indicate the possible use of sperm surface SLeX-binding protein content and/or sialidase activity determination as sperm function test for prediction of the fertilization potential of semen samples.

O-178   The impact of male partner age on cumulative incidence of live birth following in vitro fertilization

ABSTRACT UNDER PRESS EMBARGO

regulate the timing of sperm cell capacitation and induction of the acrosome reaction, as well as to stimulate sperm motility. Exosomes are universally recognized as small extracellular vesicles (30-120 nm) carrying biological information involved in most physiological and pathological processes.

Study design, size, duration: Normozoospermic men between 18 and 55 years undergoing semen analysis, for their female partner's infertility, have been considered for the enrolment in the project. Patients with varicocele, genito-urinary inflammation, seminal tract infections were excluded. Seminal plasma was collected and process to purify spermatozoa and exosomes.

Participants/materials, setting, methods: Exosomes were isolated by sequential centrifugations and characterized by Nanoparticle Tracking Analysis, transmission electron microscopy and western blot. The uptake of labelled exosomes by spermatozoa was monitored by immunofluorescence and flow cytometry.

Main results and the role of chance: Seminal plasma contain exosomes displaying canonical protein markers such as CD9, CD63, Alix and TSG101. In addition, exosomes represent a discrete population and fall in the expected size range (30-120 nm). Qualitative analysis revealed that they derive from different tissues of the male reproductive tract like epididymis and prostate, carry proteins involved in the spermatozoa maturation and fertilization capacity and in the mechanism of anti-oxidative protection. After ejaculation, sperm cells are still receptive and can continue to receive vesicle-delivered cargos. Indeed, we demonstrated that spermatozoa could uptake exosomes derived from different sources.

Limitations, reasons for caution: This is an explorative analysis of a pilot study.

Wider implications of the findings: Exosomes play a strategic role in sperm maturation and capacitation along the male reproductive tract, but also after ejaculation, opening new perspectives for the assisted *reproductive* technology.

[4]University of Western Australia, School of Women's and Infants' Health, Perth, Australia
[5]Univeristy of Adelaide, Robinson Institute, Adelaide, Australia
[6]ANZAC Research Institute, University of Sydney, Sydney, Australia

Study question: Does antenatal exposure to BPA influence testicular volume, semen parameters and serum reproductive hormone concentrations in adulthood?

Summary answer: There was no evidence that maternal circulating BPA levels, indicative of antenatal exposure, were associated with detrimental effects on adult male reproductive function.

What is known already: Despite the increasing prevalence of trace amounts of xenoestrogens, such as BPA, in the environment, domestic animal sperm production has not changed over 100 years. However, human studies of exposure to exogenous xenoestrogens suggest they may have adverse effects on spermatogenesis, and antenatal exposure to estrogenic phthalates is associated with subtle defects in male genital development. As Sertoli cell proliferation mainly occurs during fetal or early postnatal life, it is proposed that estrogenic environmental exposures during development may influence mature testicular function. We previously demonstrated that elevated cord blood oestrogen levels were associated with a reduced sperm output.

Study design, size, duration: Western Australian (Raine) Cohort men aged 20–22 years (born 1989–1991) underwent testicular ultrasound examination (n = 404) and provided semen (n = 365) and serum (n = 384) samples.

O-179   Human seminal plasma-derived exosomes display canonical exosomal markers and are uptaken by spermatozoa

[1]IRCCS San Raffaele Scientific Institute, Urological Research Institute, Milan, Italy
[2]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy
[3]Exosomics Siena S.p.A., Siena, Italy
[4]Università Vita-Salute San Raffaele, Milan, Italy

Study question: Assessment of the exosomes role in the spermatozoa maturation process

Summary answer: Molecular characterization of exosomes isolated from seminal plasma revealed that they carry proteins involved in the spermatozoa maturation and fertilization capacity.

What is known already: Several organs throughout the male reproductive tract secrete exosomes that keep in contact with sperm cells during their maturation. In animal models, the acquisition of fertilization ability by spermatozoa during epididymal transit occurs in part by the transfer of molecules from membranous vesicles called epididymosomes. Prostasomes, extracellular vesicles released into prostatic fluid by prostate epithelial cells, have been proposed to

Maternal serum collected at 18 and 34 weeks gestation (n = 156) was assayed to determine concentrations of total BPA (post-deconjugation).

Participants/materials, setting, methods: Testicular volume was calculated by ultrasonography, and semen analysis performed by WHO approved methods. Maternal serum (18 & 34 weeks' gestation) was stored at -80^0 C until thawed, when aliquots from both samples were combined to provide an estimate of overall antenatal exposure. Serum was analysed to determine concentrations of luteinising hormone (LH), follicular stimulating hormone (FSH), inhibin B by immunoassays and testosterone by liquid chromatography-mass spectrometry (LC-MS). Total BPA was measured by LC-MS after deconjugation.

Main results and the role of chance: Maternal serum was assayed for BPA from 247 males, 149 of whom underwent testicular volume examination; 136 provided a semen sample and serum hormones were measured in 141. The limit of detection (LOD) of BPA in serum was 0.001 µg/L; 11% of maternal Raine cohort samples had undetectable BPA levels. Blanks were included throughout the deconjugation, extraction and analysis steps to exclude external contamination. The significant number of non-detectable samples suggests systematic contamination was unlikely. Values ranged from ≤0.001 – 12.58 µg/L (median 0.32 µg/L). The 10th, 25th, 75th, 90th and 95th percentile concentrations were ≤0.001 µg/L, 0.12 µg/L, 0.76 µg/L, 1.64 µg/L, 2.64 µg/L, respectively.

After adjustment for time since last ejaculation, maternal serum BPA levels were associated with an increase in sperm concentration (0.18 p = 0.03), and sperm motility (0.18 p = 0.05), but not sperm output (p = 0.11). These associations were lost after adjustment for maternal smoking, and a personal history of smoking, drug use, and presence of a varicocele. No other associations with any measures of male reproductive function (testicular volume, sperm output, or serum testosterone, LH, FSH or inhibin B concentrations) in adulthood were detected. As only two men had cryptorchidism, no association with endocrine disrupter exposure could be examined.

Limitations, reasons for caution: BPA may have leached from the collection and storage vials over time, although this is unlikely as BPA was undetectable in many of the samples analysed. Total BPA was measured, representing both the free and conjugated forms. The study was limited by the sample size.

Wider implications of the findings: This is the first long term study of antenatal BPA exposure on adult male reproductive function; the reassuring findings should be viewed cautiously due to the study's limited sample size and the theoretical potential for external contamination of the analysed sample.

Trial registration number: Natioanl Health and Medical Research Council Project Grant number 634557

SESSION 50: MOSAICISM IN GAMETES AND EMBRYOS

Tuesday 4 July 2017   Room W+X   15:15–16:30

O-181   Comprehensive comparison of inner cell mass and trophectoderm reveals the complex nature of chromosomal mosaicism in human embryos

M. Popovic[1], A. Dheedene[2], C. Christodoulou[1], M. Van der Jeught[1], F. Van Nieuwerburgh[3], D. Deforce[3], P. De Sutter[1], E. Van den Abbeel[1], B. Menten[2], B. Heindryckx[1]

[1]Ghent University Hospital, Department for Reproductive Medicine, Ghent, Belgium
[2]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium
[3]Ghent University, Laboratory of Pharmaceutical Biotechnology, Ghent, Belgium

Study question: To what extent does trophectoderm (TE) biopsy reliably reflect the genomic status of the inner cell mass (ICM) in human blastocysts?

Summary answer: Although concordance between TE and ICM was confirmed in most samples analysed, the very nature of mosaicism can confound diagnosis from a single TE biopsy.

What is known already: The optimisation of next generation sequencing (NGS) platforms for pre-implantation genetic diagnosis/screening (PGD/PGS)

has recently led to an increase in reports of chromosomal mosaicism in TE biopsies. Its precise prevalence, however, particularly at the blastocyst stage of development, is controversial. To date, no comprehensive NGS analyses comparing ICM and TE have been performed. Recent studies have suggested that mosaic embryos may develop into viable pregnancies, indicating that, at present, some potentially euploid blastocysts are inadvertently being classified as clinically unsuitable. Although the ability of NGS to detect mosaicism has immense scientific value, its clinical relevance remains to be elucidated.

Study design, size, duration: We performed intra-embryo comparison of the isolated ICM and multiple TE portions. Overall, 60 samples, from 15 embryos were included in the study, which consisted of two groups. Primarily, biopsies (n = 32) were taken from blastocysts (n = 8), obtained from cryopreserved cleavage-stage embryos. These were donated following standard IVF/ICSI cycles. In addition, vitrified, genetically abnormal blastocysts (n = 7) from PGD/PGS cycles, were warmed and re-biopsied (n = 28). These embryos were selected based on their presumed mosaic chromosomal profile.

Participants/materials, setting, methods: Four biopsies were taken from good-quality blastocysts. Initially, ICMs were isolated using micromanipulation techniques, while the TE was further segregated into three portions. Sureplex whole genome amplification (WGA) followed by shallow whole genome sequencing, was performed on all embryo biopsies, at a ~5 Mb resolution. Genomic profiles were compared between samples from the same embryo, while results from pre-tested blastocysts were further correlated to the original report.

Main results and the role of chance: The overall concordance between ICM and all three TE samples was 73.3% in both embryo groups. Within the untested group, 37.5% (3/8) of embryos presented with normal profiles, while 25.0% (2/8) were abnormal, with consistent results in all four biopsies. Strikingly, a normal ICM was detected in 25.0% of the untested blastocysts, for which at least one TE sample was abnormal. Conversely, one embryo presented with an abnormal ICM, while normal profiles were observed in the respective TE samples. The trisomy 6 detected in this particular ICM, appeared to be mosaic and is not associated with a viable outcome. Evidence of mosaicism was also noted in the selected PGD/PGS blastocysts. Of these results, 42.9% (3/7) did not match the original TE biopsy. Specifically, re-analysis of an embryo with a mosaic 9q deletion, revealed a normal profile in the ICM and all TE samples. Similarly, for a further blastocyst, a mosaic monosomy 4 detected in addition to a balanced translocation in the original TE biopsy, was not observed in our analysed portions. Moreover, for one embryo we observed varying mosaic aberrations in the original profile and the biopsied segments, with additional aberrations detected in the re-biopsied portions.

Limitations, reasons for caution: To establish significance and thoroughly evaluate the occurrence and implications of mosaicism, expanding our study to include more blastocysts is necessary and currently ongoing. The known methodological artefacts of whole-genome sequencing, warrant careful interpretation.

Wider implications of the findings: Our results highlight the complex nature of chromosomal stability during early development. It is clear that a consensus regarding the clinical management of the diagnosis of mosaicism is difficult to attain. More precise quantification may enhance the embryo selection process, furthering efficiency, safety and ultimately improving IVF outcomes.

Trial registration number: N/A.

O-182   The extent of chromosomal mosaicism influence the clinical outcome of in vitro fertilization treatments

ABSTRACT UNDER PRESS EMBARGO

Participants/materials, setting, methods: The involved blastocyst were biopsied on Day 5 and 6. PGS/NGS includes whole-genome amplification, sequencing (Miseq®), and analysis of BlueFuse Multi®. Aneuploidy, low-rate aneuploidy and euploidy were defined as the aneuploid ratio over 50%, 20%–50% and under 20%, respectively. Mosaicism was classified into two categories: "pure mosaicism" as diploid/aneuploid mixture (low-rate aneuploidy), and "aneuploid mosaicism" as an absolutely aneuploidy containing low-rate aneuploidy. Total mosaicism included the pure and aneuploid mosaicism.

Main results and the role of chance: Individual chromosomes were divided into three groups according to their lengths: Group A (>150 Mbp, including chromosome 1, 2, 3, 4, 5, 6, 7, X), Group B (100–150 Mbp, including chromosome 8, 9, 10, 11, 12, 13, 14, 15), and Group C (<100 Mbp, including chromosome 16, 17, 18, 19, 20, 21, 22, Y). The incidence of total mosaicism was significantly higher in the Group A and B than in the Group C (A: 39.3%, B: 34.1%, C: 26.7%, p < 0.0001). Pure mosaicism often occurred in chromosome 1, 7, 16, and aneuploid mosaicism mostly in chromosome 1, 6, 9. Combining together, the highest prevalence of total mosaicism was seen for chromosome 1 (6.9%), 7 (5.5%), 9 (5.7%) and 11 (5.5%). Unlike the meiotic aneuploidies, the observation indicated that mitotic mosaicism tends to occur in the longer chromosomes.

Limitations, reasons for caution: The characteristic of PGS is mainly to detect the variation of chromosome dosage, and is unable to identify the micro-deletion or microduplication (<10 Mb), balanced translocation, inversion, recombination, uniparental disomy (UPD), polyploidy, monoploidy, and very-low percentage of mosaicism.

Wider implications of the findings: The present study suggested that the highest prevalence of mosaicism was mostly in the longer chromosomes, including chromosome 1, 7, 9, and 11. It implied that mosaicism of mitotic origin tends to occur in the longer chromosomes, whereas aneuploidy of meiotic origin are more likely in the shorter chromosomes.

Trial registration number: Not applicable.

O-184 Increased risk of aneuploidy in preimplantation embryos from heterochromatic chromosomal variants carriers

M. Sandalinas[1], E. Garcia-Guixé[1], E. Fernandez[2], E. Toro Toro[1], E. Alsina Xiol[1], E. Balius Fort[1], M. Palahí Bages[1], D. Campos Rodero[1], L. Alvarez[1], C. Giménez i Sevilla[1]

[1]Reprogenetics Spain, Barcelona, Spain
[2]Geniality Diagnóstico Genético, Madrid, Spain

Study question: Is there a correlation between heterochromatic variants in the karyotype of one of the members of a couple and increased risk of aneuploidy in their preimplantation embryos?

Summary answer: In this study, couples with heterochromatic variants in the karyotype show increased aneuploidy rate in preimplantation embryos compared to a control group.

What is known already: Polymorphism variations mainly refer to the variants in the length of the heterochromatic region in the chromosomes 1, 9, 16 and Y; or to the variants in the length of the short arm or the short-arm satellites and stalks of the acrocentric chromosomes (13, 14, 15, 21, 22). These are considered variants of a normal karyotype, without phenotypic effects in the carriers, but they seem to be overrepresented in infertile couples. During the last years, there have been published many articles with conflicting views on the clinical effect of chromosome variants.

Study design, size, duration: Comprehensive chromosome analysis was performed in embryos from couples undergoing IVF-PGD due to previous history of sterility and with one of the partners carrying a heterochromatic polymorphic variant in the karyotype. Results have been analyzed retrospectively. The abnormal karyotypes included in the study were: 46,XY,1qh+; 46, XY,13pss; 46,XY,22 ps+; 46,XY,9qh+; 46,XY,1qh+,9qh+; 46,XY,1qh+,21 ps +; 46,XX,21 ps+; 46,XY,21 ps+.

Participants/materials, setting, methods: 84 embryos (11 IVF-PGD cycles) from couples showing a polymorphism in the karyotype were studied. One blastomere was biopsied from each embryo on D+3 of development. Biopsied samples were amplified and processed for array CGH analysis (Illumina), except for one cycle that was analyzed by Karyolite (PerkinElmer).

O-183 Mosaicism across individual chromosome in trophectoderm biopsies by Next generation sequencing: changes with chromosome length

C.Y. Chen, T.H. Chuang, M.J. Lee, H.H. Lai, H.L. Wang, C.L. Hsieh

Stork Ladies Clinic, Assisted Reproductive Technology, Hsinchu, Taiwan R.O.C.

Study question: To investigate the individual chromosome distribution of mosaicism by next-generation sequencing (NGS) platform.

Summary answer: The highest prevalence of mosaicism was observed within chromosomes 1, 7, 9 and 11; mosaicism of mitotic origin more likely occurs in the longer chromosomes.

What is known already: The aneuploid rate considerably increases with the maternal age, while the mosaicism rate stays constant at each age span (about 25%). The aneuploidy were mainly attributed meiotic errors increased along with gradually maternal age. However, the embryonic mosaicism mostly originated from mitotic errors occurring during the post-zygotic stage, regardless of the maternal age.

Study design, size, duration: A retrospective cohort study during 2015 to 2016, a total of 379 mosaic embryos screened by NGS.

Results were compared with 82 embryos (13 IVF-PGD cycles) from a control group of patients (egg donation cycles, normal karyotypes no male factor associated) analyzed also by aCGH.

Main results and the role of chance: The group of patients with a polymorphisms in the karyotype have a maternal age mean of 30.27 y.o, and the control group of 30.07 y.o (p = 0.9048), allowing further comparisons.

In the study group, the percentage of euploid, aneuploid and other abnormalities (complex abnormalities with >12 aneuploid events and polyploidy) was 27.16%, 49.38% and 23.45%, respectively. The corresponding values observed for the control group were 58.53%, 37.80% and 3.66%.

A statistically significant increase in the percentage of abnormal embryos was observed in the studied group compared with the control one (72.84% vs. 41.46%, p < 0.0001). In 3 out of 11 cycles (27%) no euploid embryos were found.

The study group involved embryos from couples with heteromorphisms in the karyotype, showing increased heterochromatin at the chromosome centromere, telomere or at the short arm. It's been suggested that heterochromatin variation in these regions may cause partial asynapsis, defects in centromere function and kinetochore assembly, difficulty in homologous chromosome pairing, and impact on cell division. All of the above events could affect cell division and gamete formation and might cause the increased aneuploidy observed. Embryo aneuploidy consequences as implantation failure, miscarriage could explain the high percentage of patients with these altered karyotypes referring reproductive failures.

Limitations, reasons for caution: As per the difficulty in recruiting patients with this type of karyotype undergoing IVF-PGD cycle the sample size of this study is limited. More studies should be added.

Wider implications of the findings: This study shows high increase of aneuploidy in embryos from carriers of heterochromatin variant. This finding could explain the high percentage of polymorphisms carriers in infertile population. More attention must be directed to infertile couples with a karyotype revealing those chromosomal variants, and an IVF-PGS cycle should be considered.

Trial registration number: not applicable.

O-185   Reevaluation of the Frequency and Characteristics of Aneuploidy of Surgically Retrieved Spermatozoa in Light of Enhanced Molecular Genetic Techniques

S. Cheung, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We challenged the notion that sampling epididymal and testicular tissues yields spermatozoa with a higher incidence of aneuploidy than those retrieved in the ejaculate.

Summary answer: With the implementation of advanced molecular genetic techniques, we confirmed that surgically retrieved spermatozoa have at least comparable incidence of aneuploidy than those ejaculated.

What is known already: Previous studies, including our own, evidenced, on about 100 testicular spermatozoa in 8 to 13 men and by only 4 chromosome probes, that these spermatozoa have a remarkably higher (13%) occurrence of aneuploidy. This notion, however, did not translate into a higher incidence of miscarriages nor a lower rate of pregnancy. Moreover, ICSI offspring generated from surgically retrieved gametes did not suffer from increased aneuploidy than those generated from ejaculated specimen. In light of the availability of more accurate molecular genetic techniques, we have decided to challenge this dogma.

Study design, size, duration: From December 2014 to November 2016, FISH aneuploidy was carried out on the specimens 2 donor controls, on the ejaculates of 67 men, and on surgical specimens of 6 azoospermic men. To confirm our findings, DNA sequencing technology was carried out on the ejaculates and surgical samples of 20 men. A simultaneous assessment was performed on non-azoospermic men with high DNA fragmentation in their ejaculate. ICSI pregnancy outcome was also analyzed and compared.

Participants/materials, setting, methods: Consenting men treated for infertility provided their specimens. FISH was performed on at least 1000 spermatozoa with a threshold of >1.6% with 2-3% FISH error. DNA was extracted and amplified from a comparable number of spermatozoa by PCR-based random hexamer amplification (average DNA concentration 610 ± 102 ng/ul and quality of 1.7 ± 0.1 nm). By Next Generation Sequencing (NGS), duplications and deletions by Copy Number Variants (CNVs) were then calculated for all chromosomes by CASAVA and VarScan2 software programs.

Main results and the role of chance: A total of 67 couples were included in our study (maternal age 99.9 ± 9yrs and paternal age 39.4 ± 3yrs). Sperm concentration of $9 ± 0.2 \times 10^6$/ml, 25 ± 21% motility, and 1.6 ± 2% normal morphology. Aneuploidy by FISH yielded 0.9% for the donor control but rose in the study group to 3.6% in the ejaculated, 1.2% for the epididymal, and 1.1% for testicular spermatozoa. There were no differences in autosomal or gonosomal disomies, nor nullisomies. In this group, the ejaculated spermatozoa yielded 22% clinical pregnancy rate and 50% with the surgically retrieved specimen.

NGS yielded 1.2% for the control while in the study was 11.1% for the ejaculated specimen and decreased to 1.8% in the epididymal and 1.5% for the testicular (P < 0.0001). The pregnancy rate for the ejaculated specimen was 47.2% and 50% for the surgically retrieved.

Simultaneous aneuploidy assessment on the ejaculated and testicular samples in the same individual evidenced a sperm chromatin fragmentation (SCF) of 20% in the ejaculate while on the testicular spermatozoa was only 8%. The pregnancy rate was 0% with ejaculated while 100% with the testicular spermatozoa. Aneuploidy assessment by FISH evidenced 2.8% in the ejaculated and 1.2% in testicular biopsy while with NGS became 8.4% and 1.3% in testicular biopsy (P = 0.02), respectively.

Limitations, reasons for caution: This is still a limited number of observations carried out on men screened for infertility. If confirmed, this study may suggest that testicular sampling may be beneficial even in non-azoospermic men where retrieving spermatozoa with lower SCF may also control for sperm aneuploidy.

Wider implications of the findings: This study challenges the dogma that testicular spermatozoa conceal a higher proportion of aneuploidy. This implies that testicular gametes do not contribute to chromosomally related pregnancy losses. Moreover, this may explain why offspring from testicular biopsy do not evidence higher autosomal or gonosomal aneuploidy than those resulting from ejaculated spermatozoa.

O-186   Sperm transcript dysregulation: role in recurrent pregnancy loss

V. Dhawan[1], M. Kumar[1], D. Deka[2], V. Dadhwal[2], R. Dada[1]

[1]*All India Institute Of Medical Sciences, ANATOMY, New Delhi, India*
[2]*All India Institute of Medical Sciences, Obstetrics & Gynaecology, New dELHI, India*

Study question: Do sperm transcripts have any relevance in recurrent pregnancy loss?

Summary answer: Paternal transcripts delivered to the oocyte at fertilization are responsible for regulating the critical processes involved in early embryonic development

What is known already: Substantial literature has previously been cited regarding the molecular and cellular events underlying fertilization and early embryonic development. Apart from the previous studies on extensive embryo-maternal interface, the role of paternal factors in embryonic development is being brought to surface. Sperm with disrupted DNA integrity do fertilize an oocyte but on account of being transcriptionally inert and limited repair mechanisms the damage exists post fertilization. It not only affects the outcome of pregnancy but also exert profound impact on the health of the future progeny.

Study design, size, duration: A case control study of 75 male partners of couples experiencing RPL and 30 controls at AIIMS, New Delhi, India. Study duration was 1year.

Participants/materials, setting, methods: Semen samples from male partners of couples experiencing RPL were analyzed for assessing oxidative stress and DNA damage parameters by assessing ROS (reactive oxygen species) levels (RLU/sec/million sperm) and DNA fragmentation index (DFI) by chemiluminiscence assay and sperm chromatin structure assay (SCSA) respectively. q-PCR analysis was performed on the semen specimens after reverse transcribing the RNA isolated from the samples. The relative quantification of target genes was calculated with 2^{DDCt} method after normalization to β-actin.

Main results and the role of chance: The mean DFI was seen to be significantly higher (38.29 ± 9.0%) as compared to controls (27.4 ± 6.4%) (P < 0.0001) in cases as compared to controls. Seminal ROS levels were also seen to be significantly higher (356.9 ± 137.8 vs 26.7 ± 9.8) in cases with respect to controls. The odds of occurrence of RPL was 7.33 times higher, whose DFI>28 % (OR 7.33, 95% CI: (2.23–24.1), and was statistically significant (p = 0.001). While the odds of occurrence of RPL was 0.77 times higher, whose ROS>25 (OR 0.77, 95% CI: (0.3–2.0), and was not significant statistically (p = 0.587). The transcript levels of genes critical for embryonic development were analyzed by q-PCR and were correlated with DFI and ROS levels.

Limitations, reasons for caution: A potential limitation for this ongoing study is limitation in number of controls recruited for the current study. Also the role of maternal factors and other confounding factors which may affect implantation and embryogenesis cannot be negated.

Wider implications of the findings: The events underlying this extensive feto-maternal cross-talk for a successful pregnancy have the limitations of being directly studied in humans, the analysis of factors contributing to its failure will certainly provide insight into the critical steps involved in early embryonic development.

Trial registration number: N/A.

O-187   Trophoblastic spheroids derived from human embryonic stem cells as an early human embryo surrogate

C. Yue[1], Y.L. Lee[1,2], S.W. Fong[1], K.F. Lee[1,2], W.S.B. Yeung[1,2]

[1]The University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong
[2]The University of Hong Kong Shenzhen Hospital, Shenzhen Key Laboratory of Fertility Regulation, Shenzhen, China

Study question: Is the human embryonic stem cells (hESCs) derived trophoblastic 3D spheroid model better than 2D monolayer culture, as embryo surrogate?

Summary answer: The trophoblastic spheroids differentiated in 3D structure expressed significantly higher levels of early trophoblastic markers, and can be used as embryo surrogate for functional study.

What is known already: Implantation failure is a cause of infertility. However, study of human implantation is restricted by lack of a proper model. Trophoblastic cells can be derived from monolayer hESCs by BAP (mouse embryonic fibroblast conditioned medium (CM) supplement with bone morphogenic protein 4 (BMP4), A83-01 and PD173074) treatment, but the in-well differentiated cells is difficult to be used as embryo surrogate in functional study. Recently, our group established a 3D hESC-derived trophoblastic spheroid (BAP-EB) implantation model. Yet, direct comparison of the trophoblastic markers in 3D and 2D models are lacking.

Study design, size, duration: The hESCs were induced to differentiate into trophoblast in 2D (monolayer) and 3D (spheroids) format by using BAP treatment for 4 days. The usefulness of the 3D model in functional attachment assay was further explored using antibodies against adhesion molecules during attachment on endometrial epithelial Ishikawa cells.

Participants/materials, setting, methods: Human ESCs were either cultured in monolayer (2D) or aggregated to form embryoid bodies (EB, 3D) before treated with BAP from 24 to 96 hours. The expressions of trophoblastic markers in the differentiated cells were studied by real-time PCR and compared to choriocarcinoma cell JEG3 spheroids and first trimester trophoblastic (PTB) cells. The effects of antibodies against adhesion molecules (E-Cadherin,

beta3-integrin, Annexin A2) on the attachment of BAP-EB onto Ishikawa cells were studied.

Main results and the role of chance: Our results showed that the 2D trophoblastic cells and 3D BAP-EB had similar expression of the common trophoblastic markers like KRT7, beta-hCG and TFAP2C. However, compared with the 2D in well differentiation, the expression of pluripotent marker OCT4 was significantly lower in BAP-EB after 96 h of differentiation (p < 0.05, Mann-Whitney U test). On the other hand, the expression levels of the early trophoblastic markers CDX2 (at 48 h and 72 h) and ELF5 (at 72 h and 96 h) were significantly higher in BAP-EB. When compared with PTB cells, the expression level of trophoblastic markers like EOMES, ELF5, KRT7 and beta-hCG were similar in BAP-EBs at 72 h or 96 h; while the expression of OCT4, ELF5, KRT7 and beta-hCG were significantly lower in JEG3 spheroids (p < 0.05, Mann-Whitney U test). BAP-EB differentiated for 72 h was then used for the attachment assay. The attachment rate was reduced after blocking Ishikawa with E-Cadherin antibody (CDH1, 64.4% vs. control 83.3%, p < 0.01, chi-square test) but not with antibodies against other adhesion molecules like beta3-integrin (90.0%) or Annexin A2 (96.7%). The higher expression of CDH1 expression in receptive EEC lines (Ishikawa and RL95-2) than the non-receptive EEC lines (AN3CA and HEC1-B), supported a role of E-Cadherin on embryo attachment.

Limitations, reasons for caution: This is an in vitro study to mimic embryo implantation process, and the observations need to be confirmed with human blastocysts.

Wider implications of the findings: With the limited availability of human embryos, the 3D BAP-EBs could potentially be used as embryo surrogate to study implantation. The results of the functional study supported the role of CDH1 in the receptivity of endometrium during implantation.

Trial registration number: not applicable.

O-188   Altered miRNA-profile dependent on ART outcome in plasma of women at the time of embryo transfer and pregnancy test targeting Wnt-pathway

A. Freis[1], A. Keller[2], N. Ludwig[3], E. Meese[3], J. Jauckus[1], E. Capp[1], J. Rehnitz[1], T. Strowitzki[1], A. Germeyer[1]

[1]Department of Gynecologic Endocrinology and Fertility Disorders, University Hospital Heidelberg, Heidelberg, Germany
[2]Chair for Clinical Bioinformatics, Saarland University, Saarbruecken, Germany
[3]Institute of Human Genetics, Saarland University, Saarbruecken, Germany

Study question: Is there a change in microRNA (miRNA) profile of women undergoing ovarian hyperstimulation dependent on the ART outcome and which pathway is targeted?

Summary answer: The presented results show a significant change in miRNA profile dependent on the ART outcome, the most important changes target the Wnt-pathway.

What is known already: Molecular profiling is gaining traction in reproductive medicine. Small non-coding RNAs, so-called miRNAs, are key regulators in physiological but also pathophysiological processes that show a vast impact on fertilization. Recently, some miRNA-clusters targeting important processes during implantation in the embryo and the endometrium have been discovered, targeting genes like TGFbeta, Smad2, Smad 4, MUC 1 or Wnt-signaling. To deepen our knowledge on systemic molecular changes following embryo transfer (ET) we examined the genome-wide miRNA profile of women undergoing ovarian hyperstimulation.

Study design, size, duration: Blood samples were obtained after informed consent from women undergoing ovarian hyperstimulation. Changes in miRNA-expression in plasma of women, whose embryos implanted successfully (n = 6) vs. women who showed no implantation (n = 6) following day 5 embryo transfer (ET), were investigated at day of ET and pregnancy testing (PT). Protein expression to validate the finding was performed with an increased sample size of n = 20 (10 per group). Statistical analysis was performed using paired student's t-test.

Participants/materials, setting, methods: miRNA-analysis was performed using Human miRNA Microarray Kit Release 21.0. Enriched Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analyses was performed using DIANA-miRPath v3.0 software based on predicted targets by DIANA-microT-CDS.

Targets of miRNAs with a score of more than 0.8 were selected. Only KEGG pathways with a P value <0.05 and a false discovery rate (FDR) <0.05 were retained. Wnt3 and Wnt7 were measured by enzyme-linked immunosorbent assay (Cusabio Life Science®).

Main results and the role of chance: No significant differences concerning age, BMI or embryo quality were observed between the two groups. By comparing cases with clinical pregnancy after day 5 transfer with patients whose embryos did not implant, we observed, among others, miR-4327 as the most relevant marker. Systems biology analysis using DIANA-miRPath v3.0 of miRNA alterations highlighted 331 genes that have been experimentally validated as targets of altered miRNAs. Further analysis showed that the 11 miRNAs showing highest significant alterations in our analysis were all associated with regulation of Wnt 3 and Wnt7. Wnt 7 presented with a significant decrease between ET and PT in case of successful implantation (207.18 ± 6.15 pg/ml (ET) vs. 178.81 ± 10.21 pg/ml (PT), p = 0.03) while women with no implantation showed unaffected concentrations (190.37 ± 13.06 pg/ml (ET) vs. 192.48 ± 23.89 pg/ml (PT), p = 0.90). Wnt3 presented with a significant decrease in plasma levels in both groups. However, the loss of Wnt3 between ET and PT was significantly higher in patients with successful implantation compared to women without implantation (relative loss 2.06 ± 0.29 vs. 1.57 ± 0.16, p = 0.03).

Limitations, reasons for caution: Main limitation of this prospective study is its small sample size, defining it as a pilot analysis that requires further validation in a prospective clinical trail allowing to define the best biomarker among the altered miRNAs and possibly detecting even more miRNAs and related proteins predicting implantation success.

Wider implications of the findings: The presented results show a significant change in miRNA profiles dependent on the ART outcome affecting Wnt-pathway. These changes are most likely already visible at the time of embryo transfer. Our findings indicate potential downstream effects influencing pregnancies and a prospective use as biomarkers for implantation success

Trial registration number: Not applicable.

O-189 Attenuated pyruvate kinase M2 signaling pathway: the missing link in hyperhomocysteinemia-associated pregnancy loss

P. Chakraborty[1], S. Banerjee[2], S. Chatterjee[2], S.K. Goswami[3], R. Chattopadhyay[3], S. Ghosh[3], K. Dutta Chowdhury[2], S. Sarkar[4], S.N. Kabir[5], B. Chakravarty[3]

[1]Institute of Reproductive Medicine, Infertility, Kolkata, India
[2]Vidyasagar College, Genetics and Molecular Biology, Kolkata, India
[3]Institute of Reproductive Medicine, ART, Kolkata, India
[4]City College, Zoology, Kolkata, India
[5]CSIR-Indian Institute of Chemical Biology, Reproductive Biology Research, Kolkata, India

Study question: The aim was to identify potential microRNA (miRNA) markers of placental origin for hyperhomocysteinemia associated pregnancy loss.

Summary answer: Ten accurate and reliable miscarriage pathways were identified for hyperhomocysteinemia associated pregnancy loss based on microarray data sets.

What is known already: Pregnancy loss is a multifactorial disorder that often involves impaired placental function due to overt oxidative stress. The mild-to-moderate degree of hyperhomocysteinemia is considered a possible threat to women with placental abruption or recurrent miscarriage. Pyruvate kinase M2 (PKM2) prevents oxidative stress-induced apoptosis, while suppression of PKM2 reduces apoptosis resistance by dephosphorylating bcl-2. miRNAs are putative biomarkers of implantation in early embryonic–endometrial communication, and the spectrum of miRNAs differs between the normal and pathologic conditions. A pathway–based microarray approach may, therefore, identify a distinct profile of miRNAs that carries signature to attest the pathway linking hyperhomocysteinemia-associated miscarriage.

Study design, size, duration: Four-month-old female rats, weighing approximately 150–160 g, were used. Hyperhomocysteinemia was induced in a group of pregnant rats (n = 15) using a pre-validated method (gavaging an aqueous solution of DL-homocysteine at a dose of 100 mg/kg body weight/day for D1 to D18 of pregnancy). The control set (n = 8) received the vehicle at the same volume.

Placental gene expression was studied by microarray, and reconfirmed by quantitative real-time PCR (qRT-PCR) and immunohistochemistry (IHC).

Participants/materials, setting, methods: Placental tissues were isolated on gestational d19 and processed for hematoxylin-eosin staining. Tissue mRNA was extracted and subjected to microarray analysis by using Affymetrix U133 microarray platform to determine differential gene expression. Path analysis was done using Ingenuity pathway analysis. Recursive feature elimination (RFE) was used to evaluate the predictive ability. The significance of differences was evaluated by Pearson's correlation test and Student's t-test (two-tailed). P < 0.05 was considered to be significant.

Main results and the role of chance: Hyperhomocysteinemic rats developed thrombus in the chorionic plate vessels. Microarray analyses revealed alteration in a panel of candidate pathways including oxidative stress, inflammation, angiogenesis, apoptosis, and homocysteine metabolism. A novel pathway featuring PKM2 signaling was characterized. qRT-PCR validation identified a panel of 21 pathways, which were narrowed down to 10 using RFE that discriminated the treated placentas from controls. In the study cohort, the expression of selected genes associated with homocysteine metabolism (cystathionine-β-synthatase (CβS) and PKM2-involved pathways (PKM2, Akt) were down regulated by at least 3-fold while those associated with oxidative stress-mediated inflammation (hypoxia inducible factor-1α (HIF-1α), COX-2, nf-kβ), angiogenesis (sflt-1), and apoptosis (bax, caspase-9) were significantly up-regulated (p < 0.001). IHC scores using a scale from 0 to 3 based on the intensity of staining, correlated with qRT-PCR expression levels (CβS: r = 0.81, P < 0.001; HIF-1α: r = 0.82, P < 0.001; COX2: r = 0.74, P < 0.001; nf-kβ: r = 0.66, P < 0.001; bax: r = 0.62, P < 0.01; caspase 9: r = 0.76, P < 0.001; sflt-1: r = 0.83, P < 0.0001; PKM2: r = 0.79, P < 0.001; Akt: r = 0.66, P < 0.001).

Limitations, reasons for caution: Hyperhomocysteinemia is possibly one of many causes for placental abruption and pregnancy loss. The present study included no experimentally-induced threatened abortion group without involving hyperhomocysteinemia. The results, therefore, provide no evidence that attenuated PKM2 pathways were a direct attribute of hyperhomocysteinemia, rather than a consequence of placental abruption/pregnancy loss.

Wider implications of the findings: This is the first report that PKM2 is aberrantly expressed in miscarriage. The findings provide evidence that an oxidative stress-mediated placental damage perhaps represents the pathogenesis of hyperhomocysteinemia-associated pregnancy loss, which may pave the path towards development of pathway-based therapeutic options for recurrent miscarriage.

Trial registration number: Not applicable.

O-190 The accumulation of vitrified oocytes is a valid strategy to increase the number of euploid available blastocysts for transfer after preimplantation genetic testing

S. Chamayou[1], M. Sicali[2], C. Alecci[3], C. Ragolia[3], A. Liprino[4], D. Nibali[4], G. Storaci[3], C. Cardea[4], A. Guglielmino[1]

[1]Unità di Medicina della Riproduzione U.M.R. Soc.Coop a.r.l., Laboratory director, Sant'Agata Li Battiati, Italy
[2]UMR - Centro HERA, PGD laboratory, sant'agata li battiati, Italy
[3]unità di medicina della riproduzione, IVF laboratory, Sant'Agata Li Battiati, Italy
[4]unità di medicina della riproduzione, IVF department, Sant'Agata Li Battiati, Italy

Study question: The aim was to increase the number of viable euploid blastocysts in patients undergoing PGD-A using fresh oocytes together with previously accumulated vitrified oocytes.

Summary answer: Oocyte vitrification/warming do not generate aneuploidy in blastocysts. The number of viable euploid embryos is increased using for ICSI accumulated vitrified oocytes and fresh oocytes.

What is known already: In a preimplantation genetic diagnosis for aneuploidy (PGD-A) program, the more embryos available for biopsy, consequently increases the chances of obtaining euploid embryos to transfer.

Study design, size, duration: During 2 years, 69 patients with normal ovarian reserve candidates for PGD-A due to repeated implantation failure or recurrent pregnancy loss indication underwent several cycles of ovarian stimulation to accumulate and vitrify oocytes.

Participants/materials, setting, methods: 591 accumulated vitrified oocytes and 463 fresh oocytes were micro-injected with the same partner's semen sample. PGD-A was completed on 134 blastocysts from vitrified/warmed oocytes and 130 blastocysts from fresh oocytes. PGD-A was performed using Next Generation Sequencing technology.

Main results and the role of chance: The euploidy and aneuploidy rates were comparable in blastocysts obtained from micro-injected vitrified/warmed oocytes and fresh oocytes (42.5% versus 40.8% and 57.5% versus 59.2%, *p*>0.05) from the same patients. Implantation rates of euploid blastocysts were comparable between the two sources of oocytes (56.0% from vitrified/warmed oocytes versus 60.9% from fresh oocytes, *p*>0.05).

Limitations, reasons for caution: The present strategy was applied on patients with a normal ovarian reserve. Its potentiality remains to be established for patients with reduced ovarian reserve.

Wider implications of the findings: The number of available blastocysts for biopsy and consequently the number of viable euploid blastocysts for transfer can be increased by accumulating oocytes to micro-inject produced from repeated ovarian stimulations. The present strategy is potentially applicable for all preimplantation genetic protocols.

SESSION 52: NEW INSIGHTS INTO SPERM ANALYSIS
Tuesday 4 July 2017   Plenary 1   17:00–18:00

O-191   The impact of semen parameters and number of dominant follicles on the outcome of intrauterine insemination

S. Chow, M. Irani, C. O'Neill, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: What are the male and female partners' characteristics that can influence the success rate of intrauterine insemination (IUI)?

Summary answer: The number of total motile and morphologically normal spermatozoa (TMN) significantly influence IUI outcomes, particularly in patients with only one dominant follicle.

What is known already: Several factors are related to the outcome of IUI including female age, infertility diagnosis, and number of inseminated motile spermatozoa. There are conflicting data regarding the impact of strict sperm morphology on IUI outcomes. Previous studies comparing sperm morphology criteria often did not control for confounding factors that can influence IUI outcomes. Therefore, it is important to evaluate whether there is any value of normal concentration, motility, and morphology (0%, 1%, 2%, 3%, or 4%), or a combination of the above, that may affect the IUI outcomes taking into consideration the number of ovarian follicles.

Study design, size, duration: It is a retrospective cohort study at an academic medical center. Cycles were either natural or following ovulation induction with Clomiphene citrate, Letrozole, or gonadotropins. All patients who underwent IUI cycles between 2004 and 2013 were reviewed. To control for eventual concealed female factors, inclusion criteria consisted of women ≤35 years who have normal uterine cavity and patent fallopian tubes. Sperm parameters were evaluated according to WHO 2010 criteria.

Participants/materials, setting, methods: A total of 2929 IUI cycles were included. The clinical pregnancy rate (CPR) was compared between patients with different semen volume, concentration, motility, sperm morphology, and number of developing ovarian follicles. χ^2 and Fisher's exact tests were used for categorical variables. Values were expressed as mean +/− standard deviation.

Main results and the role of chance: The mean semen volume was 2.7 ± 1 mL, concentration: $48.5 \pm 22 \times 10^6$/mL, motility: 50.3 ± 9%, and morphology: 3.8 ± 2%. Maternal age was 31.4 ± 3 years and number of dominant follicles ≥16 mm was 1.4 ± 1. Among each individual parameter, morphology affected IUI outcomes only at 0% normal forms with no clinical pregnancy

versus a CPR of 12.9% for a morphology of 1% onward ($P = 0.02$). A combination of total number of motile spermatozoa (TM) at a threshold ≥25x10⁶ was associated with a CPR of 13.8% when compared to < 25x10⁶ at 7.3% ($P < 0.001$). Moreover, a total number of motile and morphologically normal (TMN) spermatozoa of <500.000 yielded only a CPR of 7.1% ($P < 0.001$). Couples whose female partner had ≥2 follicles had a higher CPR compared to those who had just one dominant follicle (16.9% vs. 12.2%; $P = 0.005$). Unless they were zero, TM and TMN spermatozoa did not affect IUI outcomes when the female partner had ≥2 follicles. On the other hand, with only one dominant follicle, the threshold of TM spermatozoa increased to ≥30x10⁶ to yield a 13.6% CPR, compared to 7.4% for those below this threshold ($P = 0.01$). The TMN spermatozoa threshold also rose to ≥800.000, with a CPR of 13.8% above versus 7.2 below threshold ($P = 0.007$).

Limitations, reasons for caution: Although this is a retrospective study, this may serve to define the basis for generating criteria that combine semen characteristics and ovarian superovulation to predict a satisfactory IUI outcome in young women.

Wider implications of the findings: The total number of morphologically normal spermatozoa as well as the number of follicles contribute to IUI outcomes. The lower availability of TMN spermatozoa can be offset by increasing the number of dominant follicles. Couples with 0% normal morphology should undergo in vitro fertilization (IVF).

Trial registration number: Not Applicable.

O-192   Search for new predictive parameters of assisted reproduction outcomes through analysis of male gamete

S. Marchiani[1], L. Tamburrino[1], R. Dolce[1], L. Fanfani[1], F. Benini[2], M. Maggi[1], S. Pellegrini[2], E. Baldi[3]

[1]University of Florence, Dept. of Experimental and Clinical Biomedical Sciences Mario Serio, Florence, Italy
[2]Centro Procreazione Assistita "Demetra", Centro Procreazione Assistita "Demetra", Florence, Italy
[3]University of Florence, Dept. of Experimental and Clinical Medicine, Florence, Italy

Study question: Are sperm chromatin maturity (by aniline blue and chromomycin A3) and expression of Catsper, a sperm-specific calcium channel, predictive of assisted reproduction technique (ART) outcomes?

Summary answer: Sperm chromatin maturity is associated with fertilization rate and embryo quality. CatSper expression is related to embryo quality and, in younger women, with pregnancy achievement.

What is known already: Infertility is a worldwide health problem affecting about 15% of couples. A widely used treatment option for couple infertility is ART. Despite recent improvements, ART success is still low and identification of predictive markers is one of the main goals of current research. Sperm chromatin status of spermatozoa is of fundamental importance for the fertilization process, embryo growth and pregnancy achievement. CatSper, sperm calcium channel, is required for hyperactivated motility, necessary for oocyte penetration. These data prompted us to evaluate chromatin maturity status and CatSper involvement in the fertilization process.

Study design, size, duration: We evaluated chromatin maturity status and expression of Catsper in spermatozoa from 206 male partners of couples undergoing ART within two years. Then, these parameters have been related to ART outcomes (fertilization rate, embryo quality and achievement of pregnancy) using SPSS statistical programme.

Participants/materials, setting, methods: Sperm chromatin status was evaluated by determination of histones persistence (Aniline Blue (AB) staining) and protamination degree (Chromomycin A3 (CMA3) staining) and reported as percentage of AB and CMA3 positive spermatozoa. CatSper expression was determined by immunofluorescence/ flow cytometric method and reported as mean fluorescence intensity.

Main results and the role of chance: Sperm percentage of AB and CMA3 positivity were correlated (r=0.5, p < 0.0001, n = 147). AB positive sperm were negatively associated with fertilization rate (r=-0.2, p = 0.004, n = 163; β=-0.2, p = 0.01 after adjustment for female age and female factor). CMA3 positivity was significantly lower in couples with higher embryo quality (EQ) (median and range values: 12.0 [6.00÷31.00] in EQ ≥0.5, n = 9 vs 23.0

[7.00÷69.00] in EQ<0.5, n = 133, p = 0.005). Conversely, CatSper expression was significantly higher in high quality embryos (median and range values: 5.3 [3.05÷11.10] in EQ≥0.5 n = 16 vs 4.3 [2.00÷14.3] in EQ<0.5, n = 120, p = 0.02). All these results were confirmed in the subgroup of couples with women age ≤ 35 (median age of the cohort), where an association between CatSper expression and achievement of pregnancy was revealed (median and range values 5.2 [3.3÷11.1] in pregnant, n = 20 vs 4.1 [2.0÷12.7] in non-pregnant, n = 44, p = 0.02).

Limitations, reasons for caution: A higher number of recruited couples could strengthen our results, particularly concerning associations with EQ and results in the subgroup of young women.

Wider implications of the findings: AB and CMA3 tests are low cost, easy and rapid to perform and could be introduced in couple infertility work-up. This is the first study evaluating the association between CatSper expression and ART outcomes and suggests a role of the channel in the achievement of a good EQ and pregnancy.

Trial registration number: N.A.

O-193 Testicular versus ejaculated sperm in men without azoospermia: a systematic review and meta-analysis

H. Awaga[1], E. Kolibianakis[2], J. Bosdou[2], D. Goulis[2], G. Grimbizis[2], B. Tarlatzis[2]

[1]Sohag University Hospital, Obstetrics and Gynecology, Sohag, Egypt
[2]Medical School- Aristotle University of Thessaloniki, Unit for Human Reproduction- 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece

Study question: In couples without azoospermia, is the probability of pregnancy higher when testicular as compared to ejaculated sperm is used for ICSI?

Summary answer: In couples without azoospermia, the probability of pregnancy is higher when testicular as compared to ejaculated sperm is used for ICSI.

What is known already: Currently, testicular sperm extraction (TESE) is performed in patients with azoospermia, while in the presence of even a few spermatozoa in the ejaculate, this invasive procedure can be avoided.

Some couples, however, repeatedly fail to achieve pregnancy despite successful fertilization. In these cases, the use of surgically retrieved spermatozoa has been proposed. In fact, this concept has also been evaluated in couples with normal semen analysis but high DNA fragmentation index. However, it is not yet clear whether the probability of pregnancy is higher when testicular as compared to ejaculated sperm is used for ICSI in couples without azoospermia.

Study design, size, duration: A systematic review and meta-analysis was performed aiming to identify trials evaluating whether the probability of pregnancy is higher when testicular as compared to ejaculated sperm is used for ICSI in couples without azoospermia. For this purpose, a relevant literature search was carried out until December 2016. Primary outcome measure was achievement of pregnancy, expressed as clinical pregnancy or live birth. Secondary outcome measures were fertilization rate, number of 2-pronuclei (2pn) oocytes and miscarriage rate.

Participants/materials, setting, methods: One prospective and five retrospective comparative studies offering data to answer the research question were identified including a total of 754 couples who performed 839 ICSI cycles. Meta-analysis of weighted data using random and fixed effects model was performed. Results are reported as relative risk (RR) or weighted mean differences (WMD) with 95% confidence intervals (CI).

Main results and the role of chance: No significant differences were observed between the two groups compared regarding male age, male FSH, testicular volume and DFI, female FSH, antral follicle count, endometrial thickness, number of retrieved oocytes, number of MII oocytes, the number of embryos transferred and the proportion of patients reaching ET.

However, female age was significantly higher in the testicular group compared with the ejaculate group (WMD +1.56, 95%CI: +0.66 to +2.46), while female BMI was significantly lower in the testicular group as compared to the ejaculate group (WMD: -1.23, 95%CI: -2.07 to -0.39).

A significantly higher probability of live birth rate both per started cycle (RR: 1.72, 95%CI 1.28–2.31) and per embryo transfer (ET) (RR: 1.66, 95%CI 1.25–2.22) was present in the TESE as compared to the ejaculate group.

Similarly, a significantly higher probability of clinical pregnancy, both per started cycle (RR: 1.51, 95%CI 1.20–1.91) and per ET (RR: 1.54, 95%CI 1.23–1.93) as well as a lower probability of miscarriage (RR: 0.38, 95%CI 0.21–0.71) were present in the TESE as compared to the ejaculate group.

No significant difference was present in the fertilization rate in the TESE as compared to the ejaculate group (WMD: -6.84, 95%CI -17.53 to +3.86).

Limitations, reasons for caution: The results of the current meta-analysis are based on a limited number of non-randomized studies that do not allow for additional subgroup analyses. In addition, differences have been observed in baseline characteristics between the populations compared that could affect the primary outcome measure assessed.

Wider implications of the findings: The findings of the current meta-analysis, if confirmed, might lead to important changes in the management of patients without azoospermia undergoing ICSI due to male factor. However, it is imperative prior to routinely adopting TESE for ICSI in these patients, to confirm the current results by appropriate randomized controlled trials.

Trial registration number: none.

O-194 The influence of ejaculatory abstinence intervals on semen quality - old concept, new evidences

E. Borges Jr.[1], A.S. Setti[2], R. Provenza[3], D.P.A.F. Braga[1], R.S. Figueira[4], A. Iaconelli Jr.[5]

[1]Fertility Medical Group, Scientific Research, São Paulo, Brazil
[2]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assitida, Scientific Research, São Paulo, Brazil
[3]Fertility Medical Group, Andrology Laboratory, São Paulo, Brazil
[4]Fertility Medical Group, IVF Laboratory, São Paulo, Brazil
[5]Fertility Medical Group, Clinical Department, São Paulo, Brazil

Study question: Do ejaculatory abstinence (EA) intervals influence semen quality and treatment outcomes in couples undergoing intracytoplasmic sperm injection (ICSI) as a result of male infertility?

Summary answer: Longer EA intervals result in higher sperm volume, concentration and TMSC. However, it increases sperm DNA fragmentation and decreases fertilization rate and blastocyst formation.

What is known already: There is no consensus in the literature as to the optimal period of EA for achieving maximum semen quality. Some studies have shown that increasing EA generally increases sperm concentration. Despite the known effects of EA on conventional semen parameters, the effects on general semen quality, such as total motile sperm count (TMSC), sperm DNA fragmentation index (DFI) and motile sperm organelle examination (MSOME) results remain unknown. Additionally, the subsequent effects of EA intervals on ICSI outcomes, such as fertilization, blastocyst formation, pregnancy, and implantation rates are yet to be elucidated.

Study design, size, duration: This prospective cohort study included 818 male patients undergoing conventional semen analysis for infertility investigation, in a private university-affiliated in vitro fertilization center, between October/2015 and October/2016. Regression analyses were used to investigate the influence of EA intervals on semen quality and ICSI outcomes. Results were expressed as regression coefficients (RC) and R-squared (R-Sq) for linear regressions. Odds ratios (OR) with 95% confidence intervals (CI) were used for binary regressions.

Participants/materials, setting, methods: The EA interval was recorded for each patient. Semen samples collected in the laboratory were evaluated for sperm concentration, motility and morphology, according to WHO recommendation. The TMSC was obtained by multiplying the volume of the ejaculate by the sperm concentration and the proportion of progressive motile spermatozoa divided by 100%. Two-hundred spermatozoa per sample were tested for DNA integrity, using the sperm chromatin dispersion test, and were analyzed by MSOME under 6,600×.

Main results and the role of chance: Mean male age was 38.2 ± 6.4 years. Increasing EA intervals positively influenced semen volume (RC: 0.1405, R-Sq: 5.28%, $p < 0.001$), sperm concentration/mL (RC: 3.1261, R-Sq: 2.59%, $p < 0.001$), total sperm concentration (RC: 18.941, R-Sq: 8.37%, $p < 0.001$) and TMSC (RC: 9.6396, R-Sq: 6.14%, $p < 0.001$), while sperm motility (RC: -0.3355, R-Sq: 0.23%, $p = 0.212$) and morphology (RC: 0.0227, R-Sq: 0.23%,

p = 0.215) were not significantly influenced. The number of sperm cells affected by nuclear vacuoles, observed by MSOME, was not influenced by EA intervals (RC: 0.022, R-Sq: 0.08%, p = 0.463), however, the number of sperm cells presenting DNA fragmentation was negatively influenced by increased EA intervals (RC: 0.5355, R-Sq: 2.57%, p < 0.001). As for ICSI outcomes, negative influences of increasing EA intervals on fertilization rate (RC: -0.2123, R-Sq: 5.25%, p = 0.029) and blastocyst formation rate (RC: -0.1252, R-Sq: 4.47%, p = 0.012), however, increasing EA intervals did not influence implantation (RC: -0.0391, R-Sq: 0.01%, p = 0.950) and pregnancy rates (OR: 0.99 CI: 0.91–1.08).

Limitations, reasons for caution: The cut-off value for the EA intervals over which sperm DNA integrity, fertilization and blastocyst formation are negatively affected, is still to be elucidated. Additionally, the lack of information concerning social habits, occupation, and use of medication by men included in the study might have biased the results.

Wider implications of the findings: Lengthening of EA intervals may be associated with sperm DNA damage perhaps because the sperm are exposed to reactive oxygen species in the testicle for prolonged time. Shortening of EA intervals could optimize sperm quality, fertilization and blastocyst formation. Accurate EA intervals should be considered when managing infertile couples.

O-195 Spontaneous activation of human primordial follicles and subsequent follicular development to the antral stage during matrix-free three-dimensional culture

J. Xu[1,2], M. Lawson[1], K. Kester[3], A. Jackman[3], F. Xu[2]

[1]Oregon National Primate Research Center- Oregon Health & Science University, Division of Reproductive & Developmental Sciences, Beaverton, U.S.A.
[2]School of Medicine- Oregon Health & Science University, Department of Obstetrics and Gynecology, Portland, U.S.A.
[3]School of Medicine- Oregon Health & Science University, Department of Pathology, Portland, U.S.A.

Study question: Can human primordial follicles be activated spontaneously in vitro for subsequent follicular development and function during long-term three-dimensional culture in a matrix-free system?

Summary answer: The two-step matrix-free culture supported human primordial follicle activation and development to the small antral stage, as indicated by steroid hormone and autocrine/paracrine factor production.

What is known already: Mouse primordial follicles were activated and grew to the antral stage during two-step culture in a matrix-encapsulated three-dimensional culture system. Human primordial follicles were activated and grew to the pre-antral (primary and secondary) stage, but rarely to the antral stage, during long-term matrix-encapsulated ovarian tissue culture.

Study design, size, duration: The two-step matrix-free culture was performed using ovarian tissue from adult, female patients (26–47 years; n = 6). Ovarian cortex containing primordial follicles was processed into 0.3 mm × 0.3 mm × 0.3 mm pieces (> 5 follicles/piece) and cultured for 3 weeks. Secondary follicles were isolated from cultured ovarian issue for subsequent 6 weeks of culture. Data were analyzed using a one-way ANOVA.

Participants/materials, setting, methods: Ovarian cortical pieces (1 piece/patient) were cultured at 20% O_2 in alpha minimum essential medium supplemented with recombinant human follicle-stimulating hormone and insulin. Secondary follicles (1–5 follicles/patient), mechanically isolated from cultured ovarian tissue at week 3, were cultured individually in the ultra-low-attachment dish. Follicle survival, growth, oocyte size and steroidogenic enzyme expression were assessed. Culture media were analyzed weekly for estradiol, progesterone (mass spectrometry), anti-Mullerian hormone (AMH) and vascular endothelial growth factor (VEGF) (ELISA) concentrations.

Main results and the role of chance: Primordial follicles (diameter 35 ± 0.8 µm) in ovarian cortical pieces were activated spontaneously and grew to the secondary stage during 3 weeks of tissue culture. AMH became detectable in the media at culture week 2 (0.2 ± 0.1 ng/ml). A total of 85% isolated secondary follicles survived additional 6 weeks of individual culture. About 97% of survived follicles formed an antrum at week 3 with diameters increased at week 6 (145 versus 514 µm; $P < 0.05$). Granulosa and theca cells developed in cultured follicles produced aromatase (CYP19A1) and 17α-hydroxylase (CYP17A1), respectively, as indicated by immunohistochemical staining. Concentrations of estradiol, progesterone and VEGF secreted by in vitro-developed follicles increased in the culture media after antrum formation and peaked at week 6 (121 versus 2472 pg/ml; 2 versus 348 ng/ml; 0.2 versus 3.3 ng/ml; $P < 0.05$). Media AMH concentrations increased during secondary follicle culture, peaked at week 3 (0.6 versus 5.5 ng/ml; $P < 0.05$), and plateaued after antrum formation. Healthy germinal vesicle oocytes were harvested from in vitro-developed antral follicles. Oocyte diameters at week 6 were greater than those of secondary follicles at the beginning of culture (90 versus 65 µm; $P < 0.05$).

Limitations, reasons for caution: In the current study, functional assessment of in vitro-developed follicles was limited to steroid hormone and autocrine/paracrine factor production. Oocyte competence following prolonged follicle culture needs further evaluation. Culture conditions could be improved in future studies with increased sample size.

Wider implications of the findings: This study developed a novel culture strategy supporting human primordial follicle activation and development to the antral stage in vitro. The model offers an opportunity to study the process and regulation of folliculogenesis. By achieving the goal of producing competent oocytes, this technique may contribute to fertility preservation in women.

Trial registration number: Not applicable.

O-196 Multicolor flow cytometry: a promising tool for ovarian tissue qualification and minimal residual disease detection in human ovarian cortex

T. Zver[1,2], E. Mouloungui[1,2,3], A. Berdin[4], C. Amiot[1,2,3,5], C. Roux[1,2,3,5]

[1]Centre Hospitalier Régional Universitaire, Biologie et Médecine de la Reproduction-Cryobiologie - CECOS, Besançon, France
[2]INSERM, UMR 1098, Besançon, France
[3]Université de Bourgogne - Franche-Comté, UFR de Sciences Médicales et Pharmaceutiques, Besançon, France
[4]Centre Hospitalier Régional Universitaire, Service de Gynécologie - Obstétrique, Besançon, France
[5]Centre Hospitalier Régional Universitaire, CIC 1431, Besançon, France

Study question: How could fresh or cryopreserved ovarian tissue be qualified from a functional and carcinological point of view?

Summary answer: Multicolor flow cytometry (MFC) is useful to evaluate the presence of leukemic cells and different ovarian cell subpopulations in the ovarian cortex.

What is known already: Ovarian tissue cryopreservation (OTC) is a fertility preservation option for women before gonadotoxic chemo- and/or radio-therapy treatments. However, autograft of cryopreserved ovarian tissue must be performed with caution in women suffering from malignancies that may metastasize to the ovaries. For this purpose, minimal residual disease (MRD) detection in ovarian cortex with sensitive methods is a crucial step. Furthermore, ischemic tissue damage occurring after autograft is currently another important issue to be resolved for successful ovarian transplantation.

Study design, size, duration: We developed an automated ovarian tissue dissociation method to obtain ovarian cell suspensions. Then, we used MFC for MRD detection in the ovarian cortex from leukemia patients and for the identification of different cell subpopulations in the cell suspension thus obtained.

Participants/materials, setting, methods: Human ovarian tissues from patients undergoing surgery for polycystic ovary syndrome (reference tissue) or ovarian tissue cryopreservation (tissue for OTC) were used in this study. Ovarian cortical biopsies (fresh or frozen-thawed) were dissociated using an automated dissociation method. We used 7-AAD and SYTO13 markers to

gate viable ovarian cells by MFC. Variable markers were then chosen to differentiate and identify leukemic cells or cell subpopulations among the viable ovarian cells.

Main results and the role of chance: The dissociation yield was on average $1.58 \pm 1.22 \times 10^6$ and $1.70 \pm 1.65 \times 10^6$ viable ovarian cells per 100 mg of reference ovarian cortex (n = 60) and tissue for OTC (n = 18), respectively (p = 0.781). No significant difference was observed for cell viability after ovarian tissue dissociation between reference ovarian tissue (31 ± 17 %, n = 60) and tissue for OTC (24 ± 20 %, n = 18) (p = 0.088). Ovarian cell subpopulations were isolated from reference ovarian tissue by MFC: on average, 28 ± 10 % of $CD34^+$ cells (n = 30) and 11 ± 6 % of $CD31^+$ cells (n = 20) were identified among viable ovarian cells. In regard to MRD detection in cryopreserved ovarian tissue from leukemia patients, one T-acute lymphoblastic leukemia and 3 acute myeloid leukemia patients showed a positive MRD by MFC among the 12 leukemia patients tested, while no molecular markers were available for these 4 patients.

Limitations, reasons for caution: We do not know if the percentage of $CD34^+/CD31^+$ ovarian cells is a factor associated or not with time for ovarian function recovery after autograft and if disease-free ovarian cortex strips are absolutely safe.

Wider implications of the findings: Functional and carcinological qualification of fresh or frozen-thawed ovarian tissue can be performed by MFC. MRD detection in ovarian cortex by MFC could be applied to all leukemia patients contrary to molecular MRD detection methods. MFC is a promising tool for ovarian cortex qualification before autograft of cryopreserved ovarian tissue.

Trial registration number: Not applicable.

O-197 Glycogen synthase kinase 3 (GSK3) inhibition decreases cisplatin-induced oocyte death in vitro

V. Rossi[1], A. Stefandottir[2], F. Lopes[2], R. Anderson[3], M. De Felici[1], N. Spears[2], F.G. Klinger[1]

[1]University of Rome Tor Vergata, Department of Biomedicine and Prevention, Rome, Italy
[2]University of Edinburgh, Centre for Integrative Physiology, Edinburgh, United Kingdom
[3]University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

Study question: Are pharmacological GSK3 inhibitors able to protect the ovary against cisplatin-induced damage?

Summary answer: GSK3 inhibitors (from GlaxoSmithKline library or commercially available) provide significant protection to oocytes against cell death induced by cisplatin (Cs) in vitro.

What is known already: Several studies have focused on the identification of compounds that, given with the chemotherapeutic drugs, may reduce gonadal toxicity. In particular, we focused on substances able to protect oocytes from Cs-induced damages. Since Cs resistance of some cell types is attributable to reduced activity of certain kinases, in particular of GSK3, we addressed the hypothesis made in the study question

Study design, size, duration: The GlaxoSmithKline library contains 63 inhibitors against the GSK3 pathway; we tested three of such compounds (GW809885X, GW827099X, GW827105X) and also CHIR99021, a commercially available inhibitor. Ovaries obtained from P4 GFP/c-Kit mice, were sliced into 7–8 pieces and cultured for 4 days in α-MEM plus 10% FBS and ITS at 37°C in 5% CO2 in air, until ovarian fragments form individual thin tissue layers containing easily to score GFP-oocytes enclosed within follicles.

Participants/materials, setting, methods: Ovarian fragments were pretreated for 1 h with increasing concentration GlaxoSmithKline inhibitors (0,003-3 μM), and CHIR99021 (3 μM, 5 μM, and 7,5 μM), before adding 10 μM Cs for 24 h plus inhibitors. In each layer, the number of morphologically healthy GFP-positive oocytes was scored before and after treatments.

Main results and the role of chance: At the higher concentration (3 μM), GW809885X and GW827105X but not GW827099X, exerted significant oocyte protection against death induced by Cs (healthy oocytes = 9885X: 55% $\pm$ 6,5%, n: 328; 827105X: 54% $\pm$ 3%, n: 160; 827099X: 59% $\pm$ 18.5%, n: 240; Ctrl: 95% $\pm$ 1,3%, n: 369 and Cs: 25%$\pm$ 2,1%, n: 257; P < 0.05, Anova);

CHIR 99021 showed a similar ovoprotection effect at all three tested concentrations.(3 μM = 50% $\pm$ 3,9%, n: 528, P < 0,01; 5 μM = 59% $\pm$ 4,1%, n: 379, P < 0,001; 7,5 μM = 51% $\pm$ 4,6%, n: 384, P < 0,01).

Limitations, reasons for caution: This screening study has been performed using short term in vitro assay in mice. Results need to be confirmed in vivo and at least in vitro in human and against other chemotherapy drugs. The molecular mechanisms underlying GSK3 ovoprotection against Cs is not known at this point.

Wider implications of the findings: The results outlined here confirm the value of our culture system for rapid and simple drug screening effects on ovarian tissues. The use of GSK pathway inhibitors may provide a novel approach to protect female fertility against chemotherapy.

Trial registration number: Not applicable.

O-198 Effect of inhibitor and activators of PI3K/Akt/mTOR pathway on human primordial follicles activation and growth in vitro: to slow down for better quality?

J. Grosbois[1], I. Demeestere[2]

[1]Research Laboratory on Human Reproduction, Université Libre de Bruxelles, Bruxelles, Belgium
[2]Research Laboratory on Human Reproduction- Fertility Clinic- Gynecology and Obstetrics Department- Erasme Hospital, Université Libre de Bruxelles, Bruxelles, Belgium

Study question: How can biochemical inhibition and activation of PI3K/Akt pathway reduce the spontaneous or induced activation of primordial follicles in vitro, and improve subsequent follicular development?

Summary answer: PI3K/Akt activators triggered a massive follicular recruitment, whereas inhibitor partially safeguarded the follicular reserve. Growing follicles expressed markers of healthy development, but displayed structural abnormalities.

What is known already: Activators of the PI3K/Akt pathway promote activation of human primordial follicles in vitro before grafting in patients with premature ovarian insufficiency, leading to the delivery of few healthy babies. However, rapid and massive follicular activation raises concerns about the quality of growing follicles and the impact on oocyte competence. Recent data challenge their benefit on follicle survival. Here, we hypothesized that everolimus, an mTORC1 inhibitor, might reduce spontaneous massive follicular activation in vitro and slow down growing process, improving subsequent follicular development, through its interaction with PI3/Akt pathway and its antiapoptotic effects observed during organ transplantations.

Study design, size, duration: Fifty-six frozen-thawed ovarian cortex fragments (4x2×1 mm) from 4 patients between 19 and 29 years old were used. Fragments were exposed to either DMSO (control vehicle), everolimus (inhibitor) or bpV (HOpic) and 740Y-P (activators) during the first 24 and 48 h respectively, and cultured for additional 5 days. After 0, 1, 3 and 6 days of culture, early activation, follicular viability, proliferation and development were evaluated by immunohistology, western blot and PCR on isolated follicles (ongoing).

Participants/materials, setting, methods: Early activation was assessed by evaluation of follicle number and developmental stage in sections of ovarian cortical tissue. The developmental potential of follicles was assessed after 6 days of tissue culture, by using GDF9 and Kit Ligand (KL) (development) and Ki67 (proliferation) immunohistochemical markers. Apoptosis was studied by detection of phosphorylated histone H2A.x and by TUNEL (terminal deoxynubocleotidyl transferase-mediated dUTP nick end labeling) analysis.

Main results and the role of chance: A total of 11403 follicles were analyzed. Spontaneous activation of human primordial follicles occurred during the culture period: primordial follicles constituted 90% of the follicular pool at Day 0 (D0) while 80% were activated at D6. The exposure to activators triggered an additional significant drop of the percentage of primordial follicles compared with control (p < 0.05 at D1 and D3; p < 0.001 at D6), whereas culture with inhibitor partially reduced quiescent follicles recruitment (p < 0.01 at D6). Follicles viability was preserved whatever the group and the culture period, and their capacity to proliferate was demonstrated by Ki67 positive staining of the granulosa cells. GDF9 and KL were expressed by the oocyte of in vitro grown follicle, reflecting their ability to develop, although morphological irregularities

were observed in all groups. We hypothesized these defects may be due to the rapid growth, as in vitro folliculogenesis is still highly accelerated compared to in vivo physiology. The assessment of the efficiency of activators and inhibitor to disrupt PI3K/Akt/mTORC1 pathway is currently ongoing by western blot and PCR, as well as the evaluation of follicular quality.

Limitations, reasons for caution: Impact of in vitro culture might cover up the potential benefit of the everolimus on growing follicles morphology after 6 days. It should be later verify in vitro using longer exposure time and in vivo using xenograft model.

Wider implications of the findings: To our knowledge, this is the first study aiming to regulate follicular activation in vitro by slowing down the follicular recruitment and the developmental time frame. The results question the use of accelerated growth systems, and provide new approach to improve in vitro culture of primordial follicle.

Study question: Day of ET is a known prognostic factor for pregnancy. Was this also observed in this study and was there a difference between treatment arms?

Summary answer: Age, site, and day of ET are significant prognostic factors that influence ongoing pregnancy rate. Treatment arm and day of ET do not significantly interact.

What is known already: Oral dydrogesterone is non-inferior (ongoing pregnancy rate at 12 weeks of gestation) to micronized vaginal progesterone (MVP) in IVF when used for luteal support. Dydrogesterone may be an attractive treatment alternative for patients because of the ease of oral administration. Day of ET can vary between day 2 and day 6 after oocyte retrieval following local clinical practice, which can significantly differ between clinical sites and countries where IVF occurs. The day of ET relative to luteal phase support treatment can have an influence on pregnancy rate.

Study design, size, duration: Lotus I was an international Phase III randomized controlled trial, performed across 38 sites, in 7 countries from August 2013 to March 2016. Subjects were premenopausal women (>18 to <42 years) with a documented history of infertility who were planning to undergo IVF. A centralized electronic system was used for randomization to oral dydrogesterone 10 mg tablets with placebo intravaginal capsules three times daily (TID) or MVP 200 mg capsules with oral placebo tablets TID.

Participants/materials, setting, methods: In total for Lotus I, 1031 subjects were randomized to receive either oral dydrogesterone (n = 520) or MVP (n = 511). Luteal support was started on the day of oocyte retrieval and continued until 12 weeks of gestation if a positive pregnancy test was obtained at 2 weeks after ET. Following local clinical practice, ET was performed on different days after oocyte retrieval. Intake of other progesterone products was not permitted during the study.

Main results and the role of chance: In the full analysis set, 497 and 477 subjects in the oral dydrogesterone and MVP groups, respectively, underwent ET. Non-inferiority was demonstrated, with pregnancy rates at 12 weeks' gestation of 37.6% and 33.1% in the dydrogesterone and MVP treatment groups, respectively (4.7% difference; 95% CI: -1.2%–10.6%). Pregnancy rates (%) at 12 weeks gestation varied depending upon the day of ET and treatment group: (dydrogesterone group [95% CI] vs MVP [95% CI], difference [95% CI]): Day 2, 25.0 (16.0, 35.9) vs 18.9 (10.8, 29.7), difference 11.0 (-1.7, 23.7); Day 3, 36.9 (31.2,43.0) vs 35.0 (29.2, 41.3) difference 1.3 (-6.7, 9.3); Day 4, 57.7 (36.9, 76.7) vs 45.2 (27.3, 64.0), difference 16.0 (-7.1, 39.0); Day 5, 42.6 (33.4, 52.2) vs 34.8 (26.1, 64.0), difference 9.4 (-2.9, 21.8). For both groups, the maximum pregnancy rate was achieved on ET Day 4. Dydrogesterone was well tolerated and had a similar safety profile to MVP. Multivariable logistic regression resulted in the following known significant prognostic factors for pregnancy rate: age (p = 0.009), site (p = 0.001), day of embryo transfer (p = 0.0077) and also the treatment group was a significant prognostic factor (p = 0.0427). There was no statistically significant interaction between treatment and day of ET.

Limitations, reasons for caution: Result analysis was powered to demonstrate non-inferiority of oral dydrogesterone vs MVP for the overall clinical pregnancy rate, not for each separate day of ET. Although pregnancy rates differed by ET day in both treatment groups, conclusions relating to the differences between treatments should be made with caution.

Wider implications of the findings: Oral dydrogesterone may replace MVP as the standard of care for luteal phase support in IVF, due to its convenience of administration and efficacy. The treatment group and day of ET were significant prognostic factors, after adjusting for other factors, with a numerically higher pregnancy rate observed with oral dydrogesterone.

Trial registration number: NCT01850030 (clinicaltrials.gov).

O-200　Liquid nitrogen sterility in sperm, oocyte and embryo banking

I. Molina Botella[1], J.V. Martinez Sanchis[1], E. Novella-Maestre[2], J.L. Lopez-Hontangas[3], J. Frasquet[3], J.M. Rubio[1], J. Peman[3]

[1]Hospital Universitari i Politecnic La Fe, Assisted Reproduction Unit, Valencia, Spain
[2]Hospital Universitari i Politecnic La Fe, Department of Genetics, Valencia, Spain
[3]Hospital Universitari i Politecnic La Fe, Department of Microbiology, Valencia, Spain

Study question: To evaluate the potential hazard of disease transmission through cryopreserved and banked gametes and embryos with special attention to the survival of pathogens in liquin nitrogen (LN)

Summary answer: Saprophytic bacteria were found in all of the containers at oocyte-embryos bank and in the 5 oldest containers container at the sperm bank

What is known already: The risk of disease transmission in humans during gamete and embryo cryopreservation and banking has been described. During assisted reproductive procedures cryostorage is the only situation where large quantities of biological materials of patients are kept together in a common liquid medium. Although the temperature of liquid nitrogen is -196°C, it may transmit infective agents from one sample to the other. Also cryoprotectants used during cryopreservation protocols protect bacteria and viruses. Contamination present in LN can be due to exposure to environmental agents during the management and transport of samples as well as to impaired sealed or cracked straws

Study design, size, duration: Retrospective study of the oocyte-embryo and sperm banks LN sterility performed from June 2014 to November 2016 in the Assisted Reproduction Unit in La Fe Hospital. The LN supplied by the company, the storage container, and the LN in the 25 containers at the oocyte-embryo and sperm bank were evaluated for bacteria, fungi and human immunodeficiency virus (HIV), hepatitis B virus (HBV) and hepatitis C virus (HCV)

Participants/materials, setting, methods: LN samples were obtained in closed 120 ml sterile bottles. Vapours LN protocol and straws heat sealed on both sides and 2 ml tubes were used for sperm freezing and storage. Cleavage embryos were stored using closed containers (CryoTip ®). For oocytes and blastocyst open containers (Cryotop®) were used. Vitek2 automated system (BioMerieux) were used for the bacteria identification. Fungus detection was performed by colonies morphology evaluation and their microscopic characteristics. Viruses were evaluated by PCR

Main results and the role of chance: No fungi or virus were observed in any LN samples tested at the sperm, oocyte and embryo banks. Only 5 of the 20 containers of sperm bank showed bacterial contamination which correspond to the oldest containers which have been used over 25 years. Saprophytic bacteria such as Bacillus spp, megaterium and circulans and Sphingomona paucimobilis were found. Bacterial contamination was observed in all of the containers of oocyte-embryos bank. Saprophytic bacteria such as: *Stenotrophomonas maltophilia, Enterobacter spp; Bacillus spp* were found. The number of stored samples was not related to the type of pollution obtained

The air in the room, the operators by contact during processing samples or handling cryogenic tanks could be the cause of bacterial contaminations in oocyte-embryo bank. Therefore it has been demonstrated that cryopreservation technology used nowadays for fertility preservation in men is effective and all methods used to collect, cryopreserve and store human sperm do not increase the risk of cross contamination through LN. Nevertheless, LN manipulation during vitrification of oocytes and embryos could lead to the bacterial contamination observed in the oocyte-embryo bankLimitations, reasons for caution:

The fact that micro-organisms can survive in gametes and embryo cryobanking is not only important for the potential of disease transmission but also for testing for health certification for national and international gamtetes and embryo movement. Periodic chemically sterilization in LN containers is specially recommended for oocyte and embryo banking

Wider implications of the findings: The use of sealed straws and closed tubes in addition to the poor LN handling in sperm freezing decreases the risk of bacterial contamination in sperm banks. LN manipulations in the process of vitrification would be responsible for the high bacterial contamination observed in the oocyte and embryo bank

Trial registration number:

O-201   Lost oocytes and embryos in the ART laboratory

__V.N. Bolton__[1]

[1]*Guy's hospital-, Assisted Conception Unit, London, United Kingdom*

Study question: What is the incidence and nature of accidents in the laboratory resulting in the loss of oocytes or embryos, and what are the contributory factors?

Summary answer: In the UK, during 2015, 73 such incidents were reported during >72,000 treatment cycles, representing an incident rate of around 1 per 1000 cycles.

What is known already: Each of the numerous procedures carried out in the ART laboratory poses technical challenges inherent in the manipulation of microscopic oocytes and embryos, whether moving them between culture dishes, from dish to catheter or between dish and cryopreservation device. Moreover, during multiple procedures, dishes containing oocytes or embryos are moved between microscope stage and incubator, and cryopreservation devices between containers of liquid nitrogen. Each process holds the risk of accidental catastrophic loss of gametes or embryos.

Study design, size, duration: All incidents resulting in loss of oocytes or embryos that were reported to the UK Human Fertilisation and Embryology Authority (HFEA) during 2015 were collated and examined for similarities, trends and contributory factors.

Participants/materials, setting, methods: The HFEA is the body responsible for licensing and regulating ART and embryo research in the UK. It is a regulatory requirement that licensed clinics submit reports, within a prescribed timeframe, of all incidents that result in damage to, or loss of gametes or embryos. The incidents reported to the HFEA by licensed clinics during 2015 were analysed.

Main results and the role of chance: The 73 reported incidents can be divided into 3 broad categories, relating to (i) moving oocytes and embryos between dishes (n = 28); (ii) failure to follow process (n = 26); and (iii) accidents (n = 19). In the first category, there were incidents where oocytes/embryos were not recovered from micropipettes (n = 18), were damaged whilst using micropipettes (n = 4), where the pipette tip had not been secured (n = 2), where oocytes were lost during denudation (n = 2), or because of difficulty with a cryopreservation device (n = 1) or other technical difficulty (n = 1).

Failure to follow process included gametes/embryos discarded in error (n = 6), oocytes not inseminated (n = 2), error during cryopreservation (n = 3), exposure to incorrect reagents (n = 5), error in preparation of culture dishes (n = 3), oocytes/embryos not accounted for (n = 4), and other process errors (n = 3). Accidents occurred where dishes were knocked (n = 4), dropped (n = 6), cryopreservation devices dropped (n = 3) and micropipette tips knocked (n = 5). A single incident reported gamete/embryo loss through bacterial contamination of culture medium.

Limitations, reasons for caution: Differences between licensed centres in interpretation of the definition of an adverse event, and possible variations in levels of adherence to regulatory requirements mean that the number of incidents may be under-reported.

Wider implications of the findings: Detailed SOPs, encompassing all essential confirmation, checking, witnessing and documentation, must be drafted and adhered to rigidly to minimise risk of loss of gametes or embryos. Experience of incidents should be shared widely, within and between clinics, in order that lessons may be learned and steps taken to minimise risk.

Trial registration number: Not applicable.

O-202   Pregnant after using the simplified Walking Egg IVF culture system: Perinatal outcome of the first 60 babies

P. Jacobs[1]**, W. Ombelet**[2]**, M. Janssen**[3]**, I. Van der Auwera**[3]**, K. Vandenborne**[2]**, N. Dhont**[2]**, G. Mestdagh**[2]**, R. Campo**[2]

[1]*Ziekenhuis Oost-Limburg, Sint-Jansziekenhuis, Genk, Belgium*
[2]*Ziekenhuis Oost-Limburg, Department of Obstetrics and Gynaecology, Genk, Belgium*
[3]*Ziekenhuis Oost-Limburg, Department of Fertility, Genk, Belgium*

Study question: What is the perinatal outcome of pregnancies resulting from a new simplified IVF procedure, the so-called Walking Egg IVF culture method?

Summary answer: 60 healthy babies are born after using the Walking Egg simplified IVF system. Results are reassuring with a low figure for prematurity and low birthweight.

What is known already: To assess the potential health risks for the offspring after assisted reproduction (ART) is important, even more crucial if a new technique of IVF culturing is used. Multiple pregnancies are undoubtedly associated with a poorer perinatal outcome but also ART singletons have an increased risk of birth asphyxia, perinatal mortality, low birth weight and preterm birth. The reason why perinatal health problems occur more frequently in ART- singletons compared to naturally conceived singletons is still unclear and probably multifactorial.

Study design, size, duration: We prospectively investigated the perinatal outcome of 60 newborns which were the result of using a new simplified culture system for clinical IVF, the so-called Walking Egg culture system. The results were compared with the perinatal outcome data from all ART (IVF/ICSI) babies born in Belgium in 2014 and the previously published IVF perinatal outcome results in Flanders.

Participants/materials, setting, methods: We studied the perinatal data of all babies born after using the Walking Egg simplified IVF system (fresh and cryo cycles). Pregnancy duration, birth weight, admission to the neonatal care unit, congenital malformations and method of delivery were noted. 60 babies are born, data of this group were compared with the 2014 perinatal outcome data of ART (IVF/ICSI) pregnancies in Belgium and IVF outcome results from the Study Center for Perinatal Epidemiology of Flanders (SPE).

Main results and the role of chance: Perinatal data of 60 newborns (study group) were compared with the perinatal data of 3265 babies born after IVF/ICSI in Belgium in 2014 (BELRAP) and 3974 babies born after IVF (SPE). We found 3 twin and 54 singleton pregnancies, 36 after fresh embryo transfer, and 18 after cryo/thawing. Considering fresh singletons: mean birth weight was 3378 +/− 468 grams, compared to 3211 +/− 588 grams (BELRAP) and 3328 +/− 520 grams (SPE). Prematurity (< 37 weeks) was found in 2.7 % (1/36) compared to 14.2 % and 9.1 % (SPE and BELRAP). Birth weight < 2.5 kg was observed in 2.7 % compared to 11.6 % and 10.4 % in the SPE and BELRAP group respectively. The Caesarean section rate was 20.1 %, 23.8 % and 33.7 % in the study group, SPE and BELRAP group respectively. Cryo babies (18) had a mean birth weight of 3827 grams, comparable with the BELRAP data.

Prematurity and low birth weight was also found in only 1/18 of cases. Twin pregnancies delivered at 34, 37 and 38 weeks, with a birth weight between 2245 and 3170 grams. No congenital malformation could be detected.

Limitations, reasons for caution: Up to December 2016, only 60 babies were born after using this new simplified IVF method. We surely have to enlarge this series to draw firm conclusions. 43 Pregnancies are still ongoing (> 14 weeks), more data can be expected very soon.

Wider implications of the findings: According to our preliminary results, the perinatal outcome of babies born after using the simplified Walking Egg IVF culture system is reassuring. Nevertheless a strict follow-up of all babies born after using this new method remains mandatory.

Trial registration number: Not applicable

O-203   Public perception of In-Vitro Fertilization (IVF) and fertility preservation: assessed by the Listening IVF and Fertility in Europe (LIFE) survey

B.C.J.M. Fauser[1], R. Levy-Toledano[2]

[1]University Medical Center Utrecht, Department of Reproductive Medicine & Gynaecology, Utrecht, The Netherlands
[2]Teva Pharmaceutical Europe, Europe Fertility Medical Manager, Amsterdam, The Netherlands

Study question: To assess the perception of in-vitro fertilization (IVF) and fertility preservation using oocyte-freezing among European men and women.

Summary answer: LIFE survey, conducted in six European countries and over 6000 individuals, indicated wide acceptance of IVF and oocyte-freezing for both lifestyle and medical reasons.

What is known already: Europe has low fertility rates and is amongst the lowest in the world. Biological and lifestyle factors may contribute to the decreasing fertility rates. Although cost and reimbursement of infertility treatment vary in Europe, there is wide access to fertility techniques and services for individuals experiencing infertility. Likewise, oocytes cryopreservation for fertility preservation is generally available throughout Europe to women diagnosed with cancer or other medical conditions that could affect fertility and to those that choose to delay parenthood for lifestyle reasons. Few local studies indicated public support for infertility treatment and fertility preservation.

Study design, size, duration: LIFE survey was conducted via an online questionnaire in September 2016 and was distributed to 8682 individuals. The survey was conducted in six European countries: France, Germany, Italy, Spain, Sweden and the United Kingdom. The survey consisted of twenty-two multiple choice and open-ended questions assessing European men and women's attitudes and opinions toward IVF and oocyte-freezing. Respondents were screened by country of origin, sex, sexual orientation and age.

Participants/materials, setting, methods: European men and women amongst five age groups (16–24 years, 25–34 years, 35–44 years, 45–54 years and >/= 55 years) were provided the online questionnaire via an independent research company. IVF questions assessed the beliefs surrounding the treatment and its success, the need for public funding and the use of IVF among different lifestyles. Oocyte freezing was evaluated in terms of social acceptance and funding.

Main results and the role of chance: A total of 6,110 (70% of total) men and women responded to the LIFE survey. Among the respondents, 55% would or have considered IVF in case of infertility for themselves or their partner or have had IVF treatment. According to the respondents' opinion, the mean maximum age for IVF should be 42 years old. The survey demonstrated support for IVF in single women (61%) and same sex couples (64%). Although 93% of all respondents believed that IVF treatment should be publically funded to some

extent, 78% were willing to pay for IVF. Oocyte freezing was supported by a majority of respondents for both medical reasons (84%) and lifestyle decisions (60%), such as starting a family later in life. Respondents believed the mean maximum age for oocyte freezing should be 39 years old. However, unlike with IVF, 50% of respondents felt the funding for oocyte freezing for medical reasons should not be provided by the government. Overall, it was generally expected that there would be an increase over the next five years in IVF treatment (76%) and oocyte freezing (69%).

Limitations, reasons for caution: With the LIFE survey conducted via an online questionnaire, individual willingness to respond might have been influenced by exposure to infertility (personal, relatives or friends) and over-representation of such individuals cannot be ruled out. Likewise, the very large sample of the individuals surveyed cannot ensure representation of the whole population.

Wider implications of the findings: The survey results provide a general acceptance of IVF and oocyte-freezing for both lifestyle or medical reasons among Europeans. These findings could potentially drive discussions among patients and prescribers to explore either IVF treatment and/or oocyte-freezing and among legislators and payers for the funding of these procedures.

Trial registration number: N/A.

O-204   Apps/calendar methods for trying to conceive – can they accurately predict ovulation?

S. Johnson[1], L. Marriott[2]

[1]SPD Development Company Ltd, Clinical and Regulatory Affiars, Bedford, United Kingdom
[2]SPD Development Company Ltd., Statistics and DataManagment, Bedford, United Kingdom

Study question: Women are only fertile for a limited number of cycle days – in women seeking to conceive, can these days be accurately predicted using calendar methods?

Summary answer: True day of ovulation varies considerably for each cycle length, therefore it is not possible for Calendar/App methods to give accurate prediction.

What is known already: Menstrual cycle characteristics are well published but are based on dated studies of the general population. Women seeking to conceive will commonly use Apps to monitor their menstrual cycle and help them to time intercourse within their fertile period. These Apps utilise historical study data to predict ovulation (assumed to be day 14 for a 28 day cycle). This may not be applicable to the population trying to conceive because they tend to be older and may include a higher incidence of subfertility (referenced by their failure to conceive necessitating use of ovulation prediction) than the general population.

Study design, size, duration: This was a home based observational study. Demographic data was self-reported. 850 volunteers seeking to conceive naturally (>18 years old) were recruited via internet advertisements from across the UK. Volunteers collected daily urine samples for one entire month and completed a daily diary characterising their menstrual cycle.

Participants/materials, setting, methods: Volunteers mean age was 32 years (range: 18–50) and mean body mass index was 26.67 (range: 14.8–63.8). Urinary luteinising hormone was measured using AutoDELFIA (Perkin Elmer, Waltham, MA, USA). Day of ovulation was determined as the day after the LH surge. A probability curve was created for each cycle length to determine likelihood of ovulation on any given day for each cycle length.

Main results and the role of chance: Mean cycle length was 28 days (range: 17–53 days); 34% of volunteers had a 28-day cycle and >90% of volunteers had a cycle length of between 25 and 30 days. On average, women had been trying to conceive for 15 months (range: 1–162 months), had had one previous live birth (range: 0–10) and reported an average of one miscarriage/stillbirth. 3% of women had endometriosis and 7% had polycystic ovary syndrome.

Women actively trying to conceive with a standard cycle length of 28 days (n = 119), only have a 14% probability of ovulating on day 14. Day 16 had the highest probability of being the day of ovulation (21%), but the probability of ovulating was spread across a range of days: day 11 (1%), day 12 (3%), day 13

(7%), day 15 (19%), day 17 (17%), day 18 (10%), day 19 (5%), day 20 (2%). A similar broad spread of probable ovulation days was observed in cycle lengths that were both shorter and longer than 28 days. Apps based on menstrual cycle lengths only, therefore cannot accurately determine ovulation day.

Limitations, reasons for caution: The study was for one menstrual cycle, thus variation in ovulation days between cycles in individual women could not be determined. Despite a large data set, some of the cycle length cohorts only consisted of a small number of women (range: 119 [28-day cycle] to 13 women [23-day cycle]).

Wider implications of the findings: Women seeking to conceive and using calendar-based smartphone apps to time intercourse with fertile days are unlikely to be using accurate information. For a smartphone app to accurately predict when ovulation is possible, it would need to provide women with a very large window during which to have intercourse.

Trial registration number: NCT01577147.

O-205 Children born prior to paternal cancer diagnosis have an increased risk of congenital malformations: a study using Swedish national registries

Y. Al-Jebari[1], L. Rylander[2], A. Giwercman[3]

[1]Lund University, Molecular Reproductive Medicine, Lund, Sweden
[2]Lund University, Department of Occupational and Environmental Medicine, Lund, Sweden
[3]Lund University, Department of Translational Medicine, Malmö, Sweden

Study question: Is paternal cancer associated with increased risk of congenital malformations in the offspring, when offspring birth precedes cancer and cancer treatment?

Summary answer: Children of men having cancer have a statistically significant increased risk of congenital malformations, independently of birth occurring before or after paternal cancer diagnosis.

What is known already: The growing number of male cancer survivors and the potential mutagenic effects of cancer therapies have prompted studies into the health of their offspring. Previously observed increases of birth abnormalities for children born to male cancer survivors have been attributed to the mutagenic effects of cancer therapies. However, the risk of congenital malformations in children fathered by men prior to diagnosis is not known and it is therefore unclear if it is the treatment that is causing the increase in malformations or if this category of men has an inherent increased risk e.g. due to genomic instability.

Study design, size, duration: This registry based study sourced data from the Swedish Medical Birth Register, the Swedish Cancer Register and the Swedish National Quality Register for Assisted Reproduction. All children born in Sweden between 1994 and 2014 (n = 2 108 574) and their fathers (n = 1 181 492) were included and their diagnoses were identified using the registers. The risk of congenital malformations of the children conceived before the father's cancer diagnosis was calculated and compared to counterparts without cancer.

Participants/materials, setting, methods: Paternal cancer diagnoses were retrieved from the Swedish Cancer Register. Similarly, the Swedish Medical Birth Register supplied congenital malformation diagnoses (ICD-8:740–759 & ICD10:Q00Q99). Associations between paternal cancer and birth abnormalities of children conceived prior and after paternal cancer diagnosis, as well as those of healthy fathers, were investigated using binary logistic regression model. The model yielded Odds Ratios (ORs) with 95% Confidence Intervals (CIs). All statistical tests were two-sided and p < 0.05 adopted as statistically significant.

Main results and the role of chance: In our cohort of 1 181 492 fathers, 24 338 (2.1%) had received a cancer diagnosis. Of the n = 28 902 children born to fathers who developed cancer after conception, 3.9 % (n = 1 132) had a congenital malformation, as opposed to 3.5% for the children born to healthy fathers (OR = 1.08, 95% CI = 1.01 to 1.15, p = 0.023). The children (n = 10859) born to fathers who had previously had cancer, had a comparable increase though not statistically significantly so (OR = 1.06, 95% CI=0.944 to 1.19, p = 0.324, 3.7% vs 3.5%). The national cancer registry is a mandatory registry of all cancers in Sweden with an approximated completeness of registration of 99%, ensuring a complete assessment of cancer diagnosis. The role of chance is hence very low.

Limitations, reasons for caution: The degree of detail of registry data was limited due to ethical considerations; therefore detailed information regarding congenital malformation and cancer diagnosis was not available at the start of this study. This data is expected to be released shortly and data thereafter reanalyzed.

Wider implications of the findings: The increase in congenital malformations for children to cancer patients cannot solely be attributed to cancer therapies, indicating that cancer *per se* is causing the observed increase in birth anomalies or that there is an underlying paternal factor, e.g. genomic instability, that gives rise to both conditions.

Trial registration number: N/A.

O-206 In-utero cigarette smoke exposure and the risk of earlier menopause

T.C. Honorato[1], M.L. Haadsma[2], J.A. Land[1], M.H. Boezen[3], H. Annemieke[1], H. Groen[3]

[1]University Medical Center Groningen, Department of Obstetrics and Gynecology, Groningen, The Netherlands
[2]University Medical Center Groningen, Department of Genetics, Groningen, The Netherlands
[3]University Medical Center Groningen, Department of Epidemiology, Groningen, The Netherlands

Study question: Is there an association between in-utero smoke exposure and age at menopause? We hypothesized that in-utero exposed women reach menopause earlier compared to non-exposed women.

Summary answer: In-utero smoke exposure was not associated with earlier menopause. There was no interaction between in-utero smoke exposure and previous or current smoking of participants themselves.

What is known already: Menopause occurs when the follicle pool is exhausted. Cigarette smoking is toxic to female germ cells and smoking women enter menopause approximately one year earlier than their non-smoking peers. Since the follicle pool is prenatally determined, harmful early life events might interfere with timing of menopause. Adult mice that were exposed to smoke in-utero show reduced follicle numbers. Likewise, exposed human embryos and fetuses show fewer germ and granulosa cells in the ovaries. It is expected that in-utero smoke exposed women are born with fewer follicles and therefore reach menopause earlier, but the few epidemiological studies available show conflicting results.

Study design, size, duration: This is a cohort study within the Avon Longitudinal Study of Parents and Children (ALSPAC). Pregnant residents (participants) of the Avon County, expected to deliver between April 1st 1991 and December 31st 1992 were included. Participants characteristics for current analysis were obtained using questionnaires from annual follow-up assessments. In 2010, questionnaires were sent to 9028/14541 (62.1%) participants of the initial cohort, 4168/9028 (46.2%) returned the questionnaires, of which 3551 were illegible after 617 exclusions.

Participants/materials, setting, methods: There were 2629/3551 (74.0%) premenopausal and 922 (26.0%) postmenopausal participants. Participants who ever had hormonal therapy (n = 154) or ovarian/uterine surgery (n = 148) were censored at event. Postmenopausal women due to chemotherapy or radiotherapy, other reasons or participants who had missing information were excluded (n = 617). When not available, age at natural menopause was estimated (481/620) by age at filling in the questionnaire minus one year. Cox proportional hazards was used to estimate hazard ratios of menopause.

Main results and the role of chance: Participants were on average 47.6 (± 4.4) years. Average age at menarche was 12.9 ± 1.5 years, 78.5% (2733/3482) of the participants had regular periods at baseline, 94.7% (3305/3491) used oral contraceptives at least once during follow-up and 39.1% (1339/3429) were ever (current or previous) smokers. Age at natural menopause was 50.6 ± 3.7 years. Of all participants, 20.1% (580/2882) were exposed to

cigarette smoke in-utero. In-utero exposure was not associated with age at menopause (HR 1 .02 95%CI 0.85–1.24 p-value=0.81). Participants who were smokers themselves had higher hazards of menopause(HR 1.49 95%CI 1.20–1.85 p < 0.0001). Sensitivity analysis in participants with available age at menopause only did not change the results (HR 1.03 95% CI 0.78–1.35 p-value=0.84). Ever smokers tended to have earlier menopause, both for smokers who had been exposed in-utero (HR 1.45 95%CI 0.87–2.42 p = 0.16) and smokers who were not exposed (HR 1.37 95%CI 0.99–1.89 p-value=0.06) though non-significant. Non-smokers who were exposed in-utero did not have higher hazards of menopause (HR 0.95 0.78–1.17 p-value=0.64).

Limitations, reasons for caution: Exposure period and number of cigarettes smoked during pregnancy by the mothers of participants and their age at menopause were unavailable. The effect of high levels of smoke exposure cannot be excluded. The 18 years follow-up resulted in high drop-out rates and could lead to attrition bias.

Wider implications of the findings: Age at menopause is strongly programmed. Despite reduction of follicles being associated with in-utero smoke exposure shown in previous studies, little variance in age at menopause was observed in our cohort. Mechanisms to spare follicles may counterbalance the effect of in-utero smoke exposure and maintain the predetermined age at menopause.

Trial registration number: not applicable

O-207   Hysteroscopic metroplasty for T-shaped uterus: 23 years of a single-center experience

G. Ducellier-Azzola[1], L. Lecointre[2], M. Hummel[2], O. Garbin[2]

[1]Pôle Mère-Enfant- Centre Hospitalo-Universitaire, Loire-Atlantique, Nantes, France
[2]Centre Médico-Chirurgical et Obstétrical, Alsace, Strasbourg, France

Study question: The primary objective of this study is to evaluate the effect of hysteroscopic metroplasty for T-shaped uterus on living births's rate.

Summary answer: Hysteroscopic metroplasty is a well established surgery. It improves the obstetrical prognosis of patients with T-shaped uterus.

What is known already: T-shaped uterus is due to myometrium excess inducing an under cornual striction. It is related with higher rates of obstetrical complications (miscarriages, tubal pregnancies, premature delivery) and infertility. This is often related with an in-utero diethylstilbestrol exposure.

Study design, size, duration: This is an observational study about 112 patients treated by hysteroscopic metroplasty for T shaped uterus between 1992 and 2016 in a university hospital of Strasbourg, France. Among this patients, 55 were treated for repeated miscarriages and 57 for infertility.

Participants/materials, setting, methods: The population average age was 33,2 years and the average desire pregnancy was about 56 months for the repeated miscarriages group and 42,2 months in the infertility group. Before surgery, 161 pregnancies had been obtained resulting in 2.5% of living births, 787.3% of early miscarriages, 1.9% of late miscarriages and 14.3% of tubal pregnancies.

Main results and the role of chance: After surgery, 51 pregnancies were obtained in the repeated miscarriages group with a significant increased rate of living births (1.4% vs 58.8%, p < 0.02) and lower rate of miscarriages (85.7% vs 19.6%, p < 0.02). In the infertility group, 49 pregnancies were obtained, spontaneously for the half, with a higher rate of living births (14.3% vs 61%, p < 0.02) and a lower rate of tubal pregnancies (71.4% vs 10.2%, p < 0.02). Anatomical results for uterus size and shape were good for respectively 85.9% and 83.5% of cases. Sixty-one percent of the patients had a caesarean section. No case of uterine rupture has been reported.

Limitations, reasons for caution: The obtained pregnancies were still high risk pregnancies with 10% of premature birth in the miscarriages group and 30% in the infertility group. This uterus were considered as scarred uterus. No uterine rupture has been reported in this study.

Wider implications of the findings: Our results are consistent with those of the literature. This surgery is sparsely responsible of complications and should be proposed for every symptomatic patient with T-shaped uterus before medically-assisted procreation.

Trial registration number: not applicable.

O-208   Expectant management may reduce overtreatment in women affected by unexplained infertility confirmed by diagnostic laparoscopy

V. Tagliaferri, S. De Cicco, L. Selvaggi, D. Romualdi, V. Immediata, C. Di Florio, A. Lanzone, M. Guido

Università Cattolica del Sacro Cuore, Gynaecology and Obstetrics, Roma, Italy

Study question: Does the mini-invasive surgery still play a role in the diagnostic work-up and in the management ofthe couples affected by unexplained infertility?

Summary answer: Combined laparoscopy and hysteroscopy allow to select women with a diagnosis of unexplained infertility and to better address these patients to a correct management.

What is known already: At present, the management of unexplained infertility represents a controversial matter. Laparoscopy is the only method able to identify specific peritoneal factors, such as minimal endometriosis and pelvic adhesions, which may impair fertility. ESHRE-ASRM guidelines indicate surgery for infertile women with symptoms, or risk factors, or abnormal hysterosonography/ultrasonography, with no other medical indications to undergo ART. However, the diagnostic and therapeutic role of laparoscopy in asymptomatic women with normal imaging is debated, as few studies previously evaluated the effect of this procedure in terms of reproductive outcome.

Study design, size, duration: Retrospective study. Size: 270 women affected by unexplained infertility (170 women underwent combined surgery, 100 control patients). Duration: 2008–- 2013

Participants/materials, setting, methods: 170 infertile women (age range 25–38 years) with documented normal ovarian, tubal and uterine function underwent combined hysteroscopic and laparoscopic surgery; 100 women refused surgery or ART treatment (control group) choosing expectant management. A retrospective assessment questionnaire was proposed to enrolled women in order to collect the rate of spontaneous or ART-induced pregnancies.

Main results and the role of chance: In the whole group of 270 patients the mean age was 33.84 ± 3.05 years, the mean BMI was $23.5 \pm 2.2 \, kg/m2$. The mean infertility duration was 42.05 ± 5.03 months. The combined surgery revealed pelvic pathologies in 49.4% of patients, confirming the diagnosis of unexplained infertility only in 86 of studied patients. In this group of 86 selected women, 28 of them achieved a spontaneous pregnancy and 23 women obtained pregnancy after ART. The chi-square analysis shows that the pregnancy rate was not influenced by the employment of ART. The rate of spontaneous pregnancy was 32.5% in the 86 subjects with "sine causa" infertility, whereas only 14% of the 100 control women achieved a pregnancy after 18 months of expectant management. The Odds Ratio to obtain a spontaneous pregnancy in women affected by unexplained infertility who underwent surgery compared to control women resulted 2.96 (confidence interval 95%: 1.43–6.11, p < 0.01).

Limitations, reasons for caution: It is a retrospective study performed in a single unit. Although we found an high percentage of spontaneous pregnancies in the surgery group compared to control patients, it cannot be ruled out that factors other than surgery may play a role.

Wider implications of the findings: Diagnostic laparoscopy should be considered in the infertility work-up to screen couples that can be really considered affected by "sine causa infertility", providing possible changes in the management plan. Our results in terms of pregnancy outcome could justify an expectant management as first approach for these patients, avoiding overtreatment.

Trial registration number: N/A.

O-209 The endometriosis fertility index (EFI) is useful for predicting the ability to conceive naturally after laparoscopic surgery, regardless of endometriosis

R. Hobo[1], K. Nakagawa[2], C. Usui[1], R. Sugiyama[1], H. Motoyama[1], Y. Kuribayashi[1], S. Akira[3], R. Sugiyama[2]

[1]Sugiyama Clinic Marunouchi, Center for Reproductive Medicine and Endoscopy, Tokyo, Japan
[2]Sugiyama Clinic, division of Reproductive Medicine, Tokyo, Japan
[3]Nippon Medical School, Center for Reproductive Medicine and Endoscopy, Tokyo, Japan

Study question: We investigated the utility of the endometriosis fertility index (EFI) for predicting the ability to conceive naturally after laparoscopic surgery.

Summary answer: The EFI possesses greater predictive power for a successful pregnancy with natural intercourse or IUI in infertile patients, regardless of endometriosis, than the (r-AFS) classification.

What is known already: The EFI was developed in 2010 as a scoring system for estimating the rate of natural conception after laparoscopic surgery for endometriosis. The EFI includes a detailed evaluation of the appendix (fallopian tubes, fimbriae of fallopian tubes, and ovaries) and accounts for any fallopian tube dysfunction after operation. The EFI was recently indicated to have greater predictive power than the r-AFS for predicting a successful pregnancy with ART in endometriosis patients. However, there have been no reports on the relationship between the EFI and successful pregnancy without ART (natural intercourse or intrauterine insemination) with or without laparoscopic surgery.

Study design, size, duration: From July 2011 through December 2012, 133 infertile patients were recruited. Forty-eight of these patients had unilateral or bilateral endometriomas. All patients underwent diagnostic laparoscopy or laparoscopic ovarian cystectomy. Patients with a history of gynecological operations, other ovarian masses, tubal obstruction or male infertility were excluded from this study, in order to focus on evaluating the correlation between the EFI and its relationship with the reproductive outcomes. Informed consent was obtained from all patients.

Participants/materials, setting, methods: Three-port laparoscopy was performed with an umbilical 3-mm scope port and two additional 3-mm operating ports. The EFI accounts for the following clinical and surgical factors: the patient's age, duration of infertility (years), pregnancy history, r-AFS and least-function (LF) score. Patients who achieved pregnancy naturally after laparoscopy were classified into the pregnant group (P group); the others were classified into the not-pregnant group (NOP group). Several clinical factors were compared between these two groups.

Main results and the role of chance: Fifty-five patients successfully achieved pregnancy after laparoscopic surgery and were therefore classified into the P group; the others (n = 78) were classified into the NOP group. The age and duration of infertility in the P group were significantly lower and shorter than those in the NOP group (p < 0.05). Although there were no significant differences in the proportion of patients with severe r-AFS between the P and NOP groups (30.9% and 39.7%, respectively), the EFI in the P group (7.6 ± 1.6) was significantly higher than in the NOP group (6.8 ± 1.6, p = 0.0063).

A univariate linear regression analysis, we found that a younger patient age, shorter duration of infertility, and higher EFI were positively associated with a successful pregnancy without ART after laparoscopic surgery (p < 0.05).

According to the ROC curve, the cut-off EFI value for predicting a successful natural pregnancy was 7 (AUC=0.713); thus, the patients were divided into two groups: patients with an EFI of 8–10 were classified into the high-EFI group, while those with an EFI ≤ 7 were classified into the low-EFI group. The pregnancy rate of the high-EFI group was 52.5%, which was significantly higher than that of the low-EFI group (31.9%, p < 0.05).

Limitations, reasons for caution: The EFI scoring system has unique characteristics, incorporates historical findings such as patient's age, duration of infertility, and pregnancy history. Patients showing disadvantageous findings among these factors had a lower EFI and the prognosis for achieving pregnancy was poor, regardless of whether they showed a normal pelvic anatomy.

Wider implications of the findings: The average durations between laparoscopic surgery and pregnancy in the high- and low- EFI groups were 4.8 ± 3.8 and 5.0 ± 3.4 months, respectively. The patients were unable to achieve pregnancy within nine months after laparoscopic surgery regardless of their EFI, if they started ART treatment.

Trial registration number: This study does not have RCT status. As a result, therefore, it did not receive a trial registration number.

O-210 Resectoscopic plasty of uterine cervical canal stenosis is effective to enable the post-surgical passage and yields high pregnancy rate

T. Fujiwara[1], F. Matsumura[2], T. Kurosawa[2], N. Watanabe[2], M. Mitsunami[2], M. Noma[2], C. Tabata[2], M. Kusumi[2], M. Murai[2], Y. Tanaka[2], O. Tsutsumi[2]

[1]International University of Health and Welfare Sanno Hospital, Center for Human Reproduction and Gynecologic Endoscopy, Tokyo, Japan
[2]Sanno Hospital, Center for Human Reproduction and Gynecologic Endoscopy, Tokyo, Japan

Study question: Can endoscopic intervention improve uterine cervical canal stenosis and contribute to successful pregnancy after the surgery?

Summary answer: Resectoscopic plasty of uterine cervical canal stenosis was successfully performed and made the passage of the canal much easier, which achieved high post-surgical pregnancy rate.

What is known already: There were several case reports with relatively small number of subject to attempt various approaches to smoothen uterine cervical canal stenosis which disturbed inserting an intra-uterine insemination(IUI) or an embryo transfer(ET) catheter, which include using a stylet with the catheter, preceding dilation of the cervix using dilators and pre-treatment with laminaria. However in some severe cases those methods cannot be applied and thus there were also some reports to surgically improve the condition using hysteroscopy, which seems effective, but the preceding reports included only small number of subject and histological finding was lacking.

Study design, size, duration: This is a retrospective study and the clinical data were picked up from the records. A total of twelve patients was included in the study, whose surgeries were done between 2010 and 2016.

Participants/materials, setting, methods: The infertility patients who had uterine cervical canal stenosis that was obstacle to IUI or ET were indicated to plastic surgery. In doing the surgery written informed consent was obtained from each patients and using a resectoscope mass in the cervical canal was cut or angulation of the canal was smoothened. After the surgery the condition of the canal was evaluated and pregnancy rate was observed.

Main results and the role of chance: The median age and the duration of infertility of the subjects were 38 years old and 34 months, respectively. In all patients the surgery using small sized resectoscopy was performed successfully without any complication. All patients could leave the hospital on the following day. After the surgery either IUI or ET catheter was inserted without difficulty in all patients and there was no case of recurrence of cervical canal stenosis. In all cases resected tissue was examined histologically; three cases had cervical polyp, four cases had mayoma and five cases had unpathological cervical tissue and there was no case of malignant disease. Following the surgery a total of eight patients got pregnant; six were conceived within six months, one within one year and one after four years and six months. All patients but one got pregnant with ET. All patients reached full term delivery without miscarriage, in which three had vaginal delivery and five had cesarean section.

Limitations, reasons for caution: This is a retrospective study and the patients who were estimated to have an indication of the surgery were all recruited to it and thus there was no control.

Wider implications of the findings: Surgical improvement of the uterine cervical canal stenosis by resectoscopic plasty is a powerful and effective tool for further treatment of infertility especially in cases with difficulty to reach intra-uterine cavity, achieving high pregnancy rate without any negative effect during pregnancy.

Trial registration number: not applicable

O-211   Stem cell derived gametes: a slippery slope towards designer babies?

S. Segers[1], H. Mertes[2], G. Pennings[2]

[1]Bioethics Institute Ghent- Ghent University, Department of Philosophy and Moral Sciences, Gent, Belgium
[2]Bioethics Institute Ghent- Ghent University, Department of Philosophy and Moral Sciences, Ghent, Belgium

Study question: Is the fear for designer babies a convincing argument against the development of stem cell derived (SCD-) gametes?

Summary answer: Although SCD-gametes can facilitate the creation of designer babies, this need not undermine the entire enterprise of *in vitro* gamete derivation.

What is known already: The dawn of new reproductive techniques is often accompanied by fears for eugenic practices, the creation of so-called designer babies in particular. The reproductive use of SCD-gametes feeds similar worries, in view of the possibility to select and design embryos with desired non-disease related traits. While such practices have a negative moral connotation, it should be investigated whether or not this moral worry is justified, both in terms of the scientific possibilities (state of the art), and the moral wrongness of selecting and or editing embryos in function of non-disease related traits.

Study design, size, duration: A literature study was performed to delineate how the terms 'eugenics' and 'designer baby' are used and how they relate to each other. Next, claims in the scientific and ethical literature about how SCD-gametes may be used for eugenic purposes were inventoried. These claims were critically evaluated for scientific accurateness. Finally, we question whether the claimed possibility of selecting or genetically designing future offspring based on non-disease related traits is necessarily a morally bad thing.

Participants/materials, setting, methods: Literature study, conceptual analysis, normative analysis.

Main results and the role of chance: A first possibility is to produce large numbers of gametes (especially oocytes) and embryos to select genetic traits. Second, stem cells could be edited via CRISPR/Cas9 and differentiated into gametes. Third, SCD-gamete technology could be used to recombine SCD-gametes with other gametes and derive gametes from the resulting embryos (and so on) to shape the genome through selective breeding, by combining desirable traits that arise in different embryos. Fourth, at present somatic cell nuclear transfer (SCNT) is hindered by the short supply of human oocytes. This could be overcome by means of SCD-gametes. By facilitating SCNT, SCD-gamete technology could ease the creation of embryos with the same genome as someone with a desirable genotype. A last possibility would be to create gametes from persons with desired traits (e.g. via induced pluripotent stem cells) and make these available via gamete banks. Each of these scenarios is premised upon further scientific developments. Given the rapid advance in CRISPR/Cas9, it might become possible to edit embryos so that SCD-gamete technology will be neither a sufficient nor a necessary condition to genetically design offspring. If SCD-gamete technology would become safe, it might nevertheless facilitate eugenic purposes, of which the moral wrongness remains contested.

Limitations, reasons for caution: Gamete derivation from human stem cells is still in the research phase. The question of the moral wrongness of enhancement and eugenics is explored but not 'answered', as it is a fundamentally normative question. Similarly, 'designer baby' is a stipulative concept, as it is contested which interventions amount to 'designing'.

Wider implications of the findings: The causal link between SCD-gamete technology and eugenics/designer babies is weak and speculative. Moreover, the wrongness of such an evolution is contested.

Trial registration number: n/a.

O-212   Are fertility clinics and sperm banks under a moral obligation to perform comprehensive genetic screening of their gamete donors?

H. Mertes

Bioethics Institute Ghent BIG Ghent University, Department of Philosphy and Moral Sciences, Gent, Belgium

Study question: Are fertility clinics and sperm banks under a moral obligation to perform comprehensive genetic screening of their gamete donors?

Summary answer: Although there are good reasons to screen gamete donors more thoroughly than reproductive partners, this moral obligation is limited in scope.

What is known already: There is a trend towards more comprehensive genetic screening of gamete donors, sometimes coupled with preconception carrier testing for the recipient. It appears that many perceive it to be the responsibility of the fertility clinic to preclude the transmission of genetic disorders from donor to child.

Study design, size, duration: Arguments for and against more comprehensive gamete donor screening were gathered and assessed for scientific correctness and normative legitimacy.

Participants/materials, setting, methods: Literature research; normative analysis

The method that is used to bring empirical data (as found in literature research) and normative ethics together is the 'Wide Reflective Equilibrium', the most commonly used method in bioethics.

Main results and the role of chance: While fertility clinics and sperm banks are partly responsible for the wellbeing of the children they help conceive, this responsibility is limited in scope. A first line of argument questioning the ethical requirement of comprehensive screening is based on the analogy with natural reproduction. The arguments that donors should be screened more thoroughly than reproductive partners due to the donor's replaceability and higher number of offspring are flawed. Other morally relevant differences which do place a higher degree of responsibility with the fertility clinic/sperm bank can be translated into a limited screening program and into providing more risk information, rather than guaranteeing a healthy baby.

A second, consequentialist, line of argument looks at the practical implications of more thorough donor screening. A first concern is the raise in cost to screen out limited risks. This negatively effects access. Also, the more screening is applied, the less donors will be found 'fit' to be used in reproduction (as we are all carriers of several harmful mutations). As a response to this, donor and recipient might be screened as a couple to prevent carriership of the same mutation in both parties. This again increases costs and impedes access.

Limitations, reasons for caution: This is a normative analysis, not an empirical study.

Wider implications of the findings: Despite the fertility clinics' and sperm banks' shared responsibility for the health of the children they help conceive, it is overly demanding to state that they have the responsibility to rule out all genetic 'defects' in the offspring. This also has implications for liability claims.

Trial registration number: N/A.

O-213   Ethics of oocyte banking: a qualitative interview study with donors, recipients, social freezers, and professionals on fair collection and distribution of donor oocytes

E. Kool[1], R. Van der Graaf[1], J. Pieters[2], I. Custers[3], B. Fauser[4], A. Bos[4], A. Bredenoord[1]

[1]Julyus Center for Health Sciences and Primary Care- University Medical Center, Department of Medical Humanities, Utrecht, The Netherlands
[2]Medical Center Child Wish, Department of Reproductive Medicine, Leiderdorp, The Netherlands
[3]Academic Medical Center, Department of Obstetrics- Gynaecology and Perinatology, Amsterdam, The Netherlands
[4]University Medical Center, Department of Reproductive Medicine and Gynaecology, Utrecht, The Netherlands

Study question: What are the opinions of oocyte donors, recipients, social freezers and professionals of Dutch oocyte banks on fair collection and distribution of donor oocytes?

Summary answer: The main themes discussed regarding fair collection and distribution were: (financial) compensation for donors, selection of donors and recipients, waiting list procedures and treatment guarantees.

What is known already: Since 2012, three donor oocyte banks in The Netherlands have been set up. However, the demand for donor oocytes exceeds the supply leading to discussion on what entails fair collection and distribution. Suggested approaches are to 1) increase financial compensation for donors, 2) widen the selection criteria for donors or 3) narrow the selection criteria for recipients. This qualitative interview study aims to collect the moral considerations of all parties involved in order to enrich the ethical discussion on fair collection and distribution of donor oocytes in time of scarcity.

Study design, size, duration: The project has been set-up as a qualitative interview study and has taken place from October 2016 to April 2017. Hitherto, 18 semi-structured in-depth interviews were conducted. We will continue inclusion until saturation is reached, which is expected at approximately 30 interviews. The interviews have been audiotaped and transcribed verbatim. Discrete pieces with relevant data were labelled and compared between the transcripts. By means of a constant comparative analysis key themes were distilled.

Participants/materials, setting, methods: The respondents were recruited in three clinics which currently provide assisted reproduction by the use of donor oocytes in the Netherlands: University Medical Center Utrecht, Medical Center Child Wish Leiderdorp and Academic Medical Center Amsterdam. The study population consisted of four groups: oocyte donors, recipients of donor oocytes, women who froze their oocytes for future use and thus have experienced the procedure and professionals engaged with the practice of oocyte donation (gynaecologists, psychologists, social workers).

Main results and the role of chance: Hitherto, interviews(n = 18) were conducted with donors (n = 4), recipients (n = 4), social freezers (n = 3) and professionals (n = 7). In the interviews we aimed to discuss what entails fair collection and distribution of donor oocytes. First, the main themes addressed by the respondents regarding fair collection were: a suitable (financial) compensation and responsible selection criteria for donors. As a reaction to questions on financial compensation respondents addressed issues such as the demand of altruistic motivation to donate, the importance of voluntary donation and the invasiveness of the donation procedure. Moreover, different justifications for the financial compensation were discussed. By questioning the selection of donors the respondents addressed the appropriate age limits for donation, necessity of a completed family and the acceptable risks for genetically transferable diseases. Second, when asking about fair distribution of donor oocytes respondents addressed the importance of proper selection of recipients, fair treatment guarantees and acceptable waiting list procedures. Additionally, respondents discussed the acceptability of distributing donor oocytes with possible increased risks for minor disabilities. Along the importance of organizing the collection and distribution of scarce donor oocytes fairly, respondents expressed the need of increasing public awareness of the possibility of treatment with donor oocytes and the serious shortage of donors.

Limitations, reasons for caution: Donors and recipients who had a positive attitude and experience regarding their treatment were more likely to participate in the study which may have caused a potential bias in the results.

Wider implications of the findings: The findings contribute to the international discussion of the need and actual appearance of altruistically motivated oocyte donation and the justification of a financial compensation. Moreover, this study provides insight in the experienced challenges in case of scarcity of donor oocytes and indications for fair collection and distribution.

Trial registration number: NA.

O-214   How should the field of assisted reproduction respond to calls for banning animal research?

V. Jans, W. Dondorp, G. De Wert

Maastricht University, Department for Health Ethics and Society, Maastricht, The Netherlands

Study question: How should the field of assisted reproduction respond to calls for banning animal research?

Summary answer: To reduce possible health risks of children conceived through assisted reproduction, the field should continue with animal research, while working on optimizing animal research models.

What is known already: There is a growing awareness of the importance of preclinical safety research on new assisted reproductive technologies (ARTs), including animal research using both so called "lower" (e.g. rodents) and so called "higher" animals (e.g. non-human primates, like macaques and baboons). At the same time, there is international support for the three R's (Replace, Reduce, Refine), and the European Union even aims at the full replacement of animals for research.

Study design, size, duration: A literature study was performed to identify and analyze the normative conditions for animal research on ARTs. Interviews with key figures in reproductive medicine were held. Furthermore, a case study on animal research for Stem Cell Derived (SCD) gametes research was performed.

Participants/materials, setting, methods: Articles have been selected from scientific journals focusing on normative aspects of ARTs and animal research. Additionally, legislative reports considering animal research were studied. Finally, for the ethical analysis, the widely accepted method of "wide reflective equilibrium" was used.

Main results and the role of chance: Two tensions were identified; (a) between the importance of safety research and reasons for reducing the use of animals for research, (b) between optimizing research protocols for specific questions and reasons for avoiding the use of non-human primates. Taking into account both the imperative of reducing avoidable reproductive risks of ARTs and the lack of adequate alternatives, at least for the time being, the use of animals in preclinical safety research on ART meets the criteria of proportionality and subsidiarity. Although the proportionality criterion seems to suggest that the use of "lower" animals is always to be preferred, paradoxically, the use of non-human primates may be more proportionate if and in so far this generates more relevant and robust data. Given the importance of the 3 R's, the main challenge is and remains to evaluate each research proposal case by case. At the same time, a further debate about the societal value of new ARTs remains important.

Limitations, reasons for caution: In the highly dynamic field of reproductive biomedicine, new developments may require reconsideration, adaption and fine-tuning of current normative guidance. The possible future availability of new options and alternatives for preclinical safety research may lead to other conclusions than the ones drawn in this article.

Wider implications of the findings: Animal research is, and may always be, necessary for responsible innovation in ARTs, aiming at risk reduction for children thus conceived. We should scrutinize currently used animal models and be open for change, allowing, on conditions, also the use of non-human primates.

Trial registration number: Not applicable

INVITED SESSION

SESSION 58: COCHRANE SESSION: EVIDENCE BASED DECISION MAKING IN FERTILITY TREATMENTS

Wednesday 5 July 2017   Plenary 1   08:30–09:30

O-215   Evidence based decision – are we there yet or have we lost our way?

S. Bhattacharya

University of Aberdeen, Obstetrics and Gynaecology, Aberdeen, United Kingdom

Abstract text
Evidence based decision making – are we there yet or have we lost our way?
   Prof Siladitya Bhattacharya, University of Aberdeen, Scotland, U.K.

Evidence based medicine (EBM) remains the accepted way of delivering high quality effective care. Both the quality of the underlying research and the precision of the findings are important factors which can refine the clarity and strength of evidence based guidelines. In recent years the application of EBM has evolved into a more personalised approach based on individual estimates of the risk of benefit and harm.

Systematic reviews of high quality primary studies remain the currency of EBM. In their absence, there is a need to utilise the best available evidence for clinical decision making. The speed of discovery in assisted reproduction has challenged standard pathways of evidence generation which can be slow and unlikely to yield a definitive answer before new techniques are incorporated into routine clinical practice.

Interventions of unproven effectiveness are not necessarily the same as those which have been proven to be ineffective. It can be argued that the former can be considered in the presence of strong biological plausibility where randomised trials are unethical (e.g. IVF for bilateral salpingectomy), or in situations where the proposed treatment is innocuous and cheap. There is, however, no justification for offering interventions which have been shown to be ineffective.

Successful implementation of EBM needs to overcome a number of recognised barriers including access to, and awareness of, the evidence base, organisational and personal resistance to change, strongly held beliefs and reverence for tradition. Implementation science research has addressed many of these factors but there is room for further improvement. The need to generate a strong evidence base remains critical but we also need effective pathways of transmitting key messages to all stakeholders including patients, clinicians, managers and funders of health services.

O-216   Cochrane hot topics: evidence based laboratory practice

S. Mastenbroek

Academic Medical Center - University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands

Abstract text

As many as one in six couples experience subfertility at least once during their reproductive lifetime. IVF has rapidly evolved as the intervention of choice to help these couples, and has established itself firmly in modern day society. More than 700.000 IVF treatments are conducted worldwide each year. But IVF treatments are not always successful, as about 30 percent of treatments result in the birth of a child. Improvements are sought in every step of the procedure. In the IVF laboratory many things have changed in recent years with the idea of improving IVF success rates. Changes in culture conditions, fertilization methods, embryo selection methods, timing of transfer, and freezing protocols amongst many others. But have these developments actually helped in achieving the goal of increasing IVF effectiveness? And how should we evaluate this? Embryologists naturally focus on embryo development and implantation rates, but what are the outcomes to evaluate in case of IVF effectiveness? And how to deal with all new upcoming technologies? Responsible innovation in reproductive medicine requires to have an answer to these questions. Cochrane evidence provides a powerful tool to assist in this quest. Cochrane evaluates and summarizes evidence from research on for example culture media, ICSI, assisted hatching, preimplantation genetic screening, time-lapse, freeze-all, and the day of transfer. This talk will discuss how, but also to what extent, Cochrane evidence can help to improve the results of the IVF laboratory.

INVITED SESSION

SESSION 59: NEW SOURCES OF GAMETES

Wednesday 5 July 2017   Plenary 2   08:30–09:30

O-217   In vitro generation of germ cells from pluripotent and somatic cells

J.V. Medrano Plaza

Instituto de Investigación Sanitaria Hospital La Fe IIS La Fe, Gynevology and Assisted Reproduction, Valencia, Spain

Abstract text

Up to 15% of people worldwide at reproductive age are affected by infertility, thus representing a significant impact to patients' quality of life. Despite the great progress of IVF treatments, the lack of functional gametes is a major handicap for their success, and usually end up with the need of gamete donation. In the search to offer patients the possibility of being the genetic parents of their children, basic approaches from Regenerative Medicine that allow the creation of functional gametes have gained attention in the last years. Important advances in this field have occurred from the first reports describing the ability of mouse embryonic stem cells to spontaneously give rise to oocyte-like structures fourteen years ago, to the latest ones, describing the complete process of in vitro oocyte generation starting from mouse iPSCs. Importantly, all these findings in animal models have helped to move forward the study of human germ line and nowadays we have evidence for robust in vitro models to differentiate human iPSCs into immature germ cells, and even transdifferentiate somatic cells into a germ cell-like phenotype by genetic modification. Thus, we can say, that today we are closer than ever to translate the in vitro gamete generation technology for future clinical applications. Here, I will try to update and discuss the most recent breakthroughs that research in Regenerative Medicine has achieved in the last years in response to the challenge offered from Reproductive Medicine.

O-218   Ethical concerns related to artificial gametes

H. Mertes

Bioethics Institute Ghent BIG Ghent University, Department of Philosphy and Moral Sciences, Gent, Belgium

Abstract text

The ethical concerns in the context of in vitro gametogenesis (IVG) are related to the goal (research vs reproduction), the source (embryonic stem cells vs induced pluripotent stem cells) and the methods (e.g. embryo research, 'therapeutic cloning' and animal research).

When it comes to the prospect of reproductive use, the main concern is safety, especially when 'personalized' gametes, resulting in genetic parenthood, are produced. This objective not only requires the procedure of deriving gametes from stem cells to become safe and reliable, but also the procedure of producing induced pluripotent stem cells (iPSCs) or somatic cell nuclear transfer (SCNT). Attempts to produce egg cells for a male patient or sperm cells for a female patient will be faced with additional technical barriers, resulting in additional safety concerns. The acceptability of different safety concerns should be evaluated in an absolute and in a relative manner. In absolute terms, the high risk of serious harm standard could be put forward. This means that a substantial amount of safety testing (genomics, epigenomics etc) will be required before clinical implementation and that a thorough follow-up should be installed after clinical implementation. In addition, however, we should consider whether the risks for the welfare of the future children are sufficiently outweighed by the benefits. This is not an easy exercise to make in the context of IVG as there is much controversy over the importance of genetic parenthood. While there is generally little room for additional risks when prospective parents would want to build in (or select for) preferred physical or psychological characteristics in their children, additional risks, costs and efforts are commonly accepted in reproductive medicine in order to establish a genetic connection. The cause of this discrepancy in moral judgement is however underexplored.

In the context of reproductive use, questions are also raised about access and resource allocation. This is an example of very high tech personalized medicine, which is unlikely to become accessible to a broad public anytime soon. Therefore, on the level of public funding and public policy, the question whether society should fund this research seems legitimate.

Regardless of whether IVG would be performed for research purposes, to produce donor gametes or to establish genetic parenthood, embryo research and in many cases the creation of embryos for research purposes will be involved. Acceptance of embryo research varies greatly between countries, given the great divergence in moral status that is attributed to the *in vitro* embryo. This means that research into IVG will necessarily be barred in countries attributing a high moral status to human embryos.

Besides these larger issues, there are also a number of specific applications which have received a lot of attention, such as same-sex couples becoming the

genetic parents of a mutual child, postmenopausal or prepubertal reproduction, involuntary (genetic) parenthood, single reproduction and genetic engineering of future children. Concerns over these applications are oftentimes a mix of an intuitive response (the so-called 'yuck-factor') and legitimate concerns over safety or the welfare of the child.

In conclusion, although the advent of 'artificial gametes' is widely anticipated by many, many ethical concerns line the road to research and especially clinical applications.

O-219   Reprogramming of the oocyte epigenome in early embryonic development

J.A. Dahl[1], I. Jung[2], G. Greggains[3], H. Aanes[1], A. Manaf[1], M. Lerdrup[4], I. Jermstad[5], M. Indahl[3], M. Bjørås[1], K. Hansen[4], K.T. Dalen[5], P. Fedorcsak[3], B. Ren[2], A. Klungland[1]

[4]University of Copenhagen, The Biotech Research and Innovation Centre and Centre for Epigenetics, Copenhagen, Denmark
[5]University of Oslo, Norwegian Transgenic Centre, Oslo, Norway

Abstract text

Maternal-to-zygotic transition is an essential process in early embryonic development. Embryos undergo a minor wave of genome activation shortly after fertilisation, followed by a major wave at late 2-cell stage in mouse, and 4–8 cell stage in human. However, the epigenetic regulation of gene expression in early embryonic development is incompletely understood.

We developed and validated a μChIP–seq method for detection of histone H3K4me3 in as few as 500 cells. Using this technique, we were able to produce histone modification maps for mouse oocytes, 2-cell and 8-cell embryos. H3K4me3 normally displays narrow promoter-specific localisation in active genes of somatic cells. Surprisingly, we found that oocytes contain broad H3K4me3 domains covering ~22% of the genome. These broad domains can exceed 10 kilobases, and can be located far away from transcription start sites.

It has previously been shown that H3K4me3 is established during oocyte growth by histone methyl transferase, MLL2, and is necessary for generation of mature oocytes (Andreu-Vieyra 2010, PLoS Biol 8). We demonstrate that H3K4me3 broad domains are established during oocyte growth, but are lost by 8-cell-stage.

We identified two histone demethylases, Kdm5a and Kdm5b, which are responsible for H3K4me3 demethylation during the 2-cell stage. Knockdown of these two histone demethylases resulted in maintenance of H3K4me3 levels, downregulation of zygotic genome activation genes, and poor embryo development.

Our findings suggest that careful regulation of epigenetic marks is crucial for gene expression in the early embryo development, and abnormalities in these processes can lead to developmental failure. This raises the possibility for a role for epigenetic regulation in infertility.

O-220   How successful is the use of oocytes with Smooth Endoplasmic Reticulum aggregates in ICSI cycles?

I. Mateizel

UZ Brussel, IVF labo CRG, Jette- Brussels, Belgium

Abstract text

Smooth endoplasmic reticulum (SER) is one of the most abundant organelles in the mature oocyte, represented by an interconnected network of membrane-enclosed sacs or tubules. Under the electron microscopy, they appear surrounded by mitochondria, forming structures located in the cortical ooplasm. These structures are involved in the storage and release of Ca2+ during the fertilization process, in the synthesis of lipids and triglycerides, and in energy production.

In gonadotropin-stimulated cycles, the SER may cluster forming SER aggregates (SERa) visible as a round flat disk in the cytoplasm under inverted microscope. The oocytes presenting SERa are considered dysmorphic and have been associated with reduced embryological outcome and an increased risk of congenital anomalies. Therefore, in 2011 the Alpha/ESHRE Consensus strongly recommended not to inseminate mature oocytes (MII) displaying SERa dysmorphism (SERa+). Not all the laboratories followed this recommendation and as a consequence, some of them reported results on the use of dysmorphic oocytes in ICSI/IVF cycles. In this sense, a retrospective analysis of all ICSI cycles carried out between 2009 and 2011 in our centre showed that SERa+ and SERa- oocytes have similar developmental competence after ICSI. Moreover, the transfer of embryos originated from SERa+ oocytes may lead to healthy newborns. Some of the subsequent reports confirmed these results. Nevertheless, data concerning the use of oocytes displaying this dysmorphism are still scarce and a follow up of the children born after the transfer of these embryos is encouraged. Studies should be performed in order to investigate the origin and possible effects of SERa on the molecular status of the oocytes and embryos.

O-221   Harnessing the potential of time-lapse microscopy reveals novel aspects of human fertilization and suggests new morphokinetic parameters

G. Coticchio[1], M. Mignini Renzini[1], P. Novara[1], M. Lain[1], E. De Ponti[2], D. Turchi[1], R. Fadini[1], M. Dal Canto[1]

[1]Biogenesi Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy
[2]San Gerardo Hospital, Department of Medical Physical, Monza, Italy

Study question: Can more accurate application of time-lapse microscopy (TLM) lead to the observation of novel or neglected aspects of human fertilization?

Summary answer: Intensive harnessing of TLM reveals novel or previously poorly characterised phenomena of fertilization, such as a cytoplasmic wave preceding pronuclear formation or pronuclear chromatin polarization.

What is known already: In recent years, preimplantation development has been the object of TLM studies with the intent to develop morphokinetic algorithms able to predict blastocyst formation and implantation. Regardless, our appreciation of the morphokinetics of fertilization remains rather scarce, currently including only times of polar body II (PBII) emission, pronuclear appearance and fading, and first cleavage. This is not consistent with the complexity and importance of this process, calling for further TLM studied aimed at describing previously unrecognised or undetected morphokinetic events and identifying novel developmental biomarkers.

Study design, size, duration: The study involved a retrospective observation by TLM of the fertilization process in 210 oocytes utilised in consecutive ICSI cycles carried out in 2016. Maximum five fertilized oocytes per patients were included in the analysis to reduce possible patient-specific biases. Oocytes of patients with different diagnoses of infertility where included in the analysis, while cases involving cryopreserved gametes or surgically retrieved sperm were excluded.

Participants/materials, setting, methods: Microinjected oocytes where assessed by a combined TLM-culture system (Embryoscope). Crucially, oocytes not amenable to TLM assessment, due to excess of residual corona cells or inadequate orientation to observe polar body II (PBII) emission, were not analysed. Twenty-eight parameters were identified and monitored, relevant to

meiotic resumption, pronuclear dynamics, chromatin organization, and cyto-plasmic/cortical modifications. Times (T) were expressed as mean±SD (hours) and analysed, where appropriate, by Paired T Student or Fisher's exact tests.

Main results and the role of chance: PBII emission (T = 3.1 ± 0.8) was rarely followed (4.3% of cases) by abortive attempt of emission of a third polar body. Pronuclear formation was always preceded by a radial cytoplasmic wave (T = 5.3 ± 1.1), whose site of origin corresponded to that of male pronucleus (PN) formation. The female PN always formed cortically, adjacent to the PBII, while the male PN formed at different central (52.9%), intermediate (33.3%) or cortical (13.8%) cytoplasmic domains. Female and male PN appearance was almost synchronous (T = 6.0 ± 1.1 and T = 6.2 ± 1.2, respectively). PN juxta-position involved rapid (up to 40 μm/hour) and straight movement of the female PN toward the male PN. Female pronuclear chromatin, i.e. nucleolar precursor bodies, became polarized (T = 8.1 ± 2.7) toward the area of pro-nuclear juxtaposition during displacement of the PN from the site of origin, while male chromatin polarization (T = 11.5 ± 4.4; P < 0.0001) was successive to contact between PNs. PN juxtaposition (T = 8.5 ± 2.5) occurred at different cytoplasmic domains (central 48.1%, intermediate 40.5% or cortical 11.4%) and was never followed by separation of PNs. A cortical cytoplasmic halo (T = 11.5 ± 2.4), in most cases (72,7%) asymmetric, formed always after PN juxtaposition and its disappearance (T = 22.9 ± 3.5) shortly preceded PN breakdown (PNBD). PNBD (female, T = 23,9 ± 4.0; male, T = 24.0 ± 4.0; P = 0.04) was rarely asynchronous (7.6%) and occurred concomitantly with chromatin fading.

Limitations, reasons for caution: Possible inter-operator variability in annotation of the novel morphokinetic parameters described in this study should be assessed.

Wider implications of the findings: To our knowledge, these data represent the most detailed description of human fertilization. Many of the illu-strated parameters are novel and should be tested to develop more potent embryo implantation algorithms. Interestingly, localization and timing of the cytoplasmic wave are reminiscent of a key fertilization event, i.e. sperm aster formation.

Trial registration number: Not applicable.

O-222 Morphokinetic differences between male and female embryos

J. Zhang[1], J. Robins[2]

[1]Northwestern Medicine, Northwestern Fertility and Reproductive Medicine, Chicago-IL, U.S.A.
[2]Northwestern Medicine, Northwestern Fertility and Reproductive Medicine, Chicago, U.S.A.

Study question: Are there morphokinetic differences between male and female embryos that are produced by intracytoplasmic sperm injection and cul-tured un-interruptedly for 5-6 days in Embryoscope incubators?

Summary answer: more female embryos reach blastocyst stage by day 5 than male embryos

What is known already: in vitro fertilization and development may alter sex ratio of human embryos

Study design, size, duration: Retrospective analysis of sex ratio of blasto-cysts on Days 5-6 and morphokinetics during the first two days of development following intracytoplasmic sperm injection (ICSI) for patients who elected pre-implantation genetic screening (PGS) for aneuploidy during the calendar year of 2016.

Participants/materials, setting, methods: Patients who elected PGS at Northwestern Fertility and Reproductive Medicine, a university affiliated out-patient facility for assisted reproduction, were included for this study. Trophoblast biopsy of 3–5 cells was performed in blastocysts on days 5 or 6, following ICSI on day 0. Biopsied embryos were vitrified and transferred in later cycle after PGS results were known.

Main results and the role of chance: During calendar year 2016 a total of 395 blastocysts from 121 patients were biopsied for PGS. No PGS results were obtained in 12 blastocysts from 11 patients. Gender information was not reported in 12 blastocysts from 6 patients at patients' request. This study ana-lyzed 371 blastocysts from 105 patients. Mean patient age was 30.8 +/− 2.8

(mean +/− std). There were 273 blastocysts biopsied on Day 5 and 98 on Day 6. Aneuploidy rates were 56.7% or 67.3% (p = 0.053, chi squared test), for blastocysts biopsied on Day 5 or Day 6, respectively. Among blastocysts biop-sied on day 5, 38.4% were males. This is compared with 52% for blastocysts biopsied on day 6 (p < 0.05). Time (hours) needed for pronuclear fadeing after ICSI, 2-cell division, and 4-cell division were 23.7 +/2.9 (mean +/std), 26.3 +/−3.2 and 38.5 +/−4.1 for these 371 blastocysts, and were similar between male and female embryos, and between aneuploid and euploid embryos. However, time for 4-cell division was 37.2 h for embryos reaching blastocysts by Day 5 and 40.5 h for those by Day 6 (p < 0.05, Student's t-test).

Limitations, reasons for caution: These observations need to be verified by further studies with larger sample sizes.

Wider implications of the findings: There are no sex related morphoki-netic differences between embryo during the first two days of development. However, after embryonic gene activation begins, female embryos exhibit faster growth rates than male embryos and are more likely to become blastocysts. This suggests that IVF may alter sex ratios of human embryos.

Trial registration number: not applicable.

O-223 Morphokinetic variables and ploidy: is there still a chance?

F. Pennetta[1], C. Lagalla[1], R. Sciajno[1], N. Tarozzi[1], M. Nadalini[1], M. Di Santo[1], M.A. Bonu[1], A. Borini[2]

[1]9.baby Family and Fertility center, Reproductive Medicine IVF Laboratory Unit, Bologna, Italy
[2]9.baby Family and Fertility center, Reproductive Medicine IVF Clinical Unit, Bologna, Italy

Study question: Despite recent experimental evidence, is it still possible to find a relationship between morphokinetic variables and human blastocyst ploi-dy status?

Summary answer: Since aneuploid human blastocysts showed a delay in the timing of pronuclear appearance (tPNa), an association could exist.

What is known already: Implantation failure is the major cause of patient drop out during infertility treatment so many efforts are directed towards the establishment of methods that can help in the selection of the best embryo. Preimplantation genetic screening (PGS) was introduced to identify genetically healthy embryos and time-lapse microscopy (TLM) was introduced as a non invasive tool for embryo evaluations based on their developmental kinetics. TLM main applications include: prediction of embryo implantation potential, prediction of blastocyst development and prediction of aneuploidy. Nevertheless, a debate is still open to understand whether TLM may or may not predict the genetic health of embryo.

Study design, size, duration: Retrospective cohort study. The normal distri-bution of data was verified using the Kolmogorov-Smirnov test with the Lilliefors' amendment and the Shapiro-Wilk test. Morphokinetic variables were expressed as median and quartiles (Q1, Q2, Q3, Q4). Mann-Whitney U-test was used to compare the median values of parameters. Univariate and multi-variate logistic regression models were used to assess relationship between ploidy and kinetics. Several confounding factors have been also assessed. ROC analysis was employed for the identified variable.

Participants/materials, setting, methods: From May 2013 to November 2015, a total of 93 patients were enrolled in a PGS program and 287 blastocysts underwent trophectoderm (TE) biopsy on day 5 or 6 followed by array com-parative genomic hybridization (aCGH). All blastocysts were cultured in a time-lapse incubator and kinetics examined. For each blastocyst, absolute and rela-tive morphokinetic parameters were collected and compared between euploid and aneuploid.

Main results and the role of chance: Mean female age was 38.4 (95% CI 37.5–39.3, range 26–48). The overall euploid rate of the blastocysts population was 50.2% (144/287; 95% CI 44.4–56.0), while the aneuploidy rate was 49.8% (143/287; 95% CI 44–55.6). First we performed univariate logistic regression and significant parameters were: time of pronuclear appearance/disappearance (tPNa/tPNf), time to two/ five/nine cells (t2, t5, t9), start blastulation (tSB), synchronization of cell divisions (s2=t4-t3), synchronization of cleavage pattern (s3=t8-t5). Taking into account these results a multivariate logistic regression model was created. To test the strength of the prediction model, the effect of

potential confounder factors (female age, BMI, causes of infertility, protocol of stimulation) were also considered. In the prediction model only time of pronuclear appearance (tPNa) (OR=1.295; 95% CI 1.121–1.498) had a good relation to ploidy outcome. The median value of tPNa was statistically different (P=0,02) between euploid and aneuploid blastocysts (euploid blastocysts = 8,85 h; aneuploid blastocysts = 10,34 h). Optimal range is defined by the Q2-Q3 consecutive quartiles (7.76 h-9.8 h) with highest euploid blastocysts probability. The model could be considered strong because the area under the ROC curve was 0.73 with a 95% confidence interval (0.64, 0.75).

Limitations, reasons for caution: Even if there is a good correlation between tPNa and ploidy outcome, it is not so strong.

Wider implications of the findings: We believe that embryo selection by time-lapse microscopy should not be considered as substitute for PGS but as a complement tool, especially for good-prognosis patients without indications for PGS and to reduce the number of patients that undertake PGS.

Trial registration number: None.

O-224 Selection of single blastocysts for transfer with time-lapse alone and with next generation sequencing to reduce multiple pregnancies: a prospective randomized pilot study

Z. Yang[1], J. Lin[2], S. Zhang[3], Y. Kuang[4], J. Liu[5]

[1]ZytoGen, Clinical studies, Timonium, U.S.A.
[2]Reproductive Fertility Center, ART, Irvine, U.S.A.
[3]Sir Run Run Shaw Hospital Zhe Jiang University School of Medicine, ART, Hangzhou, China
[4]Ninth People's Hospital Shanghai Jiao Tong University School of Medicine, ART, Shanghai, China
[5]Jiaen Hospital, ART, Beijing, China

Study question: Can time-lapse (TL) and next-generation sequencing (NGS) be efficiently used for the selection of single blastocysts for transfer in IVF patients to reduce multiple pregnancies?

Summary answer: The combined use of TL and NGS for selecting single blastocysts for transfer results in significantly higher clinical and ongoing pregnancy rates for IVF patients.

What is known already: Selection of single blastocysts with the highest potential of implantation for transfer still remains a challenge. There are obvious shortcomings with traditional methods of evaluation and selection of single blastocysts for transfer based on morphological assessment alone. Recent advances in time-lapse monitoring and next-generation sequencing have provided new methods for selecting competent embryos for transfer in IVF treatments. However, there is still very limited information about the effects of time-lapse monitoring and NGS testing on clinical and ongoing pregnancy outcomes of single embryo transfer for IVF patients to reduce multiple pregnancies in a randomized study.

Study design, size, duration: A total of 229 IVF patients who met the inclusion criteria (under 35 years old, no prior miscarriage and normal karyotype) were enrolled in this prospective randomized pilot study in our multiple IVF clinics from March 2015 to April 2016. Following IRB approval, patients singed the informed consents for selecting single blastocysts for transfer with TL and NGS. Sample size was calculated using GraphPad StatMate (San Diego, USA) to ensure power of study.

Participants/materials, setting, methods: The enrolled patients at mean age 31.4 ± 3.5 years were prospectively randomized into two groups: 1) Group A: patients (n = 115) had embryos cultured in a time-lapse system (EmbryoScope, Denmark) and tested with NGS (Yikon Genomics, China) and 2) Group B: patients (n = 114) had embryos cultured in the time-lapse system only. The statistical analyses were performed using GraphPad InStat (San Diego, USA). A two-tailed value of P < 0.05 was considered statistically significant.

Main results and the role of chance: This is the first randomized clinical study on the combined use of TL and NGS for selecting single blastocysts for transfer in IVF patients. There were no significant differences in female patient's mean age, Day 3 FSH, AMH, E2, antral follicle number between Group A and Group B (p >0.05). The fertilization and blastocyst rates were also comparable between the two groups (p >0.05). However, there was significant difference

in clinical pregnancy rates per transfer between Group A and Group B (72.5% vs. 52.6%, respectively, P < 0.05). The observed ongoing pregnancy rate per transfer was also significantly higher in Group A compared to Group B (71.6% vs. 50.8%, respectively, p < 0.05). There were no multiple pregnancies in both groups.

Limitations, reasons for caution: Although the combined use of TL and NGS brings distinct clinical benefits for many IVF patients, the approach is not for all patients, especially those with diminished ovarian reserve. Further randomized studies with a larger sample are needed to define the role of TL and NGS for all age groups.

Wider implications of the findings: With the resulting high clinical and ongoing pregnancy rates following single embryo transfer, the combined use of time-lapse and NGS has demonstrated an efficient means for selecting single competent blastocysts for transfer to reduce multiple pregnancies for IVF patients.

Trial registration number: No applicable.

O-225 Single embryo transfer on cleavage-stage(D3) using Time-lapse selection VS on blastocyst(D5) using traditional morphological selection in patients with good prognosis: a prospective randomized controlled trial

L. Yang[1], X. Kong[2], S. Zhang[3,4], J. Dai[3], F. Gong[2,5], G. Lu[5,6,7], G. Lin[2,5,6,8]

[1]Institute of Reproducitve and Stem Cell Engineering, Basic Medicine College-Central South University, Changsha- Hunan, China

[3]Reproductive and Genetic Hospital of CITIC-XIANGYA, IVF laboratory, ChangSha, China
[4]Institute of Reproducitve and Stem Cell Engineering, Basic Medicine College-Central South University, ChangSha, China
[5]Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive Center, ChangSha, China
[6]National Engineering and Research Center of Human Stem Cell, ChangSha, China
[7]Key Laboratory of Reproductive and Stem Cell Engineering, Ministry of Health, ChangSha, China
[8]Key Laboratory of Reproductive and Stem Cell Engineering-, Ministry of Health, ChangSha, China

Study question: Does single cleavage-stage embryo(D3) selection using the results from the cleavage-stage embryo hierarchical classification model achieved the equal pregnancy outcome compared to single blastocyst(D5) selection based on traditional morphological method?

Summary answer: D3 single embryo transfer using time-lapse selection model could achieve equal clinical and ongoing pregnancy rates when compared to D5 by morphological selection.

What is known already: Single embryo transfers(SETs) has been advocated as a strategy to reduce the multiple births after assisted reproductive technology(ART). Blastocyst culture and single blastocyst transfer has been widely accepted to perform elective single-embryo transfer(eSET), but the longer in vitro culture period may raise potential risk for embryos. Previous trial on single cleavage-stage embryo transfer had negative result when compared to single blastocyst transfer. Recently time-lapse provide multiple parameters for better selection of cleavage-stage embryos. But little RCT results are available to demonstrate time-lapse selection could provide equal efficiency on pregnancy outcome in eSET when compared to blastocyst morphological selection.

Study design, size, duration: A prospective randomized controlled study was conducted in single embryo transfer patients undergoing IVF/ICSI at the Reproductive and Genetic Hospital of CITIC Xiangya between October 2015 and October 2016. This sample size achieves with a power of 80%, at a significance level(α) of 0.05, we would need to randomize 492 patients, 246 in each group. A sample size of 600 patients, 300 randomized to each group, was chosen to allow for those 20% dropped out.

Participants/materials, setting, methods: Patients were required to meet the inclusion criteria: ≤36 years of age, ≤2 failed IVF attempts using fresh cycles, ≥6 normally fertilized embryos(2PN), undergoing autologous IVF or ICSI.

Randomization was done 1:1 using random numbers from sealed envelopes. Patients fulfilled the criteria on D1 were randomly assigned to conventional morphological blastocyst selection(D5,control group) or the cleavage-stage embryo hierarchical classification model for selection(D3,study group) cultured in the Primo Vision(Vitrolife;Budapest,Hungary). The primary outcome was ongoing pregnancy rate.

Main results and the role of chance: 334 patients were randomized (167 D3 vs 167 D5), 50 dropped out (23 D3 vs 27 D5) ,284 patients (144 D3 vs 140 D5) available for analyzed between 1 October 2015 and 27 October 2016 (The experiment is continuing). There were no differences in the demographic variables and cycle statistics between the two groups.The clinical 95/144 (66.0%) vs 102/140 (72.9%)(P >0.05) and ongoing pregnancy rates 93/144 (64.6%) vs 101/140 (72.1%)(P>0.05), early miscarriage rate 4.17% vs 5.71% and twin pregnancy rate 2.1% VS 1.4% respectively were not statistically different between D3 and D5.

Limitations, reasons for caution: The main limitation in this trial is the inclusion criteria were quite strict in favor of good-prognosis patients; in consequence, the potential value of the trial for improving clinical outcome might only be relevant to good-prognosis patients.

Wider implications of the findings: Time-lapse might help to establish efficient selection model for single cleavage-stage embryo transfer and it is worth to try in unselected patients to reduce multiple pregnancy rate.

Trial registration number: ChiCTR-ICR-15006600.

Trial registration date:16 June 2015.

Date of first patient's enrolment: 1 October 2015.

O-226 Time-lapse (TL) morphokinetic parameters do not predict the outcome of fresh In-Vitro Fertilization/Single Embryo Transfer (IVF/SET) cycles

G. Christou[1], I. Dimitriadis[2], L. Bourke[3], S.T. McLellan[3], P. Blowmick[4], C.L. Bormann[2], I. Souter[2]

[1]Harvard School of Public Health, Environmental and Occupational Medicine and Epidemiology, Boston, U.S.A.
[2]Harvard Medical School - Massachusetts General Hospital, Obstetrics and Gynecology/Reproductive Endocrinology and Infertility, Boston- MA, U.S.A.
[3]Massachusetts General Hospital Fertility Center, Obstetrics and Gynecology/ Reproductive Endocrinology and Infertility, Boston- MA, U.S.A.
[4]Massachusetts General Hospital Fertility Center, Obstetrics and Gynecology/ Reproductive Endocrinology and Infertility, Boston, U.S.A.

Study question: Is there an association between early- and/or late-morphokinetic parameters and either pregnancy establishment or viability following IVF/SET?

Summary answer: Neither early- nor late-morphokinetic parameters predicted either pregnancy establishment or pregnancy viability in IVF/SET cycles.

What is known already: Certain morphokinetic parameters obtained from preimplantation human embryos cultured in TL- monitored incubators have been evaluated as markers of i) embryonic quality and ploidy status, and ii) embryo's potential for blastocyst formation and implantation. These include either static or interval morphokinetic variables from the early cleavage stage and/or later stages of embryonic development and blastocyst formation. However, it still remains unclear whether blastocysts resulting in live births differ in all or some of these morphokinetic parameters from those appearing morphologically normal but failing to either implant or establish a viable pregnancy.

Study design, size, duration: Design: Retrospective cohort.

Size: 223 women undergoing IVF/SET at a major academic center. Duration: 09/2013-04/2016.

Participants/materials, setting, methods: Embryos cultured to blastocyst in a TL-monitored incubator and selected for fresh-SET.

Conception cycles were compared to non-conception ones, and viable pregnancy cycles were compared to pregnancy failures, in regards to the following early- and late-morphokinetic parameters: time period from i) pronuclei fading (tPNf) to 1st cytokinesis (P1), ii) 2- to 3-cells (P2), iii) 3- to 4-cells (P3), and iv) tPNf to early blastulation (PSB).

Statistics: *t*-test, chi-square, *one-way ANCOVA* controlling for potential confounders.

Main results and the role of chance: Groups did not differ in baseline characteristics (basal FSH, AMH, antral follicle counts, AMH). Results are presented as marginal means adjusted for maternal age (<38 vs. ≥38 years), basal-FSH, AMH, antral follicle counts and fertilization method (ICS vs. conventional insemination). In 60.5% (135/223) of cycles ICSI was utilized. Following IVF/SET, 64.1% (143/223) of the women conceived. Of those, 77.6% (111/143) had a viable pregnancy, progressing over 20 weeks gestation. When conception cycles were compared non-conception ones, no difference was noted in any of the morphokinetic parameters [marginal means(95%CI): 2.53(2.44–2.62) vs. 2.50(2.39–2.61), p = 0.66; 10.65(9.99–11.31) vs. 10.52(9.70–11.33), p = 0.81; 1.19(0.77–1.62) vs. 1.13(0.60–1.67), p = 0.86; 68.63(67.27–70.00) vs. 69.48-(67.64–71.32) hours, p = 0.48), for P1, P2, P3, and PSB, respectively]. Similarly, when viable pregnancy were compared to pregnancy failure cycles, morphokinetic parameters did not predict the outcome of the pregnancy [marginal means (95%CI): 2.57(2.46–2.66) vs. 2.44(2.23–2.66), p = 0.31; 10.57(10.00–-11.02) vs. 10.73(8.76–11.94), p = 0.83; 1.15(0.81–1.57) vs. 1.52(0.61–2.83), p = 0.63; 69.28(67.85–71.12) vs. 66.66(63.32–69.85), p:0.23), for P1, P2, P3, and PSB, respectively].

Limitations, reasons for caution: Limitations include the retrospective design, the evaluation of only those morphokinetic parameters thought to predict blastocyst formation but not pregnancy, and the potential effect of the fertilization method. Timeswere normalized to a common starting time-point, thus making it unlikely that the latter introduces bias affecting cycle outcomes.

Wider implications of the findings: In a group of unselected infertile patients undergoing fresh-IVF/SET, early-cleavage morphokinetic parameters and time to early-blastulation did not predict reproductive outcomes.

Trial registration number: Not applicable.

O-227 Comparison of morphokinetic markers which predict blastocyst formation and implantation potential from two large clinical datasets; CRM, WCM, U.S.A. and IVI, Spain

N. Zaninovic[1], Q. Zhan[2], Z. Rosenwaks[2], N. Basile[3], A. Pellicer[4], M. Meseguer[5]

[1]The Center for Reproductive Medicine and Infertility, New York- NY, U.S.A.
[2]CRM- Weill Cornell Medicine, Reproductive Medicine, New York, U.S.A.
[3]IVI Madrid, IVF, Marrid, Spain
[4]IVI Rome, IVF, Rome, Italy
[5]IVI Valencia, IVF, Valencia, Spain

Study question: To demonstrate whether the morphokinetic markers used for embryo selection have a similar relationship to blastocyst formation and implantation in two large clinical datasets.

Summary answer: Morphokinetic intervals for early cleavages were differently distributed between clinics. 2/3 morphokinetic markers in WCM and one in IVI data set were informative for implantation.

What is known already: The ability to correctly select the best embryo for transfer is a highly desirable capability as implantation is the ultimate goal of a successful IVF treatment. Time-lapse technology has assisted in determining whether key embryological events and temporal hallmarks are associated with embryo development or clinical outcome. Nevertheless, not all published algorithms based on morphokinetic markers has been found to be applicable in all clinic. The establishment of key developmental hallmarks in large datasets would demonstrate whether the published algorithms could be universally applied.

Study design, size, duration: Retrospective cohort study on two datasets of embryos cultured until the blastocyst stage (BL) (n = 27316) and/or implanted following single embryo transfers (I) (n = 816).

Participants/materials, setting, methods: Embryos in both clinics were cultured in a time-lapse system (EmbryoScope, Vitrolife, Sweden); IVI-Valencia (BL=11,414, I= 479) and Weill Cornell Medicine (WMC) (BL=15,902; I=337). Variables studied included: t2, t3, t4, up to t9 as well as the transition among all described cleavages. Two different datasets were compared using quartile plots with 95% CI on the quartile limit and the quartile average value, as well as AUC of the parameter against the relevant outcome.

Main results and the role of chance: A detailed graphical analysis was performed for t3, t5, cc2 (t3-t2) and the ratio (t5-t3)/(t5-t2). In relation with our best defined marker (t5), timings were not affected between clinics. However, WCM proportions were significantly affected by the definition of achieving BL vs. not achieving BL, when compared to IVI data. A significant decrease in the proportion of blastocysts with longer times to t5 was observed for WCM. Meanwhile, t5 were more informative in the IVI data set in relation to implantation. Similar results were observed in cc2 and the ratio (t5-t3)/(t5-t2). Although similar, t3 timings were significantly higher in IVI data than WCM for the proportion of implanted embryos in the 2nd quartile (within the confidence interval).

Limitations, reasons for caution: Although validated throughout a large datasets of two experienced time-lapse user clinics, the retrospective nature of the analysis is less than ideal.

Wider implications of the findings: These embryo selection algorithms may be suitable among two different and independent large datasets. The parameters are sensitive to the specific attributes of the data, and should not be universally applied. Evaluation of the outcomes depends on parameters used and should be evaluated before the incorporation of any selection algorithms.

O-228   Health and morbidity of women with POI due to FSH resistant ovaries

K. Luiro[1], K. Aittomäki[2], J.S. Tapainainen[3]

[1]Helsinki University Hospital and University of Helsinki, Dept of Obstetrics and Gynecology, Helsinki, Finland
[2]Helsinki University Hospital and University of Helsinki, Dept of Clinical Genetics, Helsinki, Finland
[3]Helsinki University Hospital and University of Helsinki, Dept of Obstetics and Gynecology, Helsinki, Finland

Study question: Do inactivating FSH receptor mutation and hypoestrogenism have long-term effects on health and morbidity, and can these be overcome by an adequate hormone therapy (HT)?

Summary answer: Early-onset HT with median duration of twenty years seems to be effective in preventing major health problems and morbidity in the genetic form of POI.

What is known already: Adverse long-term health outcomes of POI have been reported in several epidemiological and observational studies. FSHRO (FSH resistant ovaries), caused by mutations in FSH receptor, is a genetic form of primary ovarian insufficiency (POI). FSHRO patients have low endogenous estrogen levels and arrest of follicle development at antral stage. We have previously studied the long-term health morbidity of the FSHRO cohort by a health questionnaire. Here we report the results of a detailed clinical examination.

Study design, size, duration: The cardiovascular and metabolic health was assessed by the analysis of the lipid profile and oral glucose tolerance test with insulin measurements. Bone mineral density and whole body composition was analysed with DXA. Psychological and sexual well-being was assessed with BDI21, GAD-7 and FSFI questionnaires. The data were compared to the results of a national, age- and area-stratified population risk factor monitoring survey carried out in 5-year intervals (FINRISK).

Participants/materials, setting, methods: We identified 26 women with an inactivating A189V FSH receptor mutation. Twenty-two gave their written, informed consent to participate in the study. Fourteen (63.3%) were examined at Helsinki University Hospital and Oulu University Hospital.

Main results and the role of chance: All FSHRO women had been on HT, and the median time of use was 20 years. The FSHRO women had an elevated median A/G (android/gynoid) ratio. However, no metabolic syndrome or diabetes was detected. Based on the lipid profile analysis, there was not elevated risk to cardiovascular diseases as compared to age-matched controls. Osteoporosis was rare (one patient), but eight women (63.4%) were diagnosed with osteopenia despite the HT use. 69% of the FSHRO women were at risk, and 31% were at high risk, for sexual dysfunction irrespective of their relationship status.

Limitations, reasons for caution: FSHRO is a rare genetic form of POI, and thus the study cohort is small, which leaves a possibility for chance.

Wider implications of the findings: According to our findings, twenty years of HT in POI seems to be sufficient in preventing major cardiovascular and metabolic morbidity. However, bone health and the prevention of bone mineral density reduction may require a longer period of HT, which would better correspond to the natural duration of fertile age.

Trial registration number: The Hospital District of Helsinki and Uusimaa Ethics Committee for gynaecology and obstetrics, pediatrics and psychiatry 333/13/03/03/2013.

O-229   POR mutations as novel genetic causes of female infertility due to partial 17 alpha-hydroxylase deficiency

K. Saito[1,2], K. Kawai[2,3], K. Tatsumi[4], M. Miyado[5], M. Katsumi[1], S. Nakamura[1,6], T. Ishikawa[2], N. Miyasaka[2], M. Fukami[1]

[1]National Research Institute for Child Health and Development, Department of Molecular Endocrinology, Tokyo, Japan
[2]Graduate School- Tokyo Medical and Dental University, Department of Comprehensive Reproductive Medicine, Tokyo, Japan
[3]Kameda Medical Center, Department of Reproductive Medicine, Chiba, Japan
[4]Umegaoka Women's Clinic, Tokyo, Japan
[5]National Research Institute for Child Health and Developent, Department of Molecular Endocrinology, Tokyo, Japan
[6]Jichi Medical University- Children's Medical Center Tochigi, Department of Pediatric Urology, Tochigi, Japan

Study question: Can POR mutations underlie female infertility without apparent congenital malformations?

Summary answer: POR mutations likely represent a rare cause of infertility without other clinical features through partial 17α-hydroxylase deficiency (17OHD).

What is known already: POR encodes an electron donor for all microsomal P450 enzymes including CYP17A1. POR mutations typically cause a congenital syndrome characterized by skeletal dysplasia, adrenal insufficiency, genital abnormalities, gonadal dysfunction, and infertility. Although POR mutations have been identified in undervirilized males diagnosed with non-syndromic 17OHD, such mutations have not been detected in infertile women without other clinical features.

Study design, size, duration: Clinical and molecular analyses of two unrelated Japanese infertile women without other clinical features besides menstrual abnormality.

Participants/materials, setting, methods: Two women visited our hospitals because of infertility. We examined clinical features of these patients. Serum steroids and urine steroid metabolites were measured by liquid chromatography-tandem mass spectrometry and gas chromatography-mass spectrometry, respectively. Sequence analysis was performed for cording regions of CYP17A1 and POR. The functional significance of identified substitutions was assessed by in silico analyses.

Main results and the role of chance: Both patients had a history of menstrual irregularity and presented with borderline hypertension, but had no genital or skeletal abnormalities. Serum and urine analyses showed decreased CYP17A1 activity in both patients. Urine analysis also showed slightly decreased CYP21A2 activity only in one patient. Both patients had no mutation in CYP17A1; however, they harbored compound heterozygous mutations in POR (p.R457H;[G413S;R550W] and p.Q201X;Y607C). PolyPhen-2 predicted impaired function of these mutants. Structural analysis predicted that p.R550W disrupts hydrogen bonds between amino acids and p.Q201X eliminates more than half of the amino acids of the POR protein. Structural analysis predicted that p.R457H and p.Y607C disrupts the interaction of POR with FAD and NADPH, respectively. These results suggest that the POR mutations are responsible for partial 17OHD and resultant infertility in these women.

Limitations, reasons for caution: Our conclusions are based on the observation of only two individuals, and await further validation.

Wider implications of the findings: Various *POR* mutations may result in partial 17OHD without other clinical features. The frequency of *POR* mutations among women with non-syndromic infertility needs to be clarified in future studies.

Trial registration number: not applicable.

O-230 Serum levels of the oocyte-secreted factors GDF9 and BMP15 are associated with reproductive potential in women

A.H. Riepsamen[1], D.M. Robertson[1,2], K. Chan[2], P. Sweeten[1,3], D. Agapiou[1], D. Garrett[4], A. Anazodo[1,5,6], K. Walton[7], C. Harrison[7], R.B. Gilchrist[1], W.L. Ledger[1,3]

[1]University of New South Wales- Sydney, School of Women's and Children's Health, Sydney, Australia
[2]Hudson Institute of Medical Research, Centre for Endocrinology and Metabolism, Clayton, Australia
[3]IVF Australia, Maroubra and Bondi Junction, Sydney, Australia
[4]IVF Australia, Endocrinology, Sydney, Australia
[5]Sydney Children's Hospital, Kid's Cancer Centre, Sydney, Australia
[6]Prince of Wales Hospital, Nelune Comprehensive Cancer Centre, Sydney, Australia
[7]Monash University, Department of Physiology, Clayton, Australia

Study question: Are the oocyte-secreted growth factors (GDF9 and BMP15) detectable in human peripheral blood and are they possible biomarkers of female reproductive function?

Summary answer: GDF9 and BMP15 are detectable in female serum and their levels positively correlate with the number of oocytes retrieved during IVF.

What is known already: Oocyte quantity and quality are rate limiting to reproductive success. Current serum biomarkers of reproductive function, such as anti-Müllerian hormone (AMH), represent the follicular environment and hence are surrogate markers of oocyte biology. There are currently no serum oocyte biomarkers available for clinical use. The oocyte-secreted growth factors, growth differentiation factor-9 (GDF9) and bone morphogenetic protein-15 (BMP15), are requisite regulators of folliculogenesis, oocyte quality and fertility, and are essentially only produced by the gametes. These potential biomarkers of oocyte function have not previously been demonstrated as detectable in blood in association with reproductive potential.

Study design, size, duration: Novel immunoassays for the reliable detection of GDF9 and BMP15 were developed in-house, validated, and applied to excess serum samples from women having unstimulated or antagonist (FSH-stimulated) superovulated cycles. Bloods, matched to clinical data, were collected from women 27–45 years over six months and stored at -80° C prior to analysis. Serum levels of GDF9 and BMP15 were correlated with clinical, endocrine, and embryology data.

Participants/materials, setting, methods: For analysis of intra- and inter-cycle variation, GDF9 and BMP15 were measured in multiple bloods from unstimulated women (51 bloods from 9 women), from day 2 of the cycle prior to FSH stimulation, on multiple days during treatment, and/or across multiple cycles (167 bloods from 27 women). These data were analysed separately and combined with those of an additional 210 women for analysis in relation to clinical data.

Main results and the role of chance: The GDF9 and BMP15 immunoassays were validated for sensitivity, specificity and reproducibility using a serum pool as the reference preparation as non-parallelism was observed between recombinant protein preparations and biological samples. Stability studies using various collection methods and sample treatments further demonstrated their reliability. Assays for GDF9 and BMP15 detected proteins in female serum with notably similar profiles between the two assays. Serum GDF9 and BMP15 levels varied markedly between individual women (ranging from undetectable to 300-fold above baseline) but within subjects were unchanged throughout the ovarian cycle. Furthermore, serum levels were unchanged by antagonist stimulation treatment, regardless of FSH dose, and across different treatment cycles.

Serum levels of GDF9 positively correlated with the number of oocytes retrieved from non-PCO/PCOS women after superovulation (r = 0.439, $p < 0.05$, n = 27). However, this correlation was not observed in PCO/PCOS patients, indicative of oocyte-secreted factors being involved in this pathology. Furthermore, the GDF9:AMH ratio was on average 8.5 fold lower in PCO(S) compared to non-PCO(S) patients ($p < 0.0001$).

Serum levels of GDF9 and BMP15 did not correlate with age or baseline (day 2) endocrine measures of LH, oestradiol or progesterone. However, GDF9 positively correlated with baseline FSH (r = 0.512, $p < 0.05$, n = 17) and with AMH (r = 0.478, $p < 0.01$, n = 36).

Limitations, reasons for caution: The association of serum concentrations of GDF9 and BMP15 with oocyte yield during IVF supports the hypothesis that the proteins detected originate from the oocyte. However, the high concordance between serum levels of GDF9 and BMP15 warrants investigation into the exact form of the growth factors detected by these assays.

Wider implications of the findings: This is the first study to systematically demonstrate the diagnostic and predictive potential of oocyte-secreted GDF9 and BMP15 as serum biomarkers for use in reproductive medicine. Serum GDF9 and BMP15 may prove clinically valuable for diagnosing reproductive dysfunction and as predictors of fertility potential.

Trial registration number: Not applicable.

O-231 Effects and mechanisms of a novel mutation in basonuclin 1 gene on premature ovarian insufficiency

Y. Liu[1], J. Li[2], Y. Huang[2], Y. Wu[3], J. Liu[3], D. Zhang[3]

[1]Women's Hospital-School of Medicine-Zhejiang University, Reproductive endocrinology, Hangzhou, China
[2]Women's hospital -School of Medicine- Zhejiang University, Reproductive Endocrinology, Hangzhou, China
[3]Women's Hospital- School of Medicine- Zhejiang University, Reproductive Endocrinology, Hangzhou, China

Study question: What is the effects and mechanisms of Basonuclin1(BNC1) gene truncation mutation in premature ovarian insufficiency(POI)?

Summary answer: BNC1 dysfunction would lead to premature exhaust of follicles and POI. KLF17, CITED1, MPO, NPC2 may interact with BNC1 in maintaining normal ovarian aging.

What is known already: POI is one of the leading causes of female infertility owing to the absence, non-functionality or early depletion of ovarian reserve. We previously identified for the first time in the world a novel mutation——BNC1 truncation mutation in a large Chinese POI pedigree using whole-exome sequencing. Yet the effect and underlying molecular mechanism of BNC1 mutation on POI remains unknown.

Study design, size, duration: Transgene mouse model study. Generate BNC1 truncation mutation mice. Investigate ovarian aging of wild-type (+/+), heterozygous (+/tr), and homozygous (tr/tr) BNC1 truncation mutation mice. Assess transcriptomics study of wild-type and homozygous BNC1 truncation mutation mice ovaries. Explore the underlying mechanisms of BNC1 on ovarian aging.

Participants/materials, setting, methods: We generated BNC1 truncation mutation mice using homologous recombination. Genotypes were identified by PCR of tail DNA. Ovary size, fertility testing, serum hormone of follicle-stimulating hormone (FSH), luteinizing hormone (LH), and estradiol were detected. Histological analysis of ovary tissues was performed and follicle numbers were counted. Transcriptomics study was carried out. Key differentiated genes were confirmed by RNA extraction and real-time RT-PCR.

Main results and the role of chance: BNC1 truncation mutation female mouse model exhibited infertility or subfertility, significantly increased serum FSH and LH levels, lowered estradiol level, decreased ovary size and reduced follicle numbers at every follicle developing stage. Taken together, the data from the mouse model indicated BNC1 truncation mice had impaired folliculogenesis and premature ovarian insufficiency. Go-analysis, pathway-analysis, Gene-act-network, co-expression network of differentiated expression genes were analyzed, and KLF17, CITED1, MPO, NPC2 were considered to be the possible genes involved in the mechanisms of BNC1 truncation mutation leading to premature ovarian aging.

Limitations, reasons for caution: The mechanism study between KLF17, CITED1, MPO, NPC2 and BNC1 regulation was limited, and need to be further investigated in our future research.

Wider implications of the findings: Our study describe the first time the effects and mechanisms of BNC1 truncation mutation in ovarian aging, which will contribute to improving female reproductive health with both scientific value and translational medical significance.

Trial registration number: No.

O-232 Gonadotropin receptor variants are linked to pregnancy outcome in women undergoing in vitro fertilization

I. Lindgren[1], H. Nenonen[2], E. Henic[3], L. Bungum[4], S.O. Skouby[4], Y.A. Claus[5], Y. Giwercman L[2]

[1]Lund University, Molecular Genetic Reproductive Research, Malmö, Sweden
[2]Lund University, Molecular genetic reproductive medicine, Malmö, Sweden
[3]Skåne University Hospital, Reproductive Medicine Centre, Malmö, Sweden
[4]Herlev Hospital, Department of Obstetrics and Gynecology, Herlev, Denmark
[5]Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark

Study question: Can the gonadotropin receptor variants previously linked to pregnancy in the first *in vitro* fertilization (IVF) attempt also predict pregnancy in subsequent IVF cycles?

Summary answer: Women homozygous serine (S) in the follicle-stimulating hormone receptor (*FSHR*, N680S), and the luteinizing hormone receptor *(LHR*, N312S), had highest pregnancy rates in all IVF-cycles.

What is known already: Recently it was reported that women homozygous for S in aminoacids 680 and 312 of the FSHR and LHR, respectively, had four-fold increased pregnancy chance after their first IVF-cycle compared to women homozygous N. However, S-carriers required higher total dose of exogenous FSH before IVF compared to women with other genotypes, indicating decreased hormone sensibility for these women.

Study design, size, duration: Prospective, clinical study, in which n = 617 women were consecutively enrolled during the period 2007–2015, at Reproductive Medicine Center, Malmö, Sweden. Medical data were collected from records in 2016. The main outcome measures were age, stimulation regimens prior to IVF and pregnancy outcome after IVF.

Participants/materials, setting, methods: Inclusion criteria were: <40 years of age, body mass index <30 kg/m^2, non-smoking, regular menstruation cycle of 21–35 days and bilateral ovaries. Leucocyte DNA was extracted and *FSHR* and *LHR* polymorphisms genotyped by allele specific PCR and direct sequencing of selected samples in order to verify PCR results.

Main results and the role of chance: Of the 617 originally included women, 370 (60%) completed a second IVF cycle and 217 (35%) continued to a third. Of these, 78 (13%) sustained 4–7 cycles. A majority of all participants (77%) were treated with follitropin alpha for ovarian hyperstimulation.

The allele frequencies were similar to previously reported, 30% homozygous N, 53% heterozygous N/S and 17% homozygous S in the FSHR gene. For the LHR, 16% were homozygous N/N, 46% were N/S, and 38% homozygous S/S.

Women homozygous S had significantly higher pregnancy rate compared to women with other variants also in subsequent IVF-cycles, being stastistically significant in the second (pregnancy incidence; 69% for S/S and 40% for N/N, p = 0,044) as well as in the second and third cycle combined, (47% for S/S and 35% for N/N carriers, p = 0.040). Significance was lost due to decreasing number of subjects in cycles 4–7.

Limitations, reasons for caution: Although the cohort used in this study was large, the vast majority of women were Caucasian. Other ethnic groups may show a different picture. Most women were treated with follitropin alpha and another result may be reached using other gonadotropin preparations and therapy modalities in relation to receptor genotype.

Wider implications of the findings: Genotyping of gonadotropin receptor variants are promising candidates for prediction of pregnancy and could in the future be used in an individualized stimulation strategy for women undergoing IVF.

Trial registration number: not applicable.

O-233 Prokineticin 1 (PROK1) is a new actor in human folliculogenesis

S. Brouillet[1,2], A. Gueniffey[1], C. Dunan-faure[1], L. Villaret[1], L. Azar[1], C. Douest[1], C. Lebayle[1], P. Martin[1], C. Perrot[1], P. Zavaroni[1], J. Bessonnat[1], N. Quenard[1], N. Alfaidy[2], P. Hoffmann[1,2], S. Hennebicq[1,3]

[1]Centre Hospitalier Universitaire, Reproductive Medicine department- Grenoble university, Grenoble Cedex 09, France
[2]CEA/INSERM/iRTSV, Laboratoire BCI, Grenoble cedex 09, France
[3]Genetics Epigenetics and Therapies of Infertility- Institut Albert Bonniot, INSERM U823, La tronche, France

Study question: To characterize the regulation of PROK1 secretion in follicular fluid (FF) throughout human folliculogenesis in *in vitro* fertilization (IVF).

Summary answer: In IVF, PROK1 secretion is significantly: 1) increased throughout late folliculogenesis, 2) up-regulated by gonadotropins (hCG and FSH), 3) down-regulated by smoking.

What is known already: Follicular fluid (FF) is an important component of the oocyte microenvironment influencing the acquisition of oocyte competence and the subsequent embryo implantation ability. Recent data from our laboratory reported that FF PROK1 measurement could be a new predictive biomarker of oocyte competence and embryo implantation potential in *in vitro* fertilization (IVF). On the basis of these observations, it was intriguing to investigate the regulation of its secretion in FF.

Study design, size, duration: A prospective study was performed between November 2014 and May 2016 in the Assisted Reproduction Unit, Department of Obstetrics and Gynecology, University of Grenoble, France. A total of 981 FF from 95 infertile couples undergoing IVF +/- ICSI were collected and analyzed for PROK1 concentration, follicular size, FSH starting dose, and smoking (*in vivo* study). Regulation of PROK1 secretion by FSH and hCG was investigated in primary follicular cells cultures (*in vitro* study).

Participants/materials, setting, methods: Samples were collected through CRB Germetheque (procedure approved by the institutional ethics review board, CPP Sud-Ouest). Signed informed consent was obtained from all patients who participated in the study. Follicular size (length and width) was measured by 2D-sonography during individual follicular puncture. Individual FFs were collected immediately after oocyte retrieval. Regulation of PROK1 secretion by gonadotropins was characterized in cumulus cell (CC) primary cultures. PROK1 concentration in FF was measured by enzyme-linked immunosorbent assay (ELISA).

Main results and the role of chance: PROK1 was detected in all individual FF samples with concentration ranging from 51 to 6,241 pg/ml (mean concentration of 2,186 ± 49 pg/ml). Follicles were divided into six groups according to their size (from 10 mm to 23 mm, mean size = 17.78 ± 0.11 mm). A significant increase of PROK1 concentration was observed with the growing size of follicles (n = 981, ANOVA, p = 10^{-14}). Moreover, individual FF PROK1 secretion was significantly increased in women with high FSH starting dose (>250 UI per day, n = 95, Mann-Whitney, p < 0.01). In CC primary cultures, FSH and hCG significantly increased PROK1 secretion (n = 15, Mann-Whitney, FSH, p < 0.001 and hCG, p < 0.001, respectively), probably *via* the AMPc pathway (n = 5, Mann-Whitney, Forskolin, p < 0.001). FF PROK1 secretion was significantly decreased in smokers (n= 95, Mann-Whitney, p < 0.01).

Limitations, reasons for caution: Extensive bleeding or concomitant aspiration of follicles could distort individual FF PROK1 concentrations. However, bloodstained FF and FF with unexpected volumes according to their size were discarded. Furthermore, PROK1 is up regulated in ovarian hyperstimulation syndrome (OHSS) and recurrent miscarriage. These conditions constitute two non-inclusion/exclusion criteria in our study.

Wider implications of the findings: PROK1 quantification in individual FF by ELISA is a quick and non-expensive test, which displays an appropriate sensitivity/specificity for clinical application. The long-term objective is to correlate individual FF PROK1 quantification with embryo implantation potential in order to evaluate its input in embryo transfer strategy.

Trial registration number: none.

O-234 Gonadotropin endocytosis as a biomarker of optimal FSH dosage – a randomised clinical trial

A. Lobato-Pascual[1], M. Raki[2], G. Greggains[1], P. Fedorcsak[1]

[1]Institute of Gynecology, Department of Reproductive Medicine, Oslo, Norway
[2]Laboratory Medicine, Department of Pathology, Oslo, Norway

Study question: Can standard practice of ovarian stimulation be optimised by choosing a starting FSH dose based on gonadotropin endocytosis *in vitro*?

Summary answer: Clinical results show that FSH dosage adjusted by gonadotropin endocytosis *in vitro* allows a more optimal outcome of ovarian stimulation compared to standard practice

What is known already: A key challenge in IVF is estimating the optimal FSH starting dose to obtain the desired ovarian response and prevent treatment

complications like ovarian hyperstimulation syndrome. Peripheral blood mono-cytes are professional phagocytes that patrol and probe their environment by constitutive endocytosis. Gonadotropins are also internalised by monocytes and other phagocytes, consequently reducing the quantity that can reach target receptors in ovarian cells. We have invented a cell-based assay to measure FSH internalization by monocytes *in vitro*, and a nomogram to determine whether patients are in need of increased or reduced FSH doses

Study design, size, duration: This is an ongoing randomised controlled single-centre 2-year trial including 150 eligible patients undergoing IVF/ICSI allo-cated to FSH dosage by standard practice (control) or FSH dosage adjusted for gonadotropin endocytosis (intervention). The primary end point of the study is to assess standard deviation from optimal ovarian stimulation, *a priori* defined as 10 oocytes collected during treatment

Participants/materials, setting, methods: We recruited infertile women with tubal factor, male factor, or unexplained infertility, aged 18 – 38 years, BMI 18.5 – 33 kg/m^2, serum AMH 3 – 35 pmol/l. The patients' peripheral blood monocytes were isolated and the level of gonadotropin endocytosis *in vitro* was quantified by flow cytometry. Suggested adjustment of FSH dosage was calcu-lated by a nomogram

Main results and the role of chance: Interim analysis was conducted when 81 patients have completed treatment, herein 35 randomised to intervention and 46 to control groups. Additional 49 patients have been excluded and 14 are dropouts. The geometric mean number of oocytes collected was 9.4 in the intervention and 6.8 in the control group, and 37% of women in the interven-tion group obtained 9 – 11 oocytes during stimulation, compared to 24% in the control group. Moreover, women in the intervention group achieved more con-sistent stimulation and less deviation from the a priori defined optimal stimula-tion (log-scaled $SD_{int} = 0.17$, $SD_{cont} = 0.33$, F = 4.00, P = 0.00006)

Limitations, reasons for caution: We excluded women with expected low or high response to stimulation, women with polycystic ovarian syndrome, endometriosis, autoimmune diseases, or other co-morbidities that may affect endocytosis by monocytes *in vitro*

Wider implications of the findings: Gonadotropin endocytosis by mono-cytes *in vitro* may reflect internalization of exogenous FSH by phagocytes, which may modulate the bioavailability of the drug during ovarian stimulation. Beyond predictors of ovarian reserve, like antral follicle count or serum AMH concen-trations, gonadotropin endocytosis *in vitro* may help individualizing ovarian stimulation regimes for IVF

Trial registration number: ClinicalTrials.gov identifier: NCT02915900

[5]IVI, IVI President IVI Foundation President, Valencia, Spain
[6]IVI Madrid, Department of Immunology and Department of Reproductive Endocrinology and Infertility- Rey Juan Carlos University IVI- Madrid- Spain. IVI Madrid, Madrid, Spain

Study question: Do maternal KIR have an impact on pregnancy, miscarriage and live birth rates (LBR)/cycle in donor oocytes –ART by paternal and oocyte donor HLA-C?

Summary answer: The maternal KIR and parental donor HLA-C combin-ation could predict which couple can benefit for donor selection by HLA-C in order to increase LBR.

What is known already: Increased risk of recurrent miscarriage (RM), pre-eclampsia, fetal growth restriction has been described in KIR AA mothers when the fetus has more HLA-C2 genes than the mother. Pregnancy disorders are predicted to reduce the frequency of KIR A/HLA-C2, and this selection is thought to have originated during human evolution. In ART oocyte donor cycles, oocyte HLA-C behaves as the paternal HLA-C and KIR-HLA-C combin-ation is not presently taken into account during donors' selection. KIRAA women have lower live birth rates (LBR) after double embryo transfer (DET) in egg-donation ART cycles.

Study design, size, duration: Between April 2014 and September 2016, we performed a prospective study that included 201 women whose recurrent reproductive failure was of unknown etiology: recurrent implantation failure (RIF) (N = 113) and RM (N = 89), who had 138 oocyte donor-assisted repro-ductive (ART) transfers and 63 own oocyte transfers.

Participants/materials, setting, methods: All the patients were selected from IVI Clinics, and had normal karyotype, trombophilic, and immunological results. They had 201 embryo transfers (ET)(1 transfer/patient), of which 138 were with oocyte donation (57 DET, 81 SET). We performed genetic typing for maternal KIR and HLA-C, and for the HLA-C of their partners, oocyte and sperm donors, babies and product of conception after miscarriage. Pregnancy, miscarriage and LBR/transfer were studied by the maternal KIR haplotype and embryo HLA-C.

Main results and the role of chance: The median age of our patients was 40 years, and 25 years for oocyte donors.

In our cohort, 36.3% of women had KIR AA, 41.3% KIR AB and 22.4% KIR had the BB genotype.

Higher miscarriage rate/transfer after DET-oocyte donation was observed in KIRAA women (47.6%) compared with KIR AB (4.5%) and KIR BB (7.7%) (p < 0.01). Lower LBR/transfer was observed after DET-oocyte donation in KIR AA women (4.8%) compared with AB (22.7%) or BB (46.2%) (p < 0.03).

The study of LBR/transfer by maternal KIR and HLA-C and their embryos HLA-C revealed that LBR significantly lowered from 100% after transferring embryo HLA-C1 (N = 2) to 0% after transferring DET and HLA-C2 embryos (N = 11) in KIR AA women (p < 0.000). This trend was not observed in the KIR AB or BB patients.

LBR lowered in KIR AA patients as differences between embryo and mother HLA-C2 increased. When comparing both groups, i.e., Embryo HLA-C2 £ Mother HLA-C2 (group 1) and Embryo HLA-C2 >Mother HLA-C2 (group 2), a significantly higher LBR per transfer was noted in group 1 (57.1%) *vs.* group 2 (25%) (p>0.01) in the KIR AA women.

Limitations, reasons for caution: Our sample was small and this is the first report to observe differences in LBR by oocyte donor/embryo HLA-C in KIR AA mothers. However, apart from statistical significance, the association strength was noticeably high, which confers the findings more confidence.

Wider implications of the findings: We speculate that completing normal pregnancy is possible only for those KIR AA mothers who carry a baby with a least one non-self HLA-C1. Therefore, selecting HLA-C1 amongst oocyte and/ or sperm donors for KIR AA patients who undergo egg donation could be more efficient and safer.

Trial registration number: not applicable since no intervention was made.

O-236   Uterine natural killer (uNK) cell number in the peri-implantation endometrium of normal fertile women and women with recurrent reproductive failure

X. Chen[1], L. Jiang[2], Y. Liu[1], N. Mariee[3], C.C. Wang[1], S. Laird[3], T.C. Li[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Shatin- New Territories, Hong Kong
[2]Shenzhen People's Hospital- The Second Affiliated Hospital of Jinan University, Department of Obstetrics and Gynaecology-, Shenzhen, China
[3]Sheffield Hallam University, Biomolecular Sciences Research Centre, Sheffield, United Kingdom

Study question: What is the difference in uNK cell number between fertile women and women with recurrent miscarriage (RM) and women with recurrent implantation failure (RIF)?

Summary answer: The number of uNK cells in women with RM and women with RIF was significantly higher than it in fertile controls.

What is known already: Some studies have demonstrated an increase in number of uNK cells from women with RM and/or women with RIF, while other studies found no difference between these groups. The controversy may arise from the relatively small sample size of the fertile control cohort and the lack of standardized methodology for uNK cell counting in the earlier studies.

Study design, size, duration: A total of 189 women from 3 university centres participated in the study, including 68 fertile women, 89 women with RM and 32 women with RIF. All endometrial biopsies were collected precisely on day LH+7 of the cycle

Participants/materials, setting, methods: Endometrial sections were immunostained for CD56 to identify uNK cells. Image capture and cell counting were performed by a standardised protocol agreed and published by the participating centres. Results were expressed as percentage of positive uNK cell/total stromal cells.

Main results and the role of chance: The number of uNK cells in women with RM and women with RIF was significantly higher than the fertile controls (RM: median 3.99%, range 0.52-8.58%; RIF: median 3.61%, range 0.68-8.27%; control: median 2.64%, range 0.73-5.32%). Using 5th and 95th percentile to define the lower and upper limits of uNK cell numbers in fertile controls, the reference range was from 1.12% to 4.55%. In samples from women with RM, 24% (21/89) of them were above the range while 13% (12/89) below the range. In women with RIF, 11 out of the 32 women (34%) had uNK cells count above the range and 4/32 (13%) below the range.

Limitations, reasons for caution: The prognostic value of uNK cell count measurement has yet to be confirmed.

Wider implications of the findings: Up to date, there is limited data on whether "low" uNK cell number correlate with adverse pregnancy outcomes. An established reference range for uNK cell count by standardised method should enable progress in this field.

Trial registration number: N/A.

O-237 Comparison of ectopic pregnancy risk among transfers of embryos vitrified on day 3, day 5 and day 6

T. Du[1], H. Chen[1], S. Zhang[2], Q. Chen[1], Y. Wang[1], Q. Lyu[1], Y. Kuang[1]

[1]Shanghai 9th People's Hospital- Shanghai Jiao Tong University School of Medicine, Department of Assisted Reproduction, Shanghai, China
[2]University of Shanghai for Science and Technology, Shanghai-Hamburg College, Shanghai, China

Study question: What's the relationship between the vitrification day of the embryos transferred and the subsequent risk of ectopic pregnancy (EP) in frozen-thawed embryo transfer (FET) cycles?

Summary answer: Transfers of day 6 vitrified embryos had a significantly lower risk of EP both than transfers of day 3 and day 5 vitrified embryos.

What is known already: EP is a leading cause of maternal mortality among the first trimester worldwide with unelucidated pathogenesis. Theoretically, blastocyst transfers could lower the likelihood of EP compared with cleavage stage embryo transfers, but results from reported clinical data varied a lot, and few studies compared EP rate between day 6 and day 5 or day 6 and day 3 vitrified embryo transfers.

Study design, size, duration: This was a retrospective cohort study involving a total of 11,204 pregnancies following FET cycles of in vitro fertilization/intracytoplasmic sperm injection from March 2003 to May 2015.

Participants/materials, setting, methods: EP rate was compared by patient and treatment characteristics, including maternal age, full-term birth history, EP history, Fallopian tubal surgery history, tubal infertility, male infertility, endometrial preparation, endometrial thickness on embryo transfer day, year of treatment, number and vitrification day of embryos transferred. Thereafter,

we used goodness of fit to specify the best fitted generalized estimated equation regression models to calculate unadjusted and adjusted odds ratios for the association between EP and selected characteristics.

Main results and the role of chance: The overall rate of EP was 2.8%. In the univariate analysis, patients with EP history, Fallopian tubal surgery history and tubal factor infertility were associated with a significantly elevated proportion of EP compared with those without. In contrast, patients with male factor infertility had a significantly decreased rate of EP than those without. Additionally, EPs were less common among women who had a >11mm endometrium on the day of embryo transfer compared with those having a thinner endometrium. As to vitrification day of embryos transferred, EPs were more likely when day 3 and day 5 vitrified embryos were transferred than transferring day 6 vitrified embryos (3.1% vs. 1.9% vs. 0.6%, P<0.001). In the adjusted analysis, EP history (adjusted odds ratio [AOR] 1.62, 95% confidence interval [CI] 1.18-2.23), Fallopian tubal surgery history (AOR 1.35, 95% CI 1.04-1.76) and tubal factor infertility (AOR 2.52, 95% CI 1.67-3.81) were significantly associated with increased risk for EP. Besides, day 6 vitrified embryo transfers had a significantly lower risk for EP both than day 3 (AOR 5.29, 95% CI 2.35-11.91) and day 5 (AOR 2.88, 95% CI 1.05-7.87) vitrified embryo transfers.

Limitations, reasons for caution: The data were not derived from multiple centers. Moreover, female smoking habits were not available in the database, and the amount of day 5 vitrified embryo transfers was still limited.

Wider implications of the findings: The reduced EP risk in day 6 vitrified embryo transfers both than in day 3 and day 5 vitrified embryo transfers indicates embryo factors may play important roles in the pathogenesis of EP, and more individualized timing of embryo transfer in FET cycles may be needed to decrease EP risk.

Trial registration number: Not applicable.

O-238 The impact of granulocyte colony stimulating factor on thin endometrium of an animal model with rats

M. Oktem[1], G. Isik[1], N. Bozkurt[1], I. Guler[2], E. Ozalp Oktem[3], C. Ozogul[4], S. Saribas[4], A. Erdem[1], M. Erdem[1]

[1]Gazi University School of Medicine, Obstetrics and Gynecology, Ankara, Turkey
[2]Gazi University Faculty of Medicine, Obstetrics and Gynecology, Ankara, Turkey
[3]Akay Hospital, Obstetrics and Gynecology, Ankara, Turkey
[4]Gazi University School of Medicine, Histology and Embryology, Ankara, Turkey

Study question: Is it possible to improve endometrial thickness of thin endometrium by influencing proliferative, angiogenic and apoptotic factors with granulocyte colony stimulating factor (G-CSF) injection?

Summary answer: G-CSF significantly improved endometrial thickness along with angiogenic, proliferative and apoptotic factors that crucial for implantation.

What is known already: Thin endometrium (≤ 7 mm) unresponsive to ovarian hyperstimulation is associated with decreased pregnancy rates after IVF. In an experimental animal model, G-CSF improved endometrial thickness and morphology by immunohistochemistry and western-blot with cytokeratin and vimentin. In clinical small case series of thin endometrium G-CSF administrations between the days of ovulation trigger and embryo transfer was found to be effective on pregnancy rates regardless significantly improvement of endometrial thickness

Study design, size, duration: An experimental rat model was conducted to evaluate the effect of G-CSF injection on endometrial thickness and expression of endometrial angiogenic, proliferative, and apoptotic markers. For this purpose, a total number of 24 female adult rats with either thin (12) or normal (12) endometrium were used. Each group was further divided into G-CSF or saline injection groups with 6 rats

Participants/materials, setting, methods: 2 estrous cycles after forming of thin endometrium by uterine injection of 0.2 ml 96% ethyl alcohol to 200-250 g weighing Sprague Rawley® rat models, 5 days of subcutaneous injections of 40 µg/kg G-CSF (Nuepogen) or saline were given. Endometrial thickness,

immunohistochemically expression of vascular endothelial growth factor receptor-2 (VEGF-R2), proliferative cell nuclear antigen (PCNA) and fibronectin; apoptosis with TUNEL method were compared in specimens of hysterectomies among 4 groups of post-model rats.

Main results and the role of chance: Endometrial thickness was significantly improved with G-CSF in thin endometrium but not in normal endometrium group when compared to saline injection (239 ± 158.4 vs 151 ± 167, p = 0.025, 283.6 ± 189.1 vs 282.6 ± 94.9, p = 0.309, respectively). In thin endometrium groups, expression of PCNA (10.56 ± 4.25 vs 2.31 ± 2.01, p < 0.001) in stromal and glandular epithelium and pericapillary VEGF-R2 (3.11% vs 1.84%, p = 0.037) was significantly increased and apoptosis was significantly decreased with G-CSF when compared to saline injection (16.97 ± 4.42 vs 28.50 ± 7.92, p < 0.001). Fibronectin was also increased between G-CSF and saline in thin endometrium, but the difference was not statistically significant (0.79% vs 0.71%, p = 0.071), However, in normal endometrium, any maker was not improved by G-CSF when compared to saline injection.

Limitations, reasons for caution: The main limitation of this study is being an experimental rat model and the need of further clinical studies for confirmation of the results.

Wider implications of the findings: G-CSF improves endometrial thickness, proliferation, angiogenesis and DNA fragmentation in thin endometrium and in the light of these finding it may also have a role in recurrent implantation failure

Trial registration number: not applicable.

O-239 Live birth rate according to different treatment strategies in TPOAb-positive women with recurrent pregnancy loss

S. Bliddal[1], U. Feldt-Rasmussen[1], A. Krogh-Rasmussen[1], A.M. Kolte[2], O.B. Christiansen[2], C.H. Nielsen[3], H.S. Nielsen[2]

[1]Copenhagen University Hospital Rigshospitalet, Department of Medical Endocrinology, Copenhagen, Denmark
[2]Copenhagen University Hospital Rigshospitalet, Recurrent Pregnancy Loss Unit, Copenhagen, Denmark
[3]Copenhagen University Hospital Rigshospitalet, Institute of Inflammatory Research, Copenhagen, Denmark

Study question: Do positive thyroid peroxidase antibodies (TPOAbs) affect pregnancy outcome in women with recurrent pregnancy loss (RPL) and, if so, is this ameliorated by treatment with immunotherapy or thyroxine replacement therapy?

Summary answer: TPOAbs were not associated with pregnancy outcome. However, thyroxine replacement caused a trend towards a significant increase of live birth rate in TPOAb-positive women.

What is known already: Thyroid autoimmunity may be associated with pregnancy loss. A possible mechanism behind this is overactivation of the maternal immune system, which causes rejection of the fetal allograft. Studies of TPOAb-positivity in women with RPL are few and of limited sample size.

Study design, size, duration: Prospective cohort study of 900 women with RPL followed at the RPL Unit, Copenhagen University Hospital, from 2011-2016.

Participants/materials, setting, methods: Recurrent pregnancy loss was defined as ≥3 losses. Upon referral, women were screened for TSH (Roche Modular E170 electrochemiluminescense immunoassays) and TPOAbs (automated Kryptor immunoflourescent assay). TPOAb-positivity>60 kU/L. We performed test for trends by chi-square or independent t-tests as appropriate, and subsequently adjusted regression analyses including as covariates: maternal age at referral, TSH (logtransformed), total number of losses, immunotherapy, and thyroxine replacement therapy. The National Data Protection Agency approved the project (2017-41-5005).

Main results and the role of chance: We included 5219 pregnancies (76.6% spontaneous) in 900 women. 119 (13.2%) women were TPOAb-positive. TPOAb-positivity was neither associated with number of losses (p = 0.87, aOR 0.004(-0.3-0.3), p = 0.98), nor with number of pregnancies (p = 0.62, aOR 1.02(0.92-1-11) p = 0.76). Among TPOAb-positive women,

TPOAb-concentration was not associated with number of losses (B=0.75 (-0.12-0.27), p = 0.45).

In women with a registered first pregnancy after referral, 72 of 557 (12.9%) were TPOAb-positive. Excluding women with extrauterine pregnancies and provoked abortions (n = 65), TPOAb-positivity was not associated with live birth rate (54.4% vs 60.6%, p = 0.35, aOR 0.98(0.5-1.9) p = 0.94). Total number of losses was the only predictor of live birth rate (aOR 0.54(0.45-0.66) p = 0.000). TSH-levels were positively associated with TPOAb-positivity (p = 0.00), but not with any investigated outcome. A total of 199 (40.4%) women received immunotherapy and 30 (6.6%) women received thyroxine replacement therapy. Live birth rate was not significantly affected by treatment with immunotherapy (59.3% vs 60.1%, p = 0.93, aOR 1.17(0.77-1.78), p = 0.45) or thyroxine replacement therapy (63.3% vs 59.5%, p = 0.85, aOR 1.69(0.67-4.30), p = 0.27). However, in TPOAb-positive women, live birth rate after treatment with thyroxine replacement therapy was 68.4% as compared to 49.0% in non-treated women (p = 0.18, aOR 3.2(0.89-11.55) p = 0.08). Immunotherapy did not alter live birth rate (53.6% vs 55.0%, p = 1.0, aOR 0.92(0.31-2.71) p = 0.89).

Limitations, reasons for caution: Although this study to our knowledge is the largest to date of women with RPL, there may be a lack of power in calculations of association between live birth rate and treatment strategies.

Wider implications of the findings: Treatment of TPOAb-positive women with thyroxine replacement (but not immunotherapy) caused a trend towards a significant increase of live birth rate. Results from multicenter intervention studies are awaited. If RPL is caused by an immunological reaction, thyroid autoimmunity seems to be neither the cause nor a sensitive marker hereof.

Trial registration number: Not applicable.

O-240 Is there a role for immunotherapy in IVF and recurrent miscarriage: a systematic review and meta-analysis

C. Achilli[1], W. Saab[1], P. Serhal[1], S.K. Sunkara[2], S. Seshadri[1]

[1]Centre for Reproductive and Genetic Health, CRGH, London, United Kingdom
[2]King's College London, Division of Women's Health, London, United Kingdom

Study question: What is the current evidence on the role of immunotherapy in IVF and in the management of recurrent miscarriage (RM)?

Summary answer: Current literature does not support the use of the immunotherapy for IVF outcomes or in the prevention of the RM.

What is known already: Imbalance within the immune system has been postulated to be one of the causes for adverse IVF outcomes and RM. Within this context, immunotherapy is presumed as the next logical step with an aim to improve pregnancy outcomes in these women. Various interventions to improve uterine receptivity, enhance implantation and prevent early miscarriages have been suggested. However, the benefit of using immunomodulators is still unclear. The objective of this systematic review is to summarize objectively the efficacy of immunotherapy in IVF and RM.

Study design, size, duration: We conducted a systematic review to assess the efficacy of commonly used immunomodulators such as: intravenous use of (1) immunoglobulin (IVIG), (2) lymphocyte immunotherapy (LIT) and (3) intralipid; intrauterine infusion of (4) granulocyte-colony stimulating factor (G-CSF) and (5) peripheral blood mononuclear cells (PBMC); subcutaneous administration of (6) TNF-alpha (TNF-α) inhibitors, (7) leukaemia inhibitory factor (LIF); and oral administration of (8) glucocorticoids. A literature search was performed using MEDLINE, PUBMED and EMBASE until December 2016

Participants/materials, setting, methods: Only randomized controlled trials (RCTs) were included and a meta-analysis was carried out where appropriate. Case-control or cohort studies were considered but not included in the meta-analysis. Participants included women undergoing IVF treatment with or without a previous history of recurrent implantation failure (RIF) and women with RM. The primary outcome was live birth rate (LBR); secondary outcomes were clinical pregnancy rate (CPR) and miscarriage rate (MR).

Main results and the role of chance: Meta-analysis of two RCTs that evaluated IVIG as the sole intervention in women with RIF undergoing IVF treatment showed no significant difference in the CPR and LBR between the IVIG and

placebo control group (RR 0.92; 95% CI 0.26, 3.19; p = 0.89 and RR 1.79; 95% CI 0.67, 4.79; p = 0.25 respectively). Four RCTs evaluated the role of steroids in women undergoing IVF (heterogeneous population) showed no difference rate in CPR (RR 1.3; CI 0.90, 1.86; p = 0.16) or MR (RR 1,2; CI 0.25, 5.85, p= 0.83) versus the control group.

A total of 11 RCTs were analysed for the use of immunomodulators in women with RM. The study evaluating the role of G-CSF showed a significant improvement in the LBR compared to the control group (RR 5.14; CI 1.69, 15.63; p =0.004). Two studies evaluated LIT in women with RM, showing no significant difference in the LBR (RR 3.48; CI 0.19, 65.26; p = 0.4). Eight RCT's assessed IVIG treatment in RM showing no difference in LBR (RR 1.35; CI 0.92, 1.98; p = 0.13), CPR (RR 0.96; CI 0.54, 1.71; p = 0.90) or MR (RR 0.79; CI 0.5, 1.25, p = 0.31) versus the control group.

Limitations, reasons for caution: Limited number of RCTs with limited sample size are present in literature. Both RCTs and case-controlled studies are heterogeneous. Preparations, procedures, sample populations and outcomes vary across studies.

Wider implications of the findings: This study did not show a role for immunotherapy in the prevention of RM or in women undergoing IVF treatment. Immunotherapy should only be used in the context of research and should not be used in routine clinical practice to improve reproductive outcomes.

Trial registration number: Not required.

O-241 HLA-DR and –DQ alleles in Danish women with unexplained recurrent pregnancy loss and controls

O.B. Christiansen[1,2,3], A.M. Kolte[4], M.C. Krog[4], E.C. Larsen[4], H.S. Nielsen[4], R. Steffensen[5], C.K. Thomsen[6]

[1]Copenhagen University Hospital Rigshospitalet, Fertility Clinic 4071, Copenhagen, Denmark
[2]Aalborg University, Institute of Clinical Medicine, Aalborg, Denmark
[3]Aalborg University Hospital, Department of Obstetrics and Gynaecology, Aalborg, Denmark
[4]Rigshospitalet, Recurrent Pregnancy Loss Clinic, Copenhagen, Denmark
[5]Aalborg University Hospital, Department of Clinical Immunology, Aalborg, Denmark
[6]Aalborg University Hospital, Department og Obstetrics and Gynacology, Aalborg, Denmark

Study question: Are particular HLA-DRB1 alleles and especially HLA-DRB1*03 associated with recurrent pregnancy loss (RPL) in a Caucasian population?

Summary answer: HLA-DRB1*03 was borderline associated with RPL in this study. Combining three Danish case-control studies, HLA-DRB1*03 was significantly increased in RPL (p = 0.002).

What is known already: In two previous smaller studies, we found that the HLA-DRB1*03 allele is more frequent in Caucasian women with unexplained RPL than in controls. This HLA allele is associated with several autoimmune diseases. However, other studies have not confirmed this association.

Study design, size, duration: The study was a case-control study including 1078 RPL patients consecutively referred between January 2003 and May 2016 and 230 consecutive normal women referred for routine scan in pregnancy.

Participants/materials, setting, methods: HLA-DRB1 typing and in subsets of patients also HLA-DQB1 typing by DNA technology were done in Caucasian women with unexplained RPL (3 or more consecutive early pregnancy losses without uterine abnormalities, parental chromosomal aberrations or oligomenorrhea). The patients had been referred to the RPL clinic in Copenhagen. Similar HLA typing was done in Caucasian control women with a least one normal birth and maximum one pregnancy loss referred for routine ultrasound scan in mid-gestation.

Main results and the role of chance: The HLA-DRB1*03 allele was found borderline significantly increased in RPL patients compared with controls (Odds Ratio [OR] 1.39; 95% CI 0.99-1.93), p = 0.053. HLA-DRB1*07 was found with increased frequency in RPL compared with controls (OR = 1.56; 1.09-2.22), p = 0.015. Most HLA-DRB1*07 alleles are found on the HLA-DRB1*07-DQB1*02 haplotype and in order to investigate whether the DQB1*02 allele is

the common susceptibility allele for RPL, investigation of HLA-DQB1 was undertaken in HLA-DRB1*07 positive women. This did not reveal any significant difference between the two groups.

The frequency of the HLA-DRB1*04 was significantly decreased in patients compared with controls (OR = 0.70; 0.55-0.89), p = 0.004. When comparing the frequency of HLA-DRB1*04 homozygous patients and controls, the difference became even stronger (OR = 0.45; 0.24-0.83); p < 0.01).

The frequencies of no other HLA-DRB1 allele was different between the two groups. There was no clear correlation between primary/secondary RPL status or number of pregnancy losses and presence of specific HLA alleles except for HLA-DRB1*03, which were more frequent in patients with ≥4 pregnancy losses.

In a meta-analysis of results from three Danish case-control studies, the combined OR of HLA-DRB1*03 in RPL was 1.42 (1.14-1.77), p = 0.002.

Limitations, reasons for caution: The number of RPL patients was the largest in any similar study so far; however, the number of controls was limited. Whereas the association of HLA-DRB1*03 to RPL was hypothesized before the study, the findings regarding HLA-DRB1*07 and HLA-DRB1*04 were new and must be confirmed in further studies

Wider implications of the findings: The clear association between HLA-DRB1*03 and RPL (and maybe other HLA-DRB1 alleles) strengthens suggestions that immunologic disturbances play a significant role in RPL since autoimmune diseases are known to be strongly associated with particular HLA-DRB1 alleles.

O-242 Profiling of human spermatozoal non-coding RNA to determine the male contribution to embryonic implantation potential

P. Chung, N. Pereira, A. Parrella, S. Cheung, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: To identify vital sperm-specific noncoding RNA (ncRNA) in men with unexplained infertility and normal semen parameters that can contribute to the non-implantation of good-quality embryos.

Summary answer: Underexpression of regulatory sperm-specific methylation ncRNAs may contribute to dysfunction in de-novo embryo methylation at the time of blastulation leading to decreased implantation potential.

What is known already: NcRNAs serve as functional and regulatory RNA molecules, which are transcribed from DNA, but do not undergo translation into proteins. Recent evidence suggests that sperm-specific ncRNAs may contribute to the reproductive potential of the male gamete by regulating post-fertilization embryonic development. One mechanism through which this is achieved is via increased genomic methylation at the blastocyst stage. It is posited that some men may not be able to achieve a pregnancy even in the presence of a normal semen analysis due to dysregulation of vital regulatory ncRNAs involved in embryonic development.

Study design, size, duration: Thirty-one consenting men undergoing infertility screening donated their ejaculated samples. RNA-sequencing (RNA-seq) was performed on these specimens, with special emphasis on identifying ncRNAs of interest i.e., small noncoding RNA (sncRNA) and long noncoding RNA (lncRNA). Following RNA-Seq, the expression of sncRNAs and lncRNAs was compared between infertile men who did not achieve a pregnancy with ART and a control group of 3 fertile men who were able to conceive naturally with their female partners.

Participants/materials, setting, methods: RNA was isolated from 25×10^6 spermatozoa using a commercial spin column kit (RNeasy Mini Kit, QIAGEN, Germany). The spermatozoal nucleic acid quality and concentration were measured. After creation of paired-end libraries from RNA samples, 76 bp RNA-Sequencing (RNA-Seq) using an Illumina platform (NextSeq 500) was carried out and expanded to 60 M reads. Expression values were calculated in fragments per kilobase of transcript per million mapped reads (FPKM).

Main results and the role of chance: The 31 consenting men with a mean age of 39.6 ± 5 years had the following semen parameters: $46.3 \pm 19 \times 10^6/$mL (concentration), $44.8 \pm 14\%$ (motility), and normal morphology. Five (68.9%) men, with female partners aged 34.8 ± 1 years, underwent ART that resulted in a fertilization rate of 71.4% and generation of 2.44 ± 1 good-quality embryos on day 3. However, no implantation of embryos occurred. There was no difference in the age demographics of men or women in the ART or control groups. RNA-seq of approximately 23,260 genes was performed, of which 28 ncRNAs showed decreased expression in the ART group. These 28 ncRNAs were classified into 7 (25%) sncRNAs and 21 (75%) lncRNAs. Interestingly, the expression of 4 ncRNAs (*SNORD68, SNORD104, AVP, ALOX15P1*) involved in methylation was completely absent in the ART group ($P < 0.001$). The expression of 5 other ncRNAs (*MIR181C, MIR636, MIR3687, MIR3689B*) involved in the stabilization of messenger RNA was completely decreased in the ART group compared to controls ($P = 0.08$). Of note, the majority of ncRNAs (81.3%) were products of genes located on autosomes, while the remaining ncRNAs were coded by genes located on the sex chromosomes.

Limitations, reasons for caution: The under or absent expression of major sncRNAs and lncRNAs in men with normal semen parameters but unexplained infertility needs to be confirmed prospectively in a larger cohort. Also, the molecular mechanisms by which dysregulation of sperm-specific ncRNAs involved in methylation impact the implantation potential of embryos needs further elucidation.

Wider implications of the findings: RNA-Seq of vital sperm-specific ncRNAs can provide crucial information about the epigenetic etiology of unexplained infertility in men with normal semen parameters, and may also reflect the overall contribution of the human spermatozooan to embryonic development and establishing a viable pregnancy.

Trial registration number: Not applicable.

O-243 Identification of extracellular vesicles in human oviductal fluid and small non-coding RNAs profiling

S. Canovas[1], A. Canha[1], J. Romero-Aguirregomezcorta[1,2], M.T. Prieto[3], P. Coy[1]

[1]Universidad de Murcia-Campus Mare Nostrum. IMIB-Arrixaca-UMU, Physiology of Reproduction Group- Physiology Department, Murcia, Spain
[2]Universidad CEU Cardenal Herrera, Departamento de Producción Animal- Facultad de Veterinaria, Alfara del Patriarca- Valencia, Spain
[3]Universidad de Murcia-Campus Mare Nostrum. IMIB-Arrixaca-UMU, Departamento de Cirugía- Pediatría- Obstetricia y Ginecología. Facultad de Medicina, Murcia, Spain

Study question: Are there extracellular vesicles/exosomes in the human oviductal fluid and which is its composition?

Summary answer: Extracellular vesicles were identified in human oviductal fluid and small non-coding RNAs profile was analyzed in individual samples of human oviductal fluid.

What is known already: Extracellular vesicles (EV) in oviductal fluid were firstly reported in mouse. They carry and deliver to sperm the plasma membrane Ca^{2+}-ATPase4, which participate in the Ca^{2+} efflux pump and play an essential role in sperm fertilizing ability (Al-Dossary, et al 2013). Later, other studies reported the presence of oviductosomes in different species, showing that, in cattle, the addition of OVS from the isthmic region to the in vitro culture system without serum affects gene expression (with upregulation of factors such as AQP3, DNMT3A and, SNRPN), and improves the development and quality of the produced embryos (Lopera-Vasquez et al., 2017).

Study design, size, duration: 8 oviductal human fluid samples were collected individually from premenopausal women with benign uterine pathology submitted to abdominal hysterectomy in University Hospital Virgen Arrixaca, by direct aspiration of the tubal content with an automatic 200 μl pipette. Two of them were analyzed by western-blot, 2 were analyzed by nanoparticle tracking analysis (Nanosight) and 4 pairs oviductal fluid-serum were analyzed by small nc-RNA-seq (50 bp single end Illumina HiSeq NGS).

Participants/materials, setting, methods: After centrifugation of the samples, cellular debris was discarded and extracellular vesicles were isolated from the supernatant using the Exoquick exosome precipitation kit (SBI System Biosciences, Inc.) according to manufacturer's instruction. Similarly, EVs were isolated from serum samples for the pairs oviductal fluid-serum samples.

Main results and the role of chance: Western blot analysis revealed the presence of CD9 and CD63 in the isolated EV from oviductal fluid. Nanoparticle tracking analysis showed the existence of vesicles with a size between 150-177 nm, displaying a Brownian motion with a concentration between 6.25×10^{11} to 1.48×10^{12} particles/ml. Concentration of small RNA isolated from individual was between 131-290 (ng/μl), with an average size of 29 nucleotides in the miRNA fraction. After RNA-sequencing the number of alignments were higher than 11,5 millions for all samples, with a percentage of reads aligned between 87.85 to 93.80 %. From RNA-seq data 22 categories of small non-coding RNAs were identified, including miRNAs (micro RNAs) and piRNAs (piwi-interacting RNAs). From miRNAs, some elements such as miR-126, miR-148, miR-152, miR-185, miR-21 and miR-29, with previously described functions on epigenome by targeting DNA methyltransferases DNMT1 and/or DNMT3A/3B were identified. Relevant differences for the level of expression were detected for some factors between oviductal fluid and serum.

Limitations, reasons for caution: A limited number of samples were analyzed and individual variation between samples could mask some additional differences between serum and oviductal fluid.

Wider implications of the findings: Results showed that extracellular vesicles are present in human oviductal fluid, and those vesicles contain at least 22 types of small non coding RNAs, showing a specific profile compared with serum from the same patients.

Trial registration number: Not applicable.

O-244 Investigation of possible incompatibilities between the mitochondrial and nuclear genomes that affect preimplantation embryo development

R. Jawdat[1], S. Sengupta[2], N. Lane[3]

[1]University College - Medical School, Institute of Women's Health, London, United Kingdom
[2]Institute for women's health, Genetics, London, United Kingdom
[3]UCL, Department of Genetics, Evolution and Environment

Study question: Do particular haplotype combinations between mitochondrial and nuclear encoded genes involved in mitochondrial function lead to a mismatch affecting human embryo development?

Summary answer: Comparison of nuclear genes associated with the ETC identified SNPs in the *COQ9* gene in embryos with poor preimplantation development in three different families.

What is known already: Maternal factors that may lead to abnormal preimplantation development include mitochondria. Proteins required for mitochondrial function are encoded by both mitochondrial DNA (mtDNA) and the nuclear DNA (nDNA) necessitating the coordination between the two genomes. Mitochondrial-nuclear mismatch has been proposed as a cause of embryonic cell death. Changes in ATP synthesis and metabolic reactions in the mitochondrial electron transport chain (ETC) have been linked to female infertility. This study explores the effect of different combinations of mtDNA haplotypes with 53 nuclear encoded genes that have mitochondrial function, by assessing preimplantation embryo development.

Study design, size, duration: This was a cohort study including two groups. The first group was made up of 11 fertile couples undergoing PGD for single gene disorders and their corresponding embryos (n = 57). The embryos were collected on day 6-7 post fertilization. The other group was composed of 12 couples with repeated miscarriage (RM) for unknown reasons.

Participants/materials, setting, methods: Maternal and paternal mtDNA was analysed from 11 fertile and 12 couples suffering repeated miscarriage (RM) by Long range PCR and NGS. Each sample was assigned a mitochondrial haplogroup using HaploGrep and confirmed by EMMA software. The selected 53 nuclear genes were sequenced from parental genomic DNA and from embryos following whole genome amplification by MDA using SureSelect QXT from Agilent. Nuclear DNA genotypes that only occurred in the embryos with poor morphology were identified.

Main results and the role of chance: Several mitochondrial haplogroups were identified. Overall more couples from the repeated miscarriage group (4/12) had identical mtDNA haplotypes between partners, compared to the fertile group (1/11). Within the fertile group the presence of the T haplogroup in one of the partners was associated with poor blastocyst formation. Analysis of sequences in embryos from the selected nuclear genes identified 3 SNPs in the *COQ9* gene in embryos with poor preimplantation development in three different families. In these families, mitochondrial haplogroup T, was identified in the male partner. Although mitochondria from the male partner are not present in the embryo, we considered the male mitochondrial haplogroup as a surrogate marker for possible combinations of nuclear genes that could be transmitted to the embryo leading to a mitochondrial nuclear mismatch. This analysis suggests that the nuclear background (specifically SNPs on *COQ9*) where one partner has mitochondrial haplogroup T may contribute to poor embryo development. Other studies have suggested that haplogroup T is associated with poor sperm motility and fertilisation. Whilst most of the mitochondrial haplogroups T were present in the male partner in our study, all fertilization was achieved following ICSI, therefore sperm motility was not a factor in our observation.

Limitations, reasons for caution: The main limitation is the small number of samples due to the difficulty in obtaining human embryos. Also, many SNPs where filtered to avoid the possibility of ADO or because they were non-infomative. Another limitation is the difficulty in performing functional analysis on the same embryo.

Wider implications of the findings: COQ9 is necessary for the synthesis of Ubiquinone; a lipid found in most biological membranes and a co-factor in many redox processes including mitochondrial ETC. Changes in the sequence of *COQ9* may affect ubiquinone synthesis disturbing mitochondrial ATP production, increasing oxidative stress and apoptosis affecting many processes including embryogenesis

Trial registration number: not applicable.

O-245   Effect of FSHR gene polymorphism on the rate of chromosomal abnormalities in blastocysts

J. Diblik[1], M. Trková[2], J. Horáček[2], I. Soldátová[3], M. Sekowská[3], D. Milická[4], V. Mokrá[4], J. Míka[5], R. Křen[5], P. Potužníková[5], R. Jarošová[5], M. Brandejská[5]

[1]Gennet s.r.o., Genetics, Prague, Czech Republic
[2]Gennet s.r.o., Cytogenetics, Prague, Czech Republic
[3]Gennet s.r.o., Molecular Genetics, Prague, Czech Republic
[4]Gennet s.r.o., IVF, Liberec, Czech Republic
[5]Gennet s.r.o., IVF, Prague, Czech Republic

Study question: Is the rate of chromosomal abnormalities in human blastocysts influenced by different alleles of the c.2039 G>A (p.Ser680Asn) polymorphism in the FSH receptor gene (FSHR)?

Summary answer: We have found that patients who are not carriers of the risk allele (Asn) have the highest rate of normal embryos.

What is known already: The risk alele (Asn) of studied FSHR gene polymorphism is linked to the ovarian response to stimulation by FSH and the risk of ovarian hyperstimulation syndrome (OHSS). In vitro studies show, that high levels of FSH during oocyte maturation increase aneuploidy in resulting oocytes and it has also been shown, that higher intrafollicular FSH is associated with oocyte aneuploidy. But it is not known if individual differences in ovarian response and the occurence of OHSS are linked to the aneuploidy rate in clinical IVF cases possibly through different sensitivity of the oocytes to the FSH stimulation depending on the polymorphism.

Study design, size, duration: This is a retrospective study from the years 2012-2016. We have analyzed data from 284 cycles with PGS performed in

224 female patients. There were 42 cycles with 109 blastocysts in Ser/Ser homozygotes, 159 cycles with 449 blastocysts in Ser/Asn heterozygotes and 83 cycles with 233 blastocysts in Asn/Asn homozygotes.

Participants/materials, setting, methods: We have compared the results of preimplantation genetic screening of aneuploidy (PGS) using microarray comparative genomic hybridization (aCGH) on trophectoderm samples in patients divided according to the results of molecular genetic examination of the FSHR gene Ser680Asn polymorphism using High Resolution Melting (HRM).

Main results and the role of chance: The groups were not significantly different with regards to the age (Ser/Ser: average age 36 years, Ser/Asn: 36.8 years, Asn/Asn: 36.2 years, Kruskal-Wallis test, p = 0.3).The rates of normal embryos were in the Ser/Ser group: 57 % (95% confidence interval: 47-66 %), in Ser/Asn: 44 % (39-48 %) and in Asn/Asn 48 % (42-54 %). The differences in the proportions are significant (Fisher's Exact Test, p = 0.04). Patients with Ser/Ser genotype had the highest proportion of normal blastocysts. Our results support the hypothesis, that variants in the FSHR gene might influence the risk of aneuploidy.

Limitations, reasons for caution: We have not found any further decrease in the rate of normal embryos in Asn/Asn homozygotes compared to Ser/Asn heterozygotes.

Wider implications of the findings: Elucidating the role of individual genetic variants in the response to the controlled hyperstimulationovarian stimulation including the rate of chromosomal abnormalites in oocytes and embryos might lead to better and more personalized treatments.

Trial registration number: not applicable.

O-246   Luteinizing hormone beta gene polymorphism affects clinical pregnancy rate after in-vitro fertilization and embryo transfer in GnRH antagonist cycles

Y. Ku[1], J.Y. Jeong[1], K.Y. Moon[1], C.W. Choo[1], S.J. Chae[1], K.S. Lim[1], W.D. Lee[1], J.H. Lim[1], Y.M. Choi[2]

[1]Maria Fertility Hospital, OBGY, Seoul, Korea- South
[2]Seoul National University Hospital, OBGY, Seoul, Korea- South

Study question: Does luteinizing hormone (LH) beta gene polymorphism affect the outcome of in-vitro fertilization (IVF) and embryo transfer (ET)?

Summary answer: Clinical pregnancy rate after IVF-ET is lower in patients with LH beta gene variant in GnRH antagonist cycles.

What is known already: Trp8Arg polymorphism of LH beta gene is common and shows decreased bioactivity in vivo. Previous studies showed association between LH beta variant protein and hypo-sensitivity to exogenous FSH in controlled ovarian hyperstimulation (COH) for IVF-ET. In another study, carrier frequency of LH beta gene polymorphism was 11% (4 out of 36 patients) in poor ovarian response group, while carrier frequency in normal response group was 17% (17 out of 98 patients). Therefore, further studies are needed to evaluate the effect of LH beta gene polymorphism on the outcome of IVF-ET.

Study design, size, duration: In this retrospective cross sectional study, 591 patients who had undergone IVF-ET at Maria Fertility Hospital during 2003-2016 were recruited. Among them, 289 patients had undergone COH with GnRH antagonist protocol and 302 patients had long GnRH agonist cycles.

Participants/materials, setting, methods: Trp8Arg polymorphism of LH beta gene was analyzed in subjects using realtime TaqMan assay. Patients with wild type allele of LH beta gene were regarded as noncarrier group and those with variant allele(s) as carrier group. Age, basal FSH, AMH, number of retrieved oocytes, total dose of gonadotropin, duration of COH, serum estradiol on hCG day, pregnancy rate and clinical pregnancy rate were compared in both groups.

Main results and the role of chance: Variant LH genotype was found in 70 (11.8%) patients out of 591 subjects: 67 hetrozygous and 3 homozygous. In GnRH antagonist cycles, basal characteristics including age, basal FSH and AMH were comparable between carrier and noncarrier groups. Numbers of retrieved oocytes were similar in carrier and noncarrier groups (11.4 ± 7.9 vs. 10.4 ± 6.3, respectively, p = .377). Clinical pregnancy rate per embryo transfer was significantly lower in carrier group than that in noncarrier group (18.9% vs.

37.1%, respectively, p = .030). Other parameters including total dose of gonadotropin, duration of COH and serum estradiol on hCG day were comparable in both groups. In long GnRH agonist cycles, basal characteristics including age, basal FSH and AMH were comparable between carrier and noncarrier groups. Numbers of retrieved oocytes were similar in carrier and noncarrier groups (11.8 ± 7.0 vs. 11.8 ± 5.9, respectively, p = 0.996). Clinical pregnancy rate per embryo transfer (45.2% vs. 38.4%, respectively, p = 0.467) were similar in carrier and noncarrier groups. Other parameters including total dose of gonadotropin, duration of COH and serum estradiol on hCG day were comparable in both groups.

Limitations, reasons for caution: Because of the retrospective nature of this study, further study is necessary to apply this result to larger population. In our study, COH was done with exogenous FSH or hMG. Homogenous exogenous gonadotropin use might clarify the effect of LH beta gene polymorphism on IVF-ET outcome.

Wider implications of the findings: Common LH beta gene variant was associated with lower clinical pregnancy rate in GnRH antagonist cycles but not in long GnRH agonist cycles. Evaluating single nucleotide polymorphism might be applied to individualize COH protocol to each patient in the future.

Trial registration number: Not applicable.

O-247 A Deep Dive into the Human Blastocyst: Correlating the Embryo Transcriptome with Preimplantation Genetic Screening Results and Embryo Morphology

N. Resetkova[1], A. Groff[2], D. Sakkas[3], A. Penzias[3], J. Rinn[2], K. Eggan[2]

[1]Beth Israel Deaconess Medical Center, OBGYN, Boston- MA, U.S.A.
[2]Harvard University, Harvard Department of Stem Cell and Regenerative Biology, Cambridge- MA, U.S.A.
[3]Boston IVF, Reproductive Endocrinology and Infertility, Waltham- MA, U.S.A.

Study question: Can gene sets predict human embryo sex and morphology from RNA expression data and, subsequently, can the embryo's transcriptome be analyzed through single cell technology?

Summary answer: Embryo sex can be identified reliably from the RNA transcripts of whole embryos and trophectoderm biopsies. Identified gene sets correlate with embryo quality.

What is known already: Genomic analysis is being increasingly utilized as a clinical test for In Vitro Fertilization with aims of increasing implantation rates per embryo transfer. This tool has not yet enabled the sole selection of competent human embryos, prompting investigation of other techniques. Single cell RNA sequencing has been studied with marked improvement in techniques requiring very low input of nucleic acids, enabling application to analysis of human embryos. Deep sequencing analysis of the embryo transcriptome has the potential to unearth details about coding and non-coding RNA (Ribonucleic Acid) transcripts, both of which have likely functional relevance on the embryo's developmental potential.

Study design, size, duration: This is a cohort study in which donated embryos for research were thawed under an IRB approved protocol over a 12-month duration. Slow frozen blastocyst stage embryos were thawed and cultured overnight in a standard incubator using a single step media. Embryos were biopsied at the blastocyst stage. 30 embryos were included on the analysis over the duration of the experiment.

Participants/materials, setting, methods: Thawed slow frozen embryos meeting established morphologic criteria were selected for inclusion. Blastocyst stage embryos were double biopsied and RNA Sequencing was performed from the trophectoderm (TE) biopsy and the remaining whole embryo, while the other TE biopsy was sent for Preimplantation Genetic Screening. Some embryos were processed whole after dissolution of the zona pellucida. Using single cell RNA sequencing, a gene expression profile for each embryo was quantified and differential analysis was performed.

Main results and the role of chance: Comparative analysis of genetically screened male and female embryos identified a set of genes that are characteristically expressed in male versus female embryos at the late blastocyst stage. To validate our gene set, we used it to blindly assign the sex of individual cells and embryos of a separate recently published study (Petropoulos, 2016), and found that our sex assignments agreed with the independent assessment made

in that study. Furthermore, using embryos that underwent PGS, we identified a gene expression profile differentiating high quality (Grade 4AA or 4BB by Gardner criteria) euploid blastocysts from poorly developed blastocysts with C grade TE and inner cell mass. Intuitively, aneuploid embryos are far more likely to exhibit poor morphology than their euploid counterparts. Analysis of expression differences between poorly developed embryos and high quality embryos revealed a set of genes activated in the poor quality embryos. By GO (Gene Ontology) analysis, these genes are involved in negative regulation of cellular metabolism and signaling. These results suggest that common pathways are activated in embryos with poor morphology, regardless of the specific abnormality or mutation.

Reference: Petropoulos et al. Single-Cell RNA-Seq Reveals Lineage and X Chromosome Dynamics in Human Preimplantation Embryos. Cell, 2016. 165, 1-15

Limitations, reasons for caution: This is a small data set using samples processed in a single laboratory. All embryos were frozen-thawed embryos that had been frozen for varying durations of time; transcriptome results are thus not applicable to fresh embryos and the impact of prolonged embryo storage to the results is unknown.

Wider implications of the findings: We are able to establish embryo sex through gene expression analysis with good correlation between whole embryos and TE biopsies. We have also identified a gene set that correlates to embryo quality. Further aspects of this research examine the embryo transcriptome through developmental stages and correlate it with morphokinetic milestones.

Trial registration number: N/A.

O-248 Sex differences of histone modifications in mouse PGCs after erasure of DNA methylation

T. Kono[1], M. Kawabata[1], A. Kamio[1], Y. Jincho[1], T. Takashima[2], H. Kobayashi[3], Y. Matsui[4]

[1]Tokyo University of Agriculture, Bioscience, Tokyo, Japan
[2]Tokyo University of Agriculture, Bioscienc, Tokyo, Japan
[3]Tokyo University of Agriculture, NODAI Genome Research Centre, Tokyo, Japan
[4]Tohoku University, Cell Resource Centre for Biomedical Research, sendai, Japan

Study question: The mechanism by which the sex-specific gene expressions of PGCs are regulated by epigenetic modifications, especially histone modifications, remains to be elucidated

Summary answer: The histone modifications are major regulators for the sex-specific gene expressions in the male and female PGCs after DNA methylation erasure.

What is known already: In a mammalian germline, dynamic reprogramming of sex-specific epigenome modifications resulted in the formation of oocytes and sperms, which each have unique epigenome modifications. In mice, primordial germ cells (PGCs) are first appear at E7.5. By E13.5, after proliferation and migration into the genital ridge theses PGCs are specified into male and female cells. DNA methylation, a major epigenome modification, is erased in mouse PGCs by E13.5. Nevertheless, the PGCs exhibit sex-specific gene expression profiles at that stage. These findings indicate that the PGCs have already specified into female and male germlines, although DNA methylation marks are erased.

Study design, size, duration: Here, to obtain better understanding of the regulation of gene expression in mouse PGCs by epigenetic modifications, we conducted a genome-wide analysis of six histone modifications, H3K4me1, H3K4me3, H3K27ac, H3K9me2, H3K9me3 and H3K27me3. The histone modifications were evaluated by ChIP-seq analysis followed by next generation sequencing. The ChIP-seq data sets were then compared to the gene expression profiles.

Participants/materials, setting, methods: PGCs were collected using an FACS cell sorter to detect GFP-positive cells from E13.5 embryos of Pou5f1-⊿PE-GFP mice. A total of 10^4 cells were digested by MNase, and the chromatin was applied for immunoprecipitation. Indexed sequencing libraries were constructed using purified DNA from the immunoprecipitation followed by amplification of 12-14 PCR cycles. Sequencing was performed on an Illumina NextSeq sequencer; the generated 76–77-base pair tags were aligned to the reference (mm10), using bowtie2-2.2.3.

Main results and the role of chance: Comparison analysis showed that a positive correlation with RNA-seq data sets (Sakashita et al., 2016) was found in H3K4me3 and H3K27Ac, which were enriched to the transcription start site. In the inhibitory markers, H3K9me2 and H3K9me3 selectively accumulated in the repressed genes, which would change the chromatin structure to the repression status, and H3K27me3 was specifically enriched to the low expressed genes. In PGCs, approximately 30% of H3K4me3 modifications were found to be concentrated in CGIs, whereas 13.79% was enriched in embryonic stem cells. This indicates that the H3K4me3 modification is specifically enriched in CpG islands, which are targets of DNA methylation and regulate gene expression. The histone modification profiles, especially in H3K4me3, H3K4m1 and H3K27ac, which are active markers, were well associated with sex specific gene expression profiles of male and female PGCs. This study was supported by Grants-in-Aid for Scientific Research from AMED-CREST and JST.

Limitations, reasons for caution: Shown only one species, mice, was studied.

Wider implications of the findings: Our data could provide information for future studies to elucidate the role of epigenetic modifications in the development, function and sex differences of germline and stem cells.

Trial registration number: The data were obtained in biological duplicates at least.

SESSION 65: MARKERS AND MECHANISMS OF ENDOMETRIOSIS

Wednesday 5 July 2017   Room W+X   10:00–11:45

O-249   Impact of peritoneal fluid ceramides on endometriosis associated infertility (EAI)

X. Yang[1], C. Mattar[2], J.K.Y. Chan[3], Y.H. Lee[4]

[1]KK Women's and Children's Hospital, Division of Obstetrics and Gynaecology, Singapore, Singapore Rep. of
[2]National University University, Obstetrics and Gynaecology, Singapore, Singapore Rep. of
[3]KK Women's and Children's Hospital, Reproductive Medicine, Singapore, Singapore Rep. of
[4]KK Women's & Children's Hospital, KK Research Centre, Singapore, Singapore Rep. of

Study question: In endometriosis, do specific ceramides within the peritoneal environment lead to poor oocyte quality, impede intrinsic maturation potential and reduce a patient's ability to conceive?

Summary answer: Subfertility in endometriosis is influenced by a defective peritoneal environment rift with increased very-long-chain ceramides. These ceramides may alter oocyte maturation potential.

What is known already: Endometriosis is associated with marked subfertility, altered oocyte quality and accumulated levels of potentially oocytotoxic compounds in peritoneal fluids (PF).

Due to the juxtapositioning of ovaries and released oocytes to the PF, an altered PF may have detrimental effects on the maturation potential of oocytes thereby impairing fertilization. Ceramides have been found to be toxic to oocytes and embryos both in vivo and in vitro. Little is known, however, how PF ceramides contribute to oocyte quality and plausibly EAI.

Study design, size, duration: A case-control study of 39 women undergoing laparoscopic procedures for various indications were recruited into the study in the KK Women's and Children's Hospital, Singapore. To assess the effect of ceramides on oocyte maturation potential, 150 denuded GV oocytes from BALB/c mice were matured in PF of subjects and also in the presence of ceramides at increasing concentrations for 14 hour.

Participants/materials, setting, methods: Women between 22-40 years were recruited, presence of endometriosis recorded and staged, and fertility characteristics collected. Subjects were excluded if FSH > 10 IU/L or had male infertility contributions. PF were aspirated during laparoscopy and had their lipids profiled via liquid chromatography-mass spectrometry. Linear regression was conducted to identify PF ceramides associated with EAI. Assessment of GV to MII oocyte maturation potential was made via polar body extrusion and mitochondrial reactive oxidative species.

Main results and the role of chance: Comparing infertile women with endometriosis and non-endometriotic women, three very-long chain ceramides, C22:0 ceramide ($p = 0.006$), C24:0 ceramide ($p = 0.006$) and C24:1 ceramide ($p = 0.026$) were significantly associated with a combined Area Under Curve (95% CI) of 0.95 (0.83-1.00). With non-endometriosis subjects as reference, Odds Ratios indicated that C24:1 ceramide increases risk (OR=1.017), whereas Cer C22:0 ceramide (OR=0.927) and C24:0 ceramide (OR=0.989) mitigate the risk.

PF from women with and without endometriosis compromised the maturation potential of murine oocytes. The maturation potential of murine oocytes varied with exposure to the very long chained ceramides. By 14 hours, C24:1 ceramide arrested oocytes mainly at GV and MI stage, obtunding maturation to MII. Mitochondrial reactive oxidative species was significantly increased in C24:1 ceramide-treated oocytes. Conversely, C24:0 ceramide significantly improved the maturation potential of GVs to MIIs in a dose-dependent manner relative to vehicle control.

Collectively, the results suggest that any underlying pathology in the peritoneal fluids of women with endometriosis may contribute to compromised oocyte maturation potential and potentially affect fertility in various stages of reproduction, whether by natural conception or IVF, in the ampulla contiguous to the peritoneal cavity where fertilisation typically takes place.

Limitations, reasons for caution: Our results may be confounded by a small sample size; a larger scale study in this specific subgroup of women with non-male EAI is needed to verify our findings. In addition, murine oocytes may have varied response to ceramides compared to human oocytes

Wider implications of the findings: The identification of functionally important oocytotoxic ceramides provide a direct functional readout of pathophysiology in a defective peritoneal environment in endometriotic women. In addition, information derived from the peritoneal fluid may provide a mechanistic insight into its oocytotoxicity.

Sequencing experiments focused understanding transcriptomic changes to ceramide-exposed oocytes are ongoing.

Trial registration number: Not applicable.

O-250   The comparison of effects of ranibizumab, zoledronic acid, danazol, buserelin acetate and dienogest on experimental model of endometriosis in rats

E. Ureyen[1], E. Adali[2], M.I. Taskin[2], A. Yavasoglu[3], H. Aktug[3], F. Oltulu[3], U. Inceboz[4]

[1]Mut Devlet Hastanesi, gynecology and obstetrics, Mersin, Turkey
[2]Balikesir University, Gynecology and obstetrics, Balikesir, Turkey
[3]Ege University, Histology and embryology, Izmir, Turkey
[4]Irenbe Gynecology and Obstetrics, Gynecology and Obstetrics, Izmir, Turkey

Study question: Comperative effects of known and promising drugs in the treatment of endometriosis in rat endometriosis model.

Summary answer: Zoledronic acid and ranibizumab treatments may have a potential clinical utility in the treatment of endometriosis.

What is known already: There is no study about zoledronic acid treatment in endometriosis.

Study design, size, duration: This is an experimentally induced endometriosis study on female rats. After the treatment, volumes and histopathological properties of the implants were evaluated by scoring system and immunochemistry. Comparisons were made accordingly.

Participants/materials, setting, methods: Experimental endometriosis was induced in 52 adult female rats. The rats were divided into 6 groups; zoledronic acid, ranibizumab, dienogest, danazol, buserelin acetate and as control % 0,9 NaCl groups. After four weeks of treatment, the volumes were measured and the lesions were excised for histopathologically scoring and immunohistochemistry (CD- 31, NF-κB, BcL- 2).

Main results and the role of chance: Among the groups, the histological score was significantly lower in zoledronic acid and ranibizumab groups in when

compared with controls(p < 0.001). There was a statistically significant difference in terms of cell numbers according to the degree of BcL-2, NF-κB and CD31 staining (p < 0.001). For BcL-2 staining, the staining rate of the group treated with zoledronic acid was statistically significantly lower compared with dienogest and danazol groups(p < 0.05). CD31 and NF-κB staining were significantly lower in zoledronic acid and ranibizumab groups in when compared with controls (p < 0.05). There were no significant differences in terms of ellipsoidal volume levels between groups(p>0.05). There was no statistically significant difference in BcL-2, CD31 and NF-κB staining in the binary comparisons between the other groups(p>0.05).

Limitations, reasons for caution: There was no limitation.

Wider implications of the findings: Zoledronic acid -used in the treatment of osteoporosis- has antiangiogenic properties, and has fewer side effects, by doing so, there may be more acceptable drug option in the treatment of endometriosis. Ranibizumab is anti-VEGF drug, used in ophthalmology. Ranibizumab may serve as another logical option in the treatment of endometriosis.

Trial registration number: TUBITAK Project Number: 213S002.

O-251   ER stress-induced apoptotic cell death in human endometrial cell cycle

D. Choi[1], J. Choi[1], M. Jo[2], E. Lee[1], D.Y. Lee[1]

[1]Samsung Medical Center- Sungkyunkwan University School of Medicine, Obstetrics and Gynecology, Seoul, Korea- South
[2]Samsung Biomedical Research Institute, Center for Clinical Researc, Seoul, Korea- South

Study question: Whether is endoplasmic reticulum (ER) stress regulated by ovarian steroid hormones (estrogen and progesterone) in human endometrial stromal cells (HESCs), and is it associated with apoptosis?

Summary answer: Estrogen inhibits ER stress in HESCs. This inhibition is reversed by progesterone during the secretory phase, which is directly involved in apoptosis induction.

What is known already: ER stress is a common cellular stress response, which is known to activate apoptosis signaling to trigger cell death. Recent studies have shown that apoptotic cell death is reduced by estrogen through inhibition of ER stress in some cell types including osteoblasts and pancreatic β-cells, which suggests that ER stress-induced apoptosis can be regulated by ovarian steroid hormones. Therefore, endometrial cell apoptosis may be also controlled by ovarian steroid hormones via ER stress during human endometrial cell cycle.

Study design, size, duration: HESCs were cultured with tunicamycin to induce ER stress. To evaluate the effects of estrogen and progesterone on ER stress and apoptosis, tunicamycin-treated HESCs were cultured with estrogen and/or progesterone. And, mifepristone (progesterone receptor modulator) or salubrinal (ER stress inhibitor) were also added in culture medium to block progesterone effects and ER stress, respectively. In addition, to evaluate the cycle-dependent induction of ER stress and apoptosis, endometrial cells were collected according to menstrual cycle.

Participants/materials, setting, methods: The expression level of glucose-regulated protein 78 (GRP78) and C/EBP homologous protein (CHOP) was measured by Western blot to evaluate ER stress induction. In addition, apoptosis was evaluated by measuring the expression of apoptosis associated protein (BAX, BCL2 and cleaved caspase-12) and by performing annexin-V and PI staining.

Main results and the role of chance: The expression levels of CRP78 and CHOP protein were markedly increased in HESCs treated with tunicamycin compared with control. However, treatment with estrogen decreased tunicamycin-induced CRP78 and CHOP expression levels by dose-dependent pattern, which suggests that estrogen suppresses ER stress in HESCs. In contrast, progesterone treatment significantly increased CRP78, CHOP, cleaved caspase-12 expression, BAX/BCL2 ratio and the proportion of apoptotic cells in estrogen-treated HESCs. And, progesterone-induced CRP78 and CHOP expression was suppressed by the addition of either mifepristone or salubrinal. This suppression was accompanied by decreased apoptosis induction. These results suggest that progesterone reverses estrogen-induced inhibition of ER stress, which is directly involved in apoptosis induction in HESCs. In addition,

these data were coincided with the *in-vivo* findings that ER stress and apoptosis increased significantly at secretory phase compared to proliferative phase.

Limitations, reasons for caution: Further study regarding ER stress-related downstream pathways such as PERK, IREα1 and ATF6 pathways is needed to determine the more detailed mechanism of ER stress-induced apoptosis.

Wider implications of the findings: These results give us new insights into the hormonal regulation mechanism for endometrial cell apoptosis during menstrual cycle.

Trial registration number: This study is basic researchis basic research.

O-252   Expression patterns of mRNAs and miRNAs in adenomyosis and their potential uses as diagnostic biomarkers

C. Innocenti[1], D. Haouzi[1], A. Ferrieres Hoa[2], H. Dechaud[3], C. Vincens[4], N. Bersinger[5], M.D. Mueller[6], S. Hamamah[4]

[1]INSERM U1203, Hôpital St Eloi, MONTPELLIER, France
[2]Hôpital Arnaud de Villeneuve- CHU Montpellier, Département de Médecine et Biologie de la Reproduction, Montpellier, France
[3]Gynepole, AMP, Montpellier, France
[4]Hôpital Arnaud de Villeneuve, Département de Médecine et Biologie de la Reproduction, Montpellier, France
[5]University of Berne, Department of obstetrics and gynaecology, Berne, Switzerland
[6]University of Berne, Department of obstetrics and gynaecology-, Berne, Switzerland

Study question: The aim of this study was to improve molecular characterization of adenomyosis and identify biomarkers. For this purpose, transcriptomes and miRNomes of endometrium patients with and without adenomyosis were investigated.

Summary answer: We identified specific mRNAs and miRNAsin endometrium from patients with adenomyosis compared with endometrium from healthy patients used as control.

What is known already: Adenomyosis is a gynaecological disease which is poorly molecularly characterized. In addition, to date, there are very few studies using large scale profiling methods (OMICS) to investigate molecular signatures of this enigmatic pathology.

Study design, size, duration: Endometrial biopsies were obtained from hysterectomy specimens of patients with (n = 6) pure and without (n = 6) adenomyosis. Presence or absence of adenomyosis was validated by anatomo-pathological examination and all endometrial specimens were during the proliferative phase. RNAs were extracted and gene and miRNA expression profiles were investigated using the Affymetrix HG-U133 plus 2.0 microarrays and *Affymetrix miRNA 4.1 Arrays*. The differential gene and miRNA expression profiles between pathological and control groups were evaluated with bioinformatics system.

Participants/materials, setting, methods: The differential gene and miRNAexpression profiles between endometrial samples were investigated in patients with adenomyosis (fold-change >2, p-value <5%) without adenomyosis. The lists of significant genes were cross-intersected to identify of list of genes exclusive to the pathological group. Potential endometrial biomarkers of adenomyosis were investigated by RT-qPCR.

Main results and the role of chance: Using transcriptomic analysis, we identified a list of 542 genes exclusive to adenomyosis group with 280 and 262 genes up- and down-regulated in endometrium respectively. The top up- and down-regulated genes exclusive to the endometrium from the adenomyosis patients were ATP8A2 (x35), SH2D3A (x32), KLHL31 (x15), ADAMTS16 (x14), FOXP2 (x-31), F2RL2 (x-29), DGKB (-14), LEFTY2 (x-12) and play roles in several functions including membrane trafficking, migration and extracellular remodeling. In the other hand, miRNome analysis revealed that 3 miRNAs (miR-490-3p, miR-6738-5p, miR-4763) were differentially expressed in endometrium in patients with adenomyosis compared with control patients. Supervised clustering using these 3 miRNAs revealed a great segregation between adenomyosis and control groups, opening news perspectives in the diagnosis of adenomyosis. Interestingly, one miRNA targets 16 mRNAs identified in our transcriptomic analysis that were reached to several biological functions including the BMP signaling pathway and the estrogen receptor signaling playing crucial roles in the physiopathology of adenomyosis.

Limitations, reasons for caution: Although our pre-screening of mRNAS and miRNAs have been performed in a small number of patients, the relevance of certain biomarkers of adenomyosis in endometrium are being validated in independent cohort of patients.

Wider implications of the findings: These results could contribute for improving our understanding of the physiopathology of adenomyosis and should open new perspectives in the diagnosis of this pathology.

Trial registration number: Not applicable.

O-253 Suppression of endometrial stromal cells autophagy regulates differentiation and function of CD3- CD56+ CD16- NK cells via Hematopoietic Cellular Kinase in patients with endometriosis

Y. Wang

Shanghai Jiaotong University, reproductive, Shanghai, China

Study question: Is differentiation of CD3-CD56+CD16- NK cells affected by degree of Endometrial stromal cells(ESCs) autophagy and what mechanism is involved in it?

Summary answer: The down-regulation of Hck(Hematopoietic Cellular Kinase)mediated by suppression of ESCs autophagy regulates CD3- CD56+ CD16- NK cells differentiation and function.

What is known already: mTOR(mammalian target of rapamycin), the major negative regulator of autophagy, is abnormally increased in endometriotic lesions and is involved in the direct regulation of ESCs apoptosis. Uterine natural killer cells (uNK) constitute a major lymphocyte population during early gestation in the uterus. The uterine natural killer cells are recognized owing to their CD3-CD56+CD16- phenotype.

Study design, size, duration: Autophagy was measured by transmission electron microscopy and immunofluorescence, and in vitro analysis was used to measure HCK-mediated CD3- CD56+CD16- NK cells.

Participants/materials, setting, methods: A total of 30 controls and 30 women with histologically confirmed endometriosis were included. We transfected ESCs with plasmid GV230-Hck or Hck-RNAi, and determined the effect of plasmid transfection on Hck protein expression in ESCs by Western Blot analysis, then they were co-cultured with isolated NK cells for 48 h. And NK cells were analyzed for the expression of CD16, KIR2DL1, KIR3DL1, NKp30, NKp44, NKp46 and IFN-γ, perforin and granzyme B by flow cytometry.

Main results and the role of chance: ESCs were treated with rapamycin (autophagy inducer) or 3-methyladenine (autophagosome inhibitor, 3-MA) for 4 h, and then co-cultured with CD3-CD56+ NK cells for 48 h. The ratio of CD16-NK to CD16+NK was significantly increased after treated with 3-MA ($P < 0.05$). Surface tolerance molecules KIR2DL1、KIR3DL1 were up-regulated($P < 0.05$) and surface molecules NKp30,NKp44 were down-regulated ($P < 0.05$) in CD3-CD56+NK cells in 3-MA treated group. While expression of Intracellular cytokine IFN-γ、Perforin and Granzyme B were decreased in that group($P < 0.05$). Lysate or supernatant from control (secretory phase, n = 10), and corresponding 3-MA-treated ESCs (n = 10) were characterized by Proteomic microarray. According to Kegg database, we predicted the target of NK cells in proteomics' differential proteins. ESCs control and ESCs treated with rapamycin or 3-MA were then assessed for the differential expression of Hck by Western blot analysis, which showed that Hck is decreased along with the decreased autophagy in endometriosis-derived ESCs($P < 0.05$).We transfected ESCs with plasmid GV230-Hck or Hck-RNAi, and determined the effect of plasmid transfection on Hck protein expression in ESCs by Western Blot analysis. KIR2DL1、KIR3DL1 were up- regulated and NKp30, NKp44, IFN-γ、Perforin and Granzyme B were down-regulated in the GV230-Hck treated ESCs co-cultured group, while in the Hck-RNAi treated ESCs co-cultred group showed opposite results($P < 0.05$).

Limitations, reasons for caution: Further studies are needed to examine the mechanism of ESCs autophagy on CD3-CD16-CD56+ NK cells differentiation and function.

Wider implications of the findings: Measures to increase numbers of CD3-CD16-CD56+ NK cells might be a valid, novel approach to facilitate the implantation of embryos in patients with endometriosis.

Trial registration number: None.

O-254 Pelvic Hypoxic Microenvironment Promotes Endometrial Stromal Cells Ectopic Adhesion Ability via TGF-β1/Smad2 Signaling Pathway in Endometriosis

X. Lin, Y.D. Dai, S.Y. Zhang

Sir Run Run Shaw Hospital- School of Medicine- Zhejiang University, Assisted Reproduction Unit- Department of Obstetrics and Gynecology, Hangzhou, China

Study question: Do hypoxic microenvironment modulate endometrial stromal cell ectopic adhesion ability through mechanisms involving TGF-β1/Smad2 signaling pathway in endometriosis.

Summary answer: Hypoxic microenvironment enhanced endometrial stromal cell ectopic adhesion ability through TGF-β1/Smad2 mediated signaling pathway in endometriosis.

What is known already: Hypoxic microenvironment developed a closed relationship with endometriosis and upregulated HIF-1α played vital roles in the establishment of ectopic lesions. An important step in the aetiology of endometriosis and establish of ectopic lesion is the integrins mediated aberrant adhesion between endometrial fragments and surrounding tissues.

Study design, size, duration: This is a laboratory-based observational study that sampled primary endometrial stromal cells (ESCs) from 13 healthy volunteers to explore their response to hypoxia in vitro. We analyzed ectopic lesions from 5 patients of reproductive age with endometriosis and 5 normal endometrial samples from women without endometriosis. A total of 20 BALB/c nude mice and 22 C57BL6 mice received implantation of proliferative endometrial fragments from 21 individuals without endometriosis.

Participants/materials, setting, methods: The effects of hypoxia on ESCs adhesion, migration and invasion were evaluated by cell counting kit-8, scratch and transwell assays. The effects of hypoxia, TGF-β1 and TGF-β1 receptor inhibitoron on integrins' expression were determined by quantitative PCR and Westerns. Contribution of hypoxia on endometriosis were analyzed using a xenograft model in immunodeficient nude mice. The underlining mechanism of hypoxia influenced adhesion were explored by immunofluorescence assay, lentivirus interference test and enzyme-linked immuno sorbent assay.

Main results and the role of chance: Our results demonstrated that hypoxia culture significantly promoted ESCs adhesion, migration and invasion compared with normoxia culture. Expression levels of integrins in ESCs were dramatically elevated after hypoxia treatment. Of special note was that ESCs secreted higher levels of TGF-β1 in hypoxia culture compared with normoxia culture. Furthermore, both hypoxia culture and TGF-β1 co-culture significantly increased expression of integrin-α5 and integrin-β5, which was reversed by TGF-β1 receptor inhibitoron (SB-431542). Mechanistic researches indicated that TGF-β1/Smad2 signaling pathways in ESCs were activated by HIF-1α. Animal experiments and immunological histological chemistry of huamn endometriotic tissues showed that HIF-1α, TGF-β1 and integrins all remarkedly increased in endometriotic cysts, which enhanced the functions of HIF-1α,TGF-β1 and integrins in the establishment of ectopic lesions.

Limitations, reasons for caution: This is the first time to identify hypoxia in aberrant adhesion of ESCs in endometriosis. However, endometrial epithelial cells also contained abnormal expression of HIF1-α and TGF-β1, and maybe involved in the pathogenesis of endometriosis. Therefore, further studies are required to elucidate the exactly effects of hypoxia in endometriosis.

Wider implications of the findings: Hypoxia may be involved in the development of endometriosis through activating the classical TGF-β1/Smad2 signaling pathway and inducing high expressions of integrins, which lead to the formation of ectopic lesions.

Trial registration number: No clinical trails, none trial registration number.

O-255 TGFβ1 promotes ectopic epithelial cells activation through cadherin-11 to aggravate invasion joint inflammation in endometriosis

Y. Wang[1,2], H. Tetsuya[1], N. Kazuaki[1], F. Shinya[1], N. Akari[1], F. Tomoyuki[1], O. Yutaka[1]

[1]*Faculty of Medicine- University of Tokyo, Department of Obstetrics and Gynecology, Tokyo, Japan*
[2]*The Affiliated Hospital of Inner Mongolia Medical University, Center for Reproductive Medicine, Hohhot, China*

Study question: Previous studies showed that TGFβ1 are involved in endometriosis and we hypothesized that TGFβ1 might induce cadherin-11 (CDH11) expression and invasion in endometriosis.

Summary answer: The expression of CDH11 was enhanced by TGFβ1 and was predominantly overexpressed in endometriotic epithelial cells compared to eutopic endometrial epithelial cells.

What is known already: Previous studies showed that TGFβ1 has pivotal role in the pathogenesis of endometriosis, in terms of fibrosis, inflammatory reaction and epithelial mesenchymal transition (EMT). CDH11 is a downstream effector of TGFβ1, and a cell-to-cell adhesion molecule associated with tissue remodeling, EMT and migration. The expression and function of CDH11 in endometriosis has not been studied. According to our RNA seq data, CDH11 was significantly over-expressed in endometriotic epithelial cells compared to eutopic endometrial epithelial cells.

Study design, size, duration: The sections of endometrioma (N = 13) and endometrium (N = 3) were obtained from patients, who underwent excision of endometrioma or hysterectomy for benign gynecologic disease. All women experienced regular menstrual cycles and did not receive hormonal treatment for at least 3 months before surgery. For in vitro experiments, we used immortalized endometriotic epithelial cells.

Participants/materials, setting, methods: The sections of endometriotic tissues and eutopic endometria were obtained from patients, who underwent excision of endometrioma or hysterectomy for benign gynecologic disease with written informed consent. The expression of CDH11 in endometrioma or eutopic endometrium was examined by immunostaining. The invasion of immortalized endometriotic epithelial cells was evaluated after the induction of TGFβ1 or the stimulation of rCDH11 by transwell invasion assay and CDH11 or interlukin-6 (IL-6) was detected by qPCR and Western blot.

Main results and the role of chance: First, immunostaining showed that CDH11 was highly expressed on ectopic epithelial cells of endometrioma comparing to eutopic endometria. Second, TGF-β1 upregulated the expression of CDH11 (P < 0.05) and increased the expression of IL-6 in a time-dependent manner (P< 0.05). Third, transwell invasion assay showed that rCDH11 increase the number of infiltrated epithelial cells. Accordingly, we provided several lines of evidence to show that TGFβ potentiates cadherin-11 expression in ectopic endometrial epithelial cells, thereby contributing to epithelial cell invasion and aggravating inflammation.

Limitations, reasons for caution: In vitro experiments using immortalized cell lines.

Wider implications of the findings: We found CDH11 was predominantly overexpressed in endometriotic epithelial cells and enhanced invasive potency of endometriotic epithelial cells, which implies that CDH11 can be a new target for endometriosis treatment.

Trial registration number: Not availiable.

SELECTED ORAL COMMUNICATIONS

SESSION 66: PSYCHOLOGY AND COUNSELLING

Wednesday 5 July 2017   Room C   10:00–11:45

</div>

O-256   Psychological distress of women with primary ovarian insufficiency: effect of counseling training for clinician

P. Nayar, K.D. Nayar, R.A. Gupta, Y. Kapoor, M. Singh, G. Kant, N. Sharma, D. Nayar

Akanksha IVF Centre, Mata Chanan Devi Hospital, New Delhi, India

Study question: Does specific counselling training for clinicians in Reproductive Medicine & Infertility sub-specialty in disclosing primary ovarian insufficiency (POI) to infertile couple reduce the anxiety and alleviate distress.

Summary answer: Structured and specific training of clinician to diagnose, disclose and counsel women with primary ovarian insufficiency helps them positively to cope better with the condition.

What is known already: Infertility and its treatment have considerable impact on mental health of the couple, primary ovarian insufficiency to them becomes more challenging for the clinician because of its profound effect on quality of life and bleak chances of women begetting her genetic child. Over 75% women with POI feel unprepared to hear the news and most of them underscore the need of more considerate communication. Clinicians need to develop the skills to deliver troubling news, communicate the spectrum of problems associated with it and accurate information about the treatment modalities available to be able to reduce the emotional suffering experienced.

Study design, size, duration: A prospective study conducted in an IVF centre. Women who came for infertility workup, when diagnosed with primary ovarian insufficiency after investigations between March 2015 and October 2016 (N = 62) were included. Of which 29 women were counselled before (Group A) and 33 women after the clinicians attended specific training for information based supportive counselling (Group B). Data were represented as percentage; differences in these measures between the groups were assessed by means of chi-square analysis.

Participants/materials, setting, methods: A questionnaire consisting of 28 questions regarding the condition and counselling, was sent to all patients 2 weeks after the consultation. This questionnaire included specific questions to assess the feelings after the consultation, the adequacy of information delivered to them, whether or not all queries were answered in the consultation, how considerate the clinician was in dealing with them and whether a second consultation was taken elsewhere for this.

Main results and the role of chance: The mean age of the patients was 35 years. The women counselled by trained clinicians were significantly more satisfied as compared to women who consulted before training of clinicians (Group B-81.8% and Group A- 44.8% p = 0.002). Eighty eight percent women in group B felt they were given adequate time during counselling compared to 58.6% in group A (p = 0.02). Revisit rate was significantly higher in group B 66.7% compared to group A 31.03% (p= 0.01).

Limitations, reasons for caution: Although it is prospective study, done before and after training, it has limitation of small sample size.

Wider implications of the findings: Clinicians who convey diagnosis of POI to women present them with life-altering information. Our findings emphasise the need of specific counselling training of clinicians to deal with women with POI to significantly improve satisfaction and treatment continuity.

Trial registration number: Not Applicable.

O-257   Does ART treatment increase the risk for divorce? A registered-based study 1994-2010

ABSTRACT UNDER PRESS EMBARGO

characteristics were similar between the groups. Significant depressive symptoms, defined by EPDS$\geq$12, were reported by 12.8%, 12.4%, 13.8% and 11.9% of women at 17 and 32 gestational weeks, and at 6 weeks and 6 months postpartum, respectively. No significant differences in prevalence of depressive symptoms (at chi-square test) and EPDS scores (at Mann-Whitney U test) were observed between women who were pregnant spontaneously or through IVF. No statistically significant association between mode of conception and maternal depressive symptoms was found at any time-point, even when adjusting for several possible confounders (age, BMI, parity, education, depression history and stressful life events) at multiple logistic regression.

Limitations, reasons for caution: IVF mothers often have different characteristics than those spontaneously pregnant. Our study included only singleton pregnancies, and multiple confounders were considered. The gap between women conceiving spontaneously or via IVF in Sweden may be narrower because of factors such as universal healthcare coverage, single-embryo-transfer policy, and unmedicalized obstetric care.

Wider implications of the findings: Our findings are reassuring, considering subfertility's psychological burden. IVF mothers may be less likely to suffer from depressive symptoms than the general subfertile population. It would be interesting to verify whether health policies, such as single-embryo-transfer or unmedicalized obstetric care, reduce the risk of perinatal depression among subfertile women.

Trial registration number: not applicable.

O-259 Quality of life, physical and psychosocial wellbeing among 1023 women during their first ART treatment: Secondary outcome to RCT comparing GnRH-antagonist and GnRH-agonist protocol

M. Toftager[1], R. Sylvest[1], L. Schmidt[2], J. Bogstad[1], K. Løssl[1], L. Prætorius[1], A. Zedeler[1], T. Bryndorf[1], A. Pinborg[1]

[1]Hvidovre Hospital, Gyn/Obs- Fertility Clinic section 455, Hvidovre, Denmark
[2]University of Copenhagen, Department of Public Health, Copenhagen, Denmark

Study question: Is self-reported quality of life, psychosocial and physical wellbeing similar in short GnRH-antagonist and long GnRH-agonist protocol among women in their first ART treatment?

Summary answer: Women in short antagonist protocol rated psychosocial- and physical wellbeing during their first ART treatment superior to women in long GnRH-agonist protocol.

What is known already: It is stressful and straining to undergo ART treatment and the psychological burden for the couple can be a major reason for discontinuing treatment. However, the literature on quality of life, psychosocial- and physical wellbeing during different ART treatment protocols is scarce. GnRH-agonists have been associated with negative mood symptoms as depression, fatigue, anhedonia and anxiety due to the medically induced hypogonadism. The agonist protocol is also associated with a higher risk of severe ovarian hyperstimulation syndrome (OHSS). On the other hand, GnRH-antagonist protocol has been associated with more pronounced mood variations during the stimulation phase compared to GnRH-agonist protocol.

Study design, size, duration: Quality of life, psychosocial- and physical wellbeing was secondary outcomes in a phase IV, dual-centre, open-label, RCT including 1023 women, who started gonadotrophin stimulation in their first ART cycle. Women were randomized to either short GnRH-antagonist or long-GnRH agonist protocol using a web-based concealed randomization code in a 1:1 ratio and enrolled over a five-year period. The aim was to compare self-reported quality of life, physical- and psychosocial wellbeing in the two treatment groups.

Participants/materials, setting, methods: Women referred for first ART cycle <40 years of age were included. All started standardized ART protocols with age-adjusted rFSH doses. A questionnaire on self-reported physical wellbeing was completed 4 times during treatment and self-reported quality of life and psychosocial wellbeing was completed at the end of treatment. Quality of life and psychosocial wellbeing were analysed in a regression model controlling for; treatment protocol, age, male-factor, previous delivery, pregnancy, severe OHSS and years of infertility.

Main results and the role of chance: Baseline characteristics were similar and the overall response rate for all required questionnaires were 79.4% (419/528)

O-258 Successful IVF is not associated with maternal perinatal depressive symptoms

P. Gambadauro[1,2], S. Iliadis[2], E. Bränn[2], A. Skalkidou[2]

[1]Karolinska Institutet, LIME/NASP-C7, Stockholm, Sweden
[2]Uppsala University, Department of Women's and Children's Health, Uppsala, Sweden

Study question: Is conception by in-vitro fertilization (IVF) associated with maternal depressive symptoms during pregnancy and postpartum?

Summary answer: Successful IVF is not associated with maternal depressive symptoms during pregnancy or postpartum, even when controlling for several potential confounders.

What is known already: Subfertility and its treatment are a known psychological burden. On the other hand, maternal perinatal depressive symptoms are common and contribute to maternal morbidity and mortality. However, few and heterogeneous controlled studies have so far examined the association between successful IVF and maternal depressive symptoms.

Study design, size, duration: Longitudinal observational study of 3283 women with a singleton pregnancy receiving antenatal care and delivering in Uppsala, Sweden. These women were recruited between 2010 and 2015 into the BASIC project (Biology, Affect, Stress, Imaging, Cognition), a population-based study on psychological well-being during pregnancy and postpartum.

Participants/materials, setting, methods: Pregnant women who had conceived via IVF (n 167; 5%) or spontaneously (n 3116; 95%) were delivered a web-based questionnaire including sociodemographic, clinical and pregnancy-related items, as well as the Edinburgh Postnatal Depression Scale (EPDS), at 17 and 32 gestational weeks, as well as at six weeks and six months postpartum. The main outcome variables were the prevalence of significant depressive symptoms (defined by EPDS$\geq$12) and EPDS scores, and were compared between the groups.

Main results and the role of chance: Women older than 34 ($p < 0.001$), primiparae ($p < 0.001$), and caesarean deliveries (p 0.006) were all significantly more frequent among the IVF mothers. Other demographic and clinical

in the GnRH-antagonist group compared to 74.3% (368/495) in the GnRH-agonist group (P = 0.06). For the single item self-evaluated quality of life during ART treatment no difference was found between the two treatment groups (P = 0.25), the only covariate predictive of reduced quality of life was the development of severe OHSS (AOR=3.89; 95%CI: 2.34-6.46; P < 0.01). However, women in the short GnRH-antagonist group had a lower adjusted risk of being emotional during treatment (AOR=0.74; 95%CI: 0.56 to 0.97; P = 0.03), they had a lower adjusted risk of experiencing unexpected crying (AOR=0.69; 95% CI: 0.52 to 0.91; P = 0.01) and had a lower adjusted risk of worse quality of sleep (AOR=0.65; 95%CI: 0.48 to 0.88; P < 0.01) compared to women in GnRH-agonist treatment.

Three days after embryo transfer more women in the GnRH-agonist group felt worse physically (P < 0.01), felt bloated (P < 0.01) and had shortness of breath (P = 0.03). At the day of the pregnancy test more women in the GnRH-agonist group had stomach pain (P < 0.01). Finally, significantly more women in the long agonist group experienced side-effects to the prescribed medication during ART treatment.

Limitations, reasons for caution: Overall response rates were satisfying, however, response rates were significantly lower for women without embryo transfer. The randomization procedure makes the risk of bias less likely. Finally, neither physicians nor patients were blinded to GnRH-treatment group.

Wider implications of the findings: ART protocols have improved over the years, but less focus has been on the physical- and psychosocial wellbeing among women treated with different protocols. We found that women in short GnRH-antagonist protocol have better physical and psychosocial wellbeing during their first ART treatment compared to women in long GnRH-agonist protocol.

Trial registration number: EudraCT #: 2008-005452-24; ClinicalTrial.gov: NCT00756028.

O-260   Getting Through the Two Week Wait – A Self-Help Intervention for Women Anxiously Waiting for Their in Vitro Fertilization Result

S. Wong[1], **H.Y. Chan**[2], **Y.J. Tam**[2]

[1]Centre of Assisted Reproduction and Embryology-, The University of Hong Kong - Queen Mary Hospital, Hong Kong, Hong Kong
[2]Centre of Assisted Reproduction and Embryology, The University of Hong Kong - Queen Mary Hospital, Hong Kong, Hong Kong

Study question: How effective the I-BMS self-help intervention in reducing the anxiety among women during the two week wait?

Summary answer: The anxiety level during the 2-week-wait of the women in intervention groups increased less than that of control group. Their need for parenthood decreased after intervention.

What is known already: IVF treatment is always considered as a stressful experience to women. Among all the treatment stages, it has been proven that women's anxiety level peaks at the two week wait,i.e. the waiting period between embryo transfer and pregnancy test. The situation is especially difficult for Chinese women who bear the obligation to extend the family tree.

The psychosocial self-help model adopted Traditional Chinese Medicine (TCM) as the framework, which aims at maintaining a harmonious balance in holistic wellbeing. It has been proven effective in alleviating anxiety, improving marital satisfaction and achieving holistic well-being of the Chinese women in face of IVF treatment.

Study design, size, duration: 536 women who were going to undergo IVF treatment were recruited in infertility clinics in Hong Kong. 412 who agreed to study participation were randomly assigned to three groups after the two-hour briefing session: Spiritual-behavioral (SB) group (n = 143) received a self-help exercise book on bodily exercises and spiritual reflections for home practicing; Spiritual (S) group (n = 107) received only spiritual stories; Control group (n = 103) received health information on infertility and ART treatments.

Participants/materials, setting, methods: All participants were invited to complete a set of self-administered questionnaires which comprised of the Chinese State-trait Anxiety Inventory (C-STAI) and Fertility Problem Inventory (FPI) on the day of embryo transfer (T1) and the day of pregnancy test (T2). The results were analyzed by repeated measures of ANOVA.

Main results and the role of chance: The mean age of the participants was 36.4 years old (SD:3.2), and the mean duration of marriage was 6.7 years (SD: 3.2). They had been diagnosed of subfertility for 3.8 years (SD: 2.4) in average, and 34.2% of them had gone through more than one treatment cycle. The reasons of subfertility were mostly due to male factors (37.4%), followed by female factors (29.2%), unexplained factors (18.1%) and mixed factors (15.3%).

Participants in the intervention groups (SB group: T1=42.3+10.9, T2=49.8 +10.6, p < 0.05, Difference=+17.7%; S group: T1=42.2+11.8, T2= 48.6+14.0, p < 0.05, Difference=+15.2%) showed lowered increase in state anxiety level than the control group (T1=45.1+11.3, T2=55.5+8.8, p < 0.05, Difference= +23.1%) as measured by C-STAI.

Apart from the anxiety level, participants in SB group showed significant reduction in their need for parenthood (T1=36.4+7.7, T2=34.9+8.1, p < 0.05) as measured by the sub-scale of FPI, while S group showed no significant changes (T1=38.5+7.0, T2=39.3+7.6, p>0.05). In contrast, the control group demonstrated the highest increase in their need for parenthood (T1=37.4+6.7, T2=38.2+7.8, p < 0.05).

Limitations, reasons for caution: The sample size was not standardized for the three groups due to the on-going recruitment of the study. Moreover, since it was a quantitative study, the women's treatment experience and their opinions towards to self-help intervention during the period were subject to further study.

Wider implications of the findings: The self-help intervention allows more autonomy, flexibility and privacy at lower cost to fulfill the women's special needs during the two week wait. It could prepare them psychologically and physically for the treatment outcomes. With limited existing psychosocial services specific for this period, it could provide another choice of support.

Trial registration number: N/A.

O-261   What do people know about fertility and infertility risk factors? A systematic review on fertility knowledge (FK) levels and associated factors

J. Pedro[1], **T. Brandão**[1], **L. Schmidt**[2], **M.E. Costa**[1], **M.V. Martins**[1]

[1]University of Porto, Faculty of Psychology and Education Sciences, Porto, Portugal
[2]University of Copenhagen, 2Department of Public Health, Copenhagen, Denmark

Study question: What are the levels of fertility knowledge (FK) among study participants and how is FK associated with gender, age, educational level, reproductive status?

Summary answer: Study participants report low to moderate FK. Females, highly educated individuals and people who report difficulties in getting pregnant or previous pregnancies present higher FK.

What is known already: Recent evidence indicates that people in reproductive age groups have inadequate knowledge concerning fertility, infertility risk factors and the consequences of delaying childbearing. To date, no study tried to explore and summarize the results of these studies and analyze which factors are associated with FK; namely age, gender, educational level and reproductive status.

Study design, size, duration: A systematic review of literature was conducted to identify studies assessing FK. A literature search was performed from inception to October 2016 in EBSCO, Web of Science, Scielo and Scopus electronic databases. PRISMA guidelines were followed and the review protocol was registered at PROSPERO (registration number CRD42016050186; http://www.crd.york.ac.uk/PROSPERO).

Participants/materials, setting, methods: A search was conducted using combinations of keywords and MeSH term (e.g., ´knowledge´ AND´ fertility´; ´fertile period´; ‘assisted reprod*´). Original studies published in English, French, Spanish and Portuguese were included. Eligible studies had to evaluate quantitatively FK and to describe the measure or have a detailed description of questions used. Assessment of eligibility and data extraction was performed by two researchers independently. A narrative synthesis approach was used to conduct the review.

Main results and the role of chance: Out of 7696 studies initially identified, 63 of them met eligibility criteria and were included in the review. Studies investigating FK with separate items revealed low to moderate knowledge regarding infertility definition and the fertile period. Knowledge regarding infertility risk

factors, e.g., alcohol, smoking and sexually transmitted diseases were high. However, knowledge regarding causes of infertility was low. A significant proportion of studies showed inaccurate beliefs about infertility causes. Knowledge regarding female age as an infertility risk factor and knowledge regarding the most fertile ages was moderate to high. However, knowledge concerning age-related fertility decline was low, with study participants overestimating the fertility potential and success rates of fertility treatment. Knowledge on risks for the mother and the baby as consequences of delaying childbearing was moderate. Studies using a structured instrument for measuring FK found moderate FK. Evidence showed that being a female, having a higher educational level, difficulties in getting pregnant, and previous pregnancies were associated with higher FK. Being a parent or desiring parenthood was not associated to FK. Age seems inconsistently linked to FK, with some studies showing positive associations and others a negative or no association with FK.

Limitations, reasons for caution: Studies presented high heterogeneity in FK assessment and methodological limitations. A significant proportion of studies focused exclusively on women, undergraduate students and samples were predominantly from USA and Europe, increasing the likelihood of a risk bias on the findings. Conclusions need to be interpreted with cautions.

Wider implications of the findings: This is the first review addressing FK levels. The findings suggested that interventions to increase FK are welcomed, with particular benefits to men, low-educated groups and before preconception care takes place. Prospective high-quality studies using FK validated instruments and exploring the role of FK on reproductive decisions are needed.

O-263   Gamete origins of early pregnancy failure

L. Gianaroli

S.I.S.M.E.R. s.r.l., Day Surgery Clinic, Bologna, Italy

Abstract text

Although not unique to humans, aneuploidy is frequent in human embryos, due to malsegregation at meiosis and/or mitosis. Data from natural pregnancies report that the vast majority of aneuploidies are traced back to the maternal chromosomes in an age dependent manner. As miscarriages occurring during the first weeks of gestation may be undetected and untested, the incidence of aneuploid conceptuses can be higher than that reported by data from miscarriages or prenatal/postnatal diagnoses. This is confirmed by the data from pre-implantation genetic testing for aneuploidy (PGT-A) that has provided comprehensive information on the incidence of chromosome errors in IVF oocytes and embryos.

There are several possible causes of oocyte predisposition to aneuploidy. Although meiotic errors can occur during foetal oogenesis, PGT-A of oocytes has revealed that the incidence of malsegregation at the second meiotic division is higher than that occurring at the first division. Possibly, the long time between the initiation and the completion of oocyte maturation contributes to the alteration/degradation of factors important for chromosome fidelity. Interestingly, the origin of autosomal aneuploidy in foetuses mostly resides in the first meiotic division suggesting that those happening after oocyte activation are hardly compatible with clinical pregnancies.

The formation and positioning of the meiotic spindle is controlled by the sub-cortical maternal complex (SCMC), a multiprotein complex essential for both the meiotic spindle migration and the progression beyond the first divisions. The genes encoding for the SCMC complex are expressed during oogenesis, and the transcripts are degraded after embryonic genome activation. SCMC proteins are found until the blastocyst stage, where they segregate to the outer cells being absent in the inner cell mass. These proteins are involved in mitochondria translocation at appropriate timing during embryogenesis. Clearly, the provision of ATP at crucial steps in oocytes and embryos is fundamental for the

events associated with fertilization and developmental competence. It has been proposed that ageing may affect oocyte competence in targeting the cytoplasmic quality, and particularly mitochondria. The consequences include the generation of aneuploidy that is increased by oxidative stress, confirming the close relationship between mitochondria and oocyte quality. Interestingly, some mtDNA-haplogroups are protective against the decline of ovarian reserve.

Despite the preponderant role of the oocyte in relation to aneuploidy, sperm contribution to the resulting embryo cannot be disregarded. Following chromosomal analysis, aneuploidy is found in approximately 6% of sperm cells, but this figure increases significantly in severe male factor samples. Besides releasing into the oocyte its genome and the phospholipase C-zeta, the sperm also contributes its centrosome that, after duplicating and separating its two centrioles, pull the chromosomes apart during the first embryonic divisions. Certain forms of male infertility involve centriole abnormalities, and may induce the formation of mosaic embryos.

Results from sequential biopsies suggest the existence of aneuploidy corrective mechanisms. The potential mechanisms of aneuploidy rescue, either of meiotic or mitotic origin, include the formation of micronuclei encapsulating missegregated chromosome, multi-polar division, aneuploid blastomere exclusion or fragmentation. These corrective mechanisms existing in viable oocytes help restoring a condition compatible with the generation of euploid conceptuses.

In carriers of translocations, the risk of generating unbalanced gametes is higher in reciprocal than in Robertsonian translocations. In reciprocal translocations, this frequency varies depending upon the type of chromosomes engaged in the translocation, and the size and the position of the exchanged segments. PGT results have shown that the vast majority of embryos are unbalanced both in reciprocal and Robertsonian translocations. In case of male carriers, the analysis of sperm cells for the chromosomes involved in the translocation provides an estimation of unbalanced gametes, as well as of the type of segregation.

O-264   Genetic testing in early pregnancy failure

M. Van Wely[1], M. Goddijn[2]

[1]Center for Reproductive Medicine Academic Medical Center, Amsterdam, The Netherlands
[2]Center for Reproductive Medicine, Academic Medical Center, Amsterdam, The Netherlands

Abstract text

The loss of a pregnancy during the first trimester occurs in about 10%-15% of all clinical pregnancies. Once a woman is 40 years of age, the percentage of first trimester losses increases up to 40% of all clinical pregnancies. We know that half of the first-trimester miscarriages are caused by fetal chromosome abnormalities. The prevalence of these foetal chromosome abnormalities after a single sporadic miscarriage has been estimated to be 45% (95% CI: 38-52; 13 studies, 7012 samples). The prevalence of chromosome abnormalities in women experiencing a subsequent miscarriage after preceding recurrent miscarriage appears to lie within the same range (39%, 95% CI: 29-50; 6 studies 1359 samples).

According to conventional karyotyping nine out of 10 abnormalities are due to numerical aberrations, other reasons are structural abnormalities and more rarely problems like mosaicism and translocations. Conventional karyotyping may be hampered by maternal contamination, culture failure or overgrowth and poor quality of the chromosomal preparations. No fetal karyotype result is available in about 20% of the samples tested. Another disadvantage is the limited resolution.Chromosomal Comparative Genomic Hybridization (CGH), array-Comparative genomic hybridization (array-CGH), fluorescence in situ hybridization (FISH), multiplex ligation-dependent probe amplification (MLPA) and quantitative fluorescent polymerase chain reaction (QF-PCR) are alternative techniques that might deal with (a part of) the limitations of conventional karyotyping though each technique has its limitations. The expectations of the molecular techniques, in particular the array-CGH, are high. These techniques do not seem to detect more chromosomes but are able to detect chromosome abnormalities in case of failed cultures. Furthermore, FISH and MLPA can detect pre-selected submicroscopic abnormalities while array-CGH can detect chromosome abnormalities in the whole genome. Hence these techniques enable us to detect submicroscopic chromosome abnormalities which cannot be found with conventional karyotyping.

Knowledge on prevalence of cytogenetic abnormalities in miscarriage samples may provide important information for the woman or couple in question. Still, the relevance of the molecular techniques for daily clinical practice is a point of discussion. Opinions differ as to the usefulness of genetic testing of miscarriage samples for routine clinical practice.

SESSION 68: INTRA-UTERINE INSEMINATION: WHY, WHEN AND HOW

Wednesday 5 July 2017   Plenary 2   12:00–13:00

O-265   Evidence based IUI: what we do and do not know

B. Cohlen[1], A. Bijkerk[1], W. Ombelet[2], S. Van der Poel[3]

[1]Isala, Isala Fertility Center, Zwolle, The Netherlands
[2]Ziekenhuis Oost-Limburg, Genk Institute for Fertility Technology, Genk, Belgium
[3]WHO, WHO/HRP the UNDP/UNFPA/UNICEF/WHO/World Bank Special Programme of Research- Development and Research Training in Human Reproduction-, Geneva, Switzerland

Abstract text

Background: Intrauterine insemination (IUI) has become a first-line treatment option for many infertile couples, worldwide. However, the practice of IUI with the use of ovarian stimulation (OS) varies across centers and countries; and, complication rates, such as multiple pregnancies rates, greatly differ. The World Health Organization (WHO) had initiated a multi-year project to establish best practice guidance within the field of infertility, and had therefore recognized the need to evaluate the evidence for use of IUI.

Objective and rationale: 14 prioritized questions covering IUI with and without OS were established through WHO processes. The best available evidence was collected and research gaps identified during development of draft global, evidence-based guidelines.

Methods: Specific search terms were used to find the available evidence in MEDLINE (1950 to May 2015) and The Cochrane Library (until May 2015). We also hand searched references of relevant reviews and included more recent studies up to January 2016. Articles found relevant were read and analyzed by two investigators (AB and BC) and critically appraised using the Cochrane Collaboration's tool for assessing risk of bias and AMSTAR in case of systematic reviews. The quality of the evidence was assessed using the WHO GRADE system.

Outcomes: An assessment and synthesis of the evidence will be presented, as well as with identification of evidence gaps. In general, quality of the evidence found was poor and in many cases, outdated. Recent studies showed IUI with OS still to be the most cost-effective treatment option in couples with moderate male or unexplained subfertility when prognosis is less than 30% of becoming pregnant without assistance in the forthcoming year. There is insufficient evidence to recommend for or against IUI (with or without OS) in male infertility because of the lack of high quality evidence. Evidence-based details on how to perform IUI will be presented. Patient-centred practice and the importance of patient groups in writing guidelines is highlighted, with a need that patients be provided options for what can be a preferred less invasive intervention of IUI over IVF//ICSI.

Clinical judgment completes the triad of evidence-based medicine. Preventing complications such as multiple pregnancies, especially in low resource settings, are critical to decrease maternal/newborn morbidity and mortality. Primary and secondary measures will be presented to keep multiple pregnancy rates to a minimum.

Wider implications: Because IUI is a widely applied treatment option, there is great need for clear practical best practice guidance that are cost-effective and better ensure preventable complication rates. Future research should focus on the gaps that were identified in the search for evidence that will help to support worldwide guidelines.

O-266 Prognostic factors influencing IUI success

N. Dhont[1]

[1]ZOL Campus St. Jans, Genk, Belgium

Abstract text

Background: Intra uterine insemination aims to increase gamete density at the site of fertilization. It is a widely used treatment mainly for couples with unexplained infertility, cervical factor and mild male factor. Questions remain about the effectiveness of this method. There is a considerable amount of literature on several prognostic factors either related to patient characteristics or the IUI procedure itself, often with controversial results.

Objective and rationale: In this lecture we will review the prognostic factors influencing success rates of IUI.

Methods: For all the prognostic factors we searched the available evidence in MEDLINE (up to January 2017) and The Cochrane Library (until January 2017) using specific search terms. We also hand searched references of relevant reviews and included more recent studies up to January 2017.

Outcomes: Female age is the most important prognostic factor influencing the likelihood of pregnancy in IUI with a sharp decline after 40 years. For IUI with donor sperm acceptable pregnancy rates can be achieved up until 42 years. In general IUI is performed if one tube is patent; there is some evidence however that in case of unilateral distal tubal blockage IUI pregnancy rates decrease significantly. The effects of female weight, male and female smoking and male age are controversial. The most important male factor is sperm quality parameters. Based on a literature review the following cutoff parameters can be identified: TM (Total Motility) >30%, TMSC (Total motile count native sample) > 5-10 million and IMC (Inseminating Motile Count) > 1-2 million.

For unexplained infertility, minimal to mild endometriosis and mild male factor addition of ovarian stimulation improves pregnancy rates in IUI, gonadotrophins more than clomiphene citrate. This is not the case for moderate male factor and cervical factor. The increase in pregnancy rates with ovarian stimulation need to be balanced against the increase in multiple pregnancy rates. There is some evidence that luteal support with progesterone after IUI with gonadotrophin ovarian stimulation improves pregnancy rates.

IUI should be performed once 12-36 hours after HCG injection. There is no sperm preparation technique (wash and centrifugation, swim up, density gradient centrifugation) proven to be superior. 15 minutes of bed rest after IUI has been generally advocated, based on 2 RCTs showing beneficial effect. However this has recently been challenged by a new RCT showing no improvement after bed rest.

Wider implications: IUI remains a relatively simple, noninvasive, cheap treatment option for a well selected population with patent tubes and a sufficient number of motile sperm. If performed with proper timing and with ovarian stimulation when indicated, IUI result in cumulative pregnancy rates up to 50 % after 6 cycles and can prevent couples moving on to IVF.

Abstract text

Human Endogenous Retroviruses (hERV) are derived from ancestral retroviruses, which have been co-opted in our genome for over several million years. These sequences harbour viral-like genes, some of which have retained their encoding capacity. Interestingly, two hERV sequences encode former envelope proteins, known as Syncytin-1 and Syncytin-2, which are implicated in the formation of the syncytiotrophoblast, a multinucleated cell layer localized on the periphery of placental villi. This structure plays a pivotal role in the process of nutrient and gas exchange but also contributes in producing important hormones. Most importantly, this layer is very dynamic and its maintenance is ensured by constant fusion events with underlying villous cytotrophoblasts. Our team has been focussing on the role of Syncytin-2 in placental function through its association to the membrane of cytotrophoblasts and have shown that this protein, via its fusogenic properties, is greatly responsible in mediating cytotrophoblast fusion. In addition, we have accumulated other evidence showing that Syncytin-2 contributes to placental formation and function in a similar manner to envelope proteins at the surface of retroviruses. We have in fact recently demonstrated that Syncytin-2 is present at the surface of placental exosomes and that this latter protein can provide a form of tropism to these extracellular vesicles towards target cells through receptor-mediated binding and fusion. Herein, two additional examples of such retrovirus-related functions of Syncytin-2 are provided. Galectin-1 is an extracellular lectin, which acts as a dimer and binds specific glycans. This soluble protein has been associated to apoptosis and can increase infection by various viruses, such as HIV-1. Interestingly, this factor is highly expressed by cytotrophoblasts and has been shown to increase fusion between trophoblasts. We thus hypothesized that, like for other viruses, galectin-1 might favour the interaction between Syncytin-2 and its receptor. Using HIV-1 retroviral particles pseudotyped with Syncytin-2 and expressing the luciferase reporter gene, we demonstrate that galectin-1 importantly augmented the rate of infection of Syncytin-2-positive viruses. This increment in infectivity was more pronounced on 293 T cells overexpressing the Syncytin-2 receptor, MFSD2a. No such positive impact was noted when galectin-3 was added and, in addition, non-pseudotyped or VSV envelope-pseudotyped viruses were not responsive toward galectin-1 treatment. Incubation of galectin-1 with pseudotyped viruses during contact with cell target was shown to be essential for its effect on viral infection and suggested no role for galectin-1 on the fusion process. As a second approach, we assessed the immunosuppressive function of the Syncytin-2 protein through the analysis of its immunosuppressive domain, a domain which is shared with envelope proteins from various retroviruses. When a dimerized form of the synthesized peptide corresponding to the amino acid sequence of the immunosuppressive domain was tested, cytokine production of T cells lines or activated PBMCs was greatly hampered. Using the same assay, the inhibitory potential of exosomes isolated from cultured primary cytotrophoblasts was confirmed over activated PBMCs. Of interest, when the presence of Syncytin-2 was strongly reduced at the surface of exosome by siRNA-mediated silencing of its expression in cultured villous cytotrophoblasts, the immunosuppressive potential of resulting exosomes was severely downmodulated, thereby suggesting that Syncytin-2 plays a very important role in the immunosuppressive feature of placental exosomes. Overall, our results have demonstrated that Syncytin-2 plays multiple roles in the placenta and that its functions are reminiscent of those associated to envelope proteins of exogenous retroviruses. Through its association with placental exosomes, Syncytin-2 might also contribute to intercellular communication during pregnancy. Furthermore, this association has a potential diagnostic value to obstetric disorders in which Syncytin-2 presents important variation in its expression, such as preeclampsia.

O-268 Retroviruses facilitate the rapid evolution of the mammalian placenta

E. Chuong

University of Utah School of Medicine, Department of Human Genetics, Salt Lake City- Utah, U.S.A.

Abstract text

Endogenous retroviruses (ERVs) are remnants of ancient retroviruses that invaded host germline DNA, and constitute 6-14% of vertebrate genomes.

Multiple genome defense mechanisms have evolved to repress ERV activity, which has long been associated with diseases including cancer and autoimmunity. Nonetheless, ERVs contain sequences capable of modulating transcription, and the propagation of these "pre-built" regulatory sequences throughout the genome has long been proposed to fuel the evolution of gene regulatory networks.

We are investigating a role for ERVs in shaping the evolution of transcriptional networks underlying various processes involved in reproduction and immunity. Our previous work identified ERVs as a substantial source of species-specific enhancers in the developing placenta. More recently, we identified ERV-derived enhancer elements that are activated during the interferon (IFN) response, a major branch of innate immunity. Through an analysis of STAT1 and IRF1 ChIP-seq data from IFN-treated human cell lines, we identified over 7,000 IFN-inducible binding sites that derived from ERV elements. We focused on an ERV family named MER41 that invaded primate genomes 50 million years ago and deposited hundreds of IFN-inducible enhancers by "copy and pasting" multiple STAT1 binding motifs. CRISPR-Cas9 deletion of individual MER41 elements in the human genome impaired expression of adjacent IFN-induced genes and revealed their involvement in the regulation of essential immune functions, including activation of the AIM2 inflammasome in response to viral infection. In mouse, we identify a largely distinct repertoire of rodent-specific ERVs that may have independently rewired the mouse IFN regulatory network. While these regulatory sequences likely arose in ancient viruses, they now constitute a dynamic reservoir of regulatory variation that may be co-opted for host biological functions, catalyzing the evolution of gene regulatory networks.

SELECTED ORAL COMMUNICATIONS
SESSION 70: CLINICAL IMPACT OF LABORATORY TECHNIQUES

Wednesday 5 July 2017   Plenary 1   14:00–15:15

O-269   Prospective evaluation of a cumulus-corona gene expression based scoring, combined with morphological scoring, reveals improved clinical pregnancy rates

T. Adriaenssens[1], I. Van Vaerenbergh[1], W. Couck[2], I. Segers[3], G. Verheye[3], M. De Vos[3], J. Smitz[1]

[1]Vrije Universiteit Brussel VUB, Follicle Biology Laboratory, Jette Brussels, Belgium
[2]Scientific Institute of Public Health- 1050 Brussels- Belgium, Department of Clinical Biology-, Brussel, Belgium
[3]Universitair Ziekenhuis Brussel UZ Brussel, Centre for Reproductive Medicine, Jette Brussels, Belgium

Study question: Can quantitative cumulus cell gene expression analysis in addition to embryo morphology scoring improve the clinical pregnancy rate in patients undergoing single embryo transfer (SET)?

Summary answer: The Corona-test significantly improves the clinical pregnancy rates of day 3 SET compared to day 3 and 5 SET with morphological selection only.

What is known already: Because clinical pregnancy rates from IVF/ICSI cycles with SET stagnate between 30% and 40%, multiple embryo transfer is still common practice to increase the chance of live birth per treatment cycle. Cumulus and corona cells (CC) communicate bidirectionally with the oocyte, can be easily collected and are dispensable. CC mRNA analysis with quantitative PCR (qPCR) can provide an objective approach to oocyte competence evaluation.

Study design, size, duration: A prospective case-matched control study, performed from 2013 until 2016, comprised one experimental arm where the Corona-test complemented the morphological scoring with transfer on day 3 (n = 62) and two case-matched control arms where elective SET (eSET) was done on day 3 (n = 62) or day 5 (n = 44) based on morphological scoring only.

Participants/materials, setting, methods: All patients were stimulated with HP-hMG in a GnRH antagonist protocol and scheduled for ICSI and eSET.

Case-control pairs were matched for age, number of good quality embryos (GQE) on day 3, and to be nearest in treatment time. In the experimental arm, the oocytes were denuded individually and CC were used to calculate a Corona-test score based on the normalized gene expression of specific genes. The GQE with the highest Corona-test score was transferred.

Main results and the role of chance: eSET decided on the basis of the Corona-test score yielded a significantly higher clinical pregnancy rate of 63%, compared to the clinical pregnancy rate of 27% (p < 0.001) and 43% (p < 0.05, Chi-square test) in the controls with eSET based on only morphological scoring and transfer on day 3 and day 5, respectively. Further analysis of the data indicated that the gain in clinical pregnancy rates using the Corona-test is independent of patients' age or number of available GQE. More importantly, the time-to-pregnancy was significantly shorter with three frozen/thawed embryo transfer cycles that could be avoided by performing a Corona-test analysis in the fresh cycle (p < 0.05, Kaplan-Meier analysis).

Limitations, reasons for caution: The Corona-test was evaluated in patients who underwent HP-hMG stimulation before ICSI treatment and with eSET on day 3. Wider generalization would necessitate validation studies in diverse stimulation protocols, other ethnicity and in patients undergoing IVF without ICSI.

Wider implications of the findings: The Corona-test reduces the time-to-pregnancy. This will have a great impact on the reduction of patient burden and the workload in the ART clinic and health care expenses for ART. The Corona-test further decreases the need to transfer multiple embryos and its associated risk of neonatal and maternal complications.

Trial registration number: not applicable.

O-270   Intracytoplasmic sperm injection versus conventional in vitro fertilization for non-male factor infertility and decreased ovarian reserve: a systematic review and meta-analysis

C. Wu[1], R. Bassil[2], J. Haas[2,3], E. Barzilay[3], D. Nayot[2], R. Casper[2,4]

[1]University of Saskatchewan, Department of Obstetrics- Gynaecology- and Reproductive Sciences, Regina, Canada
[2]TRIO Fertility Partners- University of Toronto, Department of Obstetrics and Gynecology- Division of Reproductive Sciences, Toronto, Canada
[3]Sheba Medical Center- Tel-Hashomer- Sackler School of Medicine- Tel Aviv University, Department of Obstetrics and Gynecology, Tel Aviv, Israel
[4]Lunenfeld-Tanenbaum Research Institute, Division of Reproductive Sciences, Toronto, Canada

Study question: Does intracytoplasmic sperm injection (ICSI) yield improved fertilization and clinical pregnancy rates compared to conventional in vitro fertilization (IVF) for non-male factor infertility with and without decreased ovarian reserve (DOR)?

Summary answer: ICSI yields better fertilization but similar clinical pregnancy rates when compared to conventional IVF in couples with non-male factor infertility.

What is known already: ICSI has surpassed conventional IVF as the preferred method of insemination in recent years. Threshold for using ICSI has been consistently lowered, and ICSI is now widely used for non-male-factor infertility and DOR. Previous studies examining fertility outcomes following IVF versus ICSI for these indications have yielded conflicting results.

Study design, size, duration: We systematically searched the Cochrane Library, EMBASE and MEDLINE databases from inception to November 2016. Keywords used included ICSI, IVF, non-male factor infertility, female infertility, and pregnancy. Studies were included if they examined couples with normal semen parameters, had insemination performed with either or both conventional IVF and ICSI depending on study design, and reported at least one of the outcomes of interest (fertilization, implantation, pregnancy, or miscarriage rates).

Participants/materials, setting, methods: Two reviewers independently extracted data from included studies. Fertilization and clinical pregnancy data were pooled across trials using a random-effects model.

Main results and the role of chance: Eighteen randomized controlled trials (RCTs) and 7 observational studies investigating fertility outcomes in couples with non-male-factor infertility were included in our systematic review. Six of

the included studies examined couples with DOR and were included as part of a subgroup analysis. The systemic review included 1,884 IVF cycles and 2,038 ICSI cycles performed on a total of 3,583 patients. When data were pooled across RCTs, ICSI yielded better fertilization rates when compared to conventional IVF (odds ratio [OR] = 1.43; 95% CI = 1.05, 1.94) but similar clinical pregnancy rates (OR = 0.93; 95% CI = 0.69, 1.27) in non-male-factor-infertile couples. In the subgroup analysis of patients with DOR, IVF was superior to ICSI in clinical pregnancy rates (OR = 0.48; 95% CI = 0.32, 0.72), but comparable in fertilization rates (OR = 1.19; 95%; CI = 0.63, 2.24).

Limitations, reasons for caution: Studies comparing IVF and ICSI are heterogenous in methodology, patient selection, and outcome measures, making direct comparisons and data aggregation challenging.

Wider implications of the findings: Our meta-analysis provides an updated overview of currently published literature on fertility outcomes following IVF and ICSI cycles. It does not yield demonstrable evidence in favor of the routine use of ICSI in patients with non-male-factor infertility or DOR.

Trial registration number: Not applicable.

O-271   The reproductive outcome of donor ICSI cycles and embryo morphokinetic parameters are not compromised by high levels of sperm DNA fragmentation

D. Nikiforaki[1], N. Billias[2], S.M. Morou[1], D. Tzeferakos[1], D. Papadopoulos[1], S. Mantzouranis[1]

[1]REA Maternity Hospital, REA Fertility Unit, Athens, Greece
[2]National and Kapodistrian University of Athens, Faculty of Biology- Department of Genetics, Athens, Greece

Study question: Is there an association between the level of sperm DNA damage and the reproductive outcome of ICSI cycles with donor oocytes?

Summary answer: An increased level of sperm DNA damage does not have a negative impact on the reproductive outcome of ICSI cycles with donor oocytes.

What is known already: The degree of sperm DNA fragmentation reflects the integrity of the genetic material and chromatin integrity seems essential for sperm to fully express their fertilizing capacity. Transmission of damaged sperm DNA, particularly at levels that exceed the DNA repair capacity of the oocyte, could have serious consequences on embryo quality (morphokinetic parameters, morphology), fertilization and live birth rates in couples with high sperm DNA fragmentation index (DFI). Whether the extent of DNA damage is a prognostic factor of a man's fertility potential and if it is linked to embryo quality and miscarriage rates is still a matter of debate.

Study design, size, duration: For this prospective study, semen samples were collected from 54 men undergoing ICSI cycles with donor oocytes in a private IVF center (October 2015-June 2016). Sperm was subjected to DNA fragmentation analysis before and after sample processing utilizing a previously defined cut-off value. Morphokinetic parameters (t5, s2, CC2) of 352 embryos were evaluated with time-lapse. Maximum 2 embryos were transferred and supernumerary embryos were vitrified. Cycles were followed up to record their reproductive outcome.

Participants/materials, setting, methods: Sperm samples from men undergoing ICSI cycles with donor oocytes were assessed using the Sperm Chromatin Dispersion test with a cut-off value 24.8% following ejaculation and after density-grade processing. The development of 352 embryos was monitored with time-lapse (Primo Vision). Student's t-test was used to assess statistical differences, with $p < 0.05$ considered significant. Means were compared with one-way ANOVA. The Spearman rank correlation was performed with raw scattered plots. The results are expressed as means ± SD.

Main results and the role of chance: Cycles were classified based on the DFI prior to sperm sample processing into: Group A with DFI<24.8% ($n = 29$) and Group B with DFI>24.8% ($n = 25$). Fifty-four ICSI cycles using donor oocytes resulted in 70.4% pregnancy rate, 66.6% clinical pregnancy rate, 59.3% ongoing pregnancy rate and 53.7% delivery rate per embryo transfer. There was no statistical difference between groups A and B with regards to the pregnancy rate ($p = 0.341$), clinical pregnancy rate ($p = 0.173$), ongoing pregnancy rate ($p = 0.4$), miscarriage rate ($p = 0.532$) and delivery rate ($p = 0.435$). Regarding the embryo morphokinetic parameters, no correlation was found

between the DFI and t5, s2, CC2 ($p = 0.401$) nor with embryo quality on day 3. Scatter plot analysis showed a negative correlation of the DFI with sperm concentration. Furthermore, there was a significant decrease in the DFI of sperm samples (26.63 ± 13.57%) following density-grade centrifugation (15.02 ± 13.82%) ($p < 0.0001$).

Limitations, reasons for caution: The results need to be confirmed with a larger sample size. It is possible that current methods for determining the DFI cannot detect the DNA damage that is clinically important. New DFI cut-off values may need to be validated. The effect of SDF on blastocyst formation should also be evaluated.

Wider implications of the findings: A successful reproductive outcome depends both on the traits of sperm quality and function, as well as the influences of the oocyte. However, it seems plausible that the DNA repair mechanisms of high quality donor oocytes offset the negative impact of increased sperm DNA damage on the reproductive outcome.

Trial registration number: N/A.

O-272   Influence of commercial embryo culture media on preimplantation development and pregnancy outcome after IVF: a single-center RCT

M. Murakami[1], S. Mizumoto[2], K. Tanaka[2], H. Otsubo[2], A. Egashira[2], T. Kuramoto[3]

[1]Kuramoto Women's Clinic, Research Laboratory, Fukuoka, Japan
[2]Kuramoto Women's Clinic, IVF Laboratory, Fukuoka, Japan
[3]Kuramoto Women's Clinic, President, Fukuoka, Japan

Study question: An RCT was conducted to compare preimplantation development and pregnancy outcome between three embryo culture media systems that are used widely in IVF programs.

Summary answer: Embryo culture media used in IVF affected preimplantation development, including blastocyst yield, but the overall pregnancy rates (PRs) after ET did not differ between media.

What is known already: Numerous commercial embryo culture media are now available for IVF, which raises the question as to whether any medium is superior. Significantly, the ability of a particular culture medium to yield a high embryo development percentage *in vitro* does not necessarily mean that these embryos are viable. For example, it was previously common to include blood serum in animal embryo culture media to stimulate blastocyst formation, but this resulted in impaired embryonic, fetal, and offspring health. Given the importance of culture media for treatment outcome, well-designed RCTs are needed, but the existing data are insufficient to select the best medium.

Study design, size, duration: This study included 525 healthy patents receiving their first IVF treatment cycle at our clinic between February and December 2016. They were randomized by computer-generated tables into three groups and underwent our standard oocyte retrieval and IVF/ICSI procedures, and the embryos were cultured in G1/G2 Plus (Vitrolife) (A), Global Total (LifeGlobal) (B), or Sequential Cleav/Blast (Origio) (C) media. Of the patients, 27 with no 2PN oocytes 18 h after insemination were excluded from the study.

Participants/materials, setting, methods: During embryo culture (1-5/ 50 μL), for cycles where the patients had only one good-quality (GQ) embryo by day 3 (D3), the embryos were vitrified on D2/3. When the patients had ≥2 GQ embryos by D3, ≤2 GQ embryos were vitrified on D2/3, the culture of the remaining embryos was extended, and all GQ blastocysts were vitrified on D5/6. The ET data for these vitrified embryos performed by the end of December 2016 were analyzed.

Main results and the role of chance: Patient age (years) was similar between groups A (35.8 ± 0.3, n = 165), B (36.2 ± 0.4, n = 170), and C (36.5 ± 0.3, n = 163). A total of 1098, 1170, and 1145 2PN oocytes were cultured in groups A, B, and C, respectively. The percentages of vitrified D2/3 embryos per 2PN oocytes were similar between groups A (19.3%), B (19.6%), and C (19.0%). The percentages of vitrified D5/6 blastocysts per 2PN oocytes were 25.7%, 38.4%, and 32.5% in groups A, B, and C, respectively (A vs. B, $P < 0.0001$; A vs. C, $P = 0.0004$; B vs. C, $P = 0.0031$). Groups A, B, and C underwent a total of 186 (D2/3 ET=56, D5/6 ET=115, 2-step ET (combining a D2/3 ET with a D5/6 ET)=15), 192 (D2/3 ET=55, D5/6 ET=120, 2-step

ET=17), and 163 (D2/3 ET=55, D5/6 ET=96, 2-step ET=12) ET cycles with these vitrified embryos, respectively. Most embryos survived warming (A=220/220, B=222/225, C=191/192), and only one ET cycle was cancelled, which was in group C. The mean number of embryos transferred (A=1.16 ± 0.03, B=1.17 ± 0.03, C=1.18 ± 0.03), implantation rates (A=44.0%, B=40.6%, C=36.6%), clinical PRs per ET (A=48.9%, B=45.3%, C=40.7%), and ongoing PRs per ET (A=37.6%, B=35.9%, C=30.9%) did not differ between the groups.

Limitations, reasons for caution: Our single-center prospective RCT will help clarify whether commercial embryo culture media have an effect on IVF success rates. Further studies with more participants, including a follow-up study on the perinatal and long-term health of children born after embryo culture, are warranted.

Wider implications of the findings: In this RCT, the PR of a culture system yielding fewer blastocysts was comparable to or slightly better than those of other systems yielding more blastocysts. It would be important to differentiate between the ability of commercial culture media to support preimplantation development and its ability to yield viable embryos.

Trial registration number: UMIN000020910.

O-273   Cumulative live birth rates after fresh cleavage-stage versus blastocyst-stage transfer in combination with vitrification on day 5

I. De Croo, K. Tilleman, F. Vandekerckhove, E. Vanden Abbeel, P. De Sutter

Ghent University Hospital, Centre for Reproductive Medicine, Ghent, Belgium

Study question: What is the cumulative live birth rate per oocyte-collection-cycle (OCC) after cleavage-stage and blastocyst-stage transfer in combination with day 5 vitrification?

Summary answer: The cumulative live birth rate after fresh blastocyst-stage transfer is significantly higher as compared to fresh cleavage-stage transfer.

What is known already: A recent Cochrane analysis (2016) demonstrated a benefit favouring blastocyst transfer in fresh cycles, however it remains unclear whether the day of transfer impacts on cumulative live birth rates. In day 3 transfer cycles, freezing supernumerary embryos at the cleavage stage results in high cumulative live birth rates as compared to freezing at the blastocyst stage in day 5 transfer cycles. Recent published data however, reveal that vitrification of blastocysts results in equal or even better cumulative live birth rates in day 5 transfers cycles.

Study design, size, duration: In patients (n =1216) treated between January 2012 and December 2015 and having between 5 and 9 zygotes available on day 1, we retrospectively analysed cumulative live birth rate in patients having fresh embryo transfer on day 3 (n = 629) (group 1) or on day 5 (n = 587) (group 2). Cumulative live birth rate was defined as the outcome of the fresh treatment cycle in combination with warming cycles within 1 year following the OCC.

Participants/materials, setting, methods: In both groups, supernumerary blastocysts with at least an expansion status 1, inner cell mass score A, B or C and trophectoderm score A, B or C were vitrified. Continuous variables were compared using Mann-Whitney U test and categorical variables were compared using Fisher's exact test. Cox's hazard regression was used to estimate the hazard ratio (HR) (p < 0.05).

Main results and the role of chance: In group 1 and 2, mean number of oocytes retrieved (11.4 ± 4.1 vs 11.6 ± 4.3; NS) and mean number of embryos vitrified (2.5 ± 1.4 vs 2.5 ± 1.4; NS) were similar. The transfer cancellation rate was significantly lower in group 1 as compared to group 2 (2.7% (17/629) versus 8.0% (47/587) (p < 0.0001). The cumulative live birth rate per OCC in group 1 was significantly lower (36.4% (229/629) as compared to group 2 (42.1% (247/587) (p = 0.046). Cox regression analysis showed that for fresh transfer, group 2 had significantly higher hazards for live birth rates compared to group 1 (HR=1.54, 95% CI=1.24-1.92, P < 0.001). For the first, second and more warming cycles, the hazard rate did not differ significantly (p = 0.17 and p = 0.556, respectively).

Limitations, reasons for caution: This study is limited by its retrospective design and patients in group 1 were treated from January 2012-December 2013 and patients in group 2 from January 2014-December 2015. For both groups, not all vitrified blastocysts have been warmed yet.

Wider implications of the findings: In patients having between 5 and 9 zygotes on day 1 of the oocyte-collection-cycle, the fresh transfer policy should be blastocyst transfer.

Trial registration number: not applicable

O-274   Investigation of the protective effect of erythropoietin against cisplatin-induced ovarian damage: a rat model

C. Dayangan Sayan[2], O. Banu Tulmac[1], G. Karaca[4], Z.S. Ozkan[1], S. Yalçın[5], T. Devrim[3], N. Dindar Badem[6]

[1]*kırıkkale university, department of obstetrics and gynecology, kırıkkale, Turkey*
[2]*Kırıkkale University, Deparrtment of Obstetrics and Gynecology, Kırıkkale, Turkey*
[3]*Kırıkkale University, department of Pathology, Kırıkkale, Turkey*
[4]*Kırıkkale University, Department of General surgery, Kırıkkale, Turkey*
[5]*Kırıkkale University, Deparrtment of Medical Oncology, Kırıkkale, Turkey*
[6]*Kırıkkale University, Deparrtment of Biochemistry, Kırıkkale, Turkey*

Study question: Could erythropoietin (EPO) reduce the cisplatin induced ovarian damage in rats?

Summary answer: Concomitant EPO treatment with cisplatin chemotherapy preserves rat ovarian reserve.

What is known already: Cisplatin is a widely used chemotherapeutic agent for treatment of epithelial carcinomas. Cisplatin kills the dividing cells. It's toxic effects on central nervous system, kidney, testis, ovary have been notified widely. Ovarian failure due to cisplatin has been announced with an odd ratio of 1.77. Ovarian damage of cisplatin brings on menstrual irregularity, premature menopause, infertility, decreased life quality and raised medical costs. EPO, hematopoietic growth factor originated from kidney, has antiapoptotic and antioxidant effects. Recent studies have also shown that EPO can reduce the damage of cisplatin on neural system, kidney and heart.

Study design, size, duration: Thirty, female, 10-12 weeks old, 250–280 g, Wistar-Albino rats were used in the study. Rats were randomly divided into three groups: Control group (N = 10): Intraperitoneal salin infusion. Cisplatin group (N = 10): Intraperitoneal 7 mg/kg cisplatin (Cisplatin®, Koçak Farma, Turkey) twice a week. Cisplatin+EPO group (N = 10): Intraperitoneal 7 mg/kg cisplatin (Cisplatin®, Koçak Farma, Turkey) twice a week and subcutaneous 200 IU/kg/day EPO (Eprex®; Janssen-Cilag AG, Switzerland) for 7 days.

Participants/materials, setting, methods: After a midline laparatomy, the right ovaries were removed and blood samples were obtained from heart. Serum AMH concentrations were measured by ELISA method. Primordial, preantral, small antral and large antral follicles were counted after hematoxylin and eosin staining. Ovarian damage; including follicular cell degeneration, vascular congestion, hemorrhage and inflammation (neutrophil infiltration), was scored histologically using a graduated scale (0 = none; 1 = mild; 2 = moderate; and 3 = severe).

Main results and the role of chance: In cisplatin group, there was a significant decrement in posttreatment AMH level compared to pretreatment AMH level (17.69 ± 5.6 vs 14.93 ± 5.1; p < 0.01). But, there was no significant difference between pre- and post-treatment serum AMH levels in control and Cisplatin + EPO groups. Total ovarian damage score of cisplatin group was significantly higher than scores of control and cisplatin+EPO groups. The mean primordial follicle counts of control (7.8 vs 3.8, p>0.01) and cisplatin+EPO (8.4 vs 3.8, p < 0.01) groups were significantly higher than that of cisplatin group. The mean preantral follicle count of control group was significantly higher than that counts of cisplatin (8.4 vs 3.1) and cisplatin+EPO (8.4 vs 3.4) groups. We observed positive correlation between preantral follicle counts and posttreatment AMH levels (R=0.45, p = 0.012). After categorization of cisplatin and cisplatin+EPO groups according to having total ovarian damage score and post-treatment AMH level higher or lower than mean value, binary logistic regression

analysis was performed. Total ovarian damage score showed no influence on posttreatment AMH level.

Limitations, reasons for caution: We could not investigate ovarian tissue AMH level, so we could not be able to compare serum AMH levels with tissue AMH levels. This is an experimental study and our results can not generalize in humans.

Wider implications of the findings: EPO administration to cisplatin chemotherapy could ameliorate the ovarian damage, serum AMH levels and get better ovarian reserve in female rats. After additional studies in animals and humans, EPO administration to cisplatin therapy might be suggested against ovarian reserve decrement.

Trial registration number: none.

O-275 Metaphase II oocytes obtained after luteal phase stimulation have the same intrinsic quality as eggs from the follicular phase stimulation.Results from a multicentre prospective study

Study question: Are metaphase II (MII) oocytes obtained after the follicular phase stimulation (FPS) and luteal phase stimulation (LPS) equivalent in terms of developmental and reproductive competence?

Summary answer: MII oocytes from LPS showed a similar intrinsic quality as eggs from FPS for fertilization,blastulation,euploidy rates and ongoing pregnancy after euploid single embryo transfer (eSET)

What is known already: Follicular development is a dynamic process. Evidences suggest that 'waves"of antral follicles develop cyclically 2-3 times during the same menstrual cycle, overtaking the classic theory that in women only one cohort of antral follicles grows during the follicular phase (FP) of a menstrual cycle. Indeed, ovarian stimulation could be initiated at any time of the cycle, also in the luteal phase (LP). These observations led to the introduction of two new protocols for ovarian stimulation: double stimulation in the same menstrual cycle (Duostim) for poor prognosis patients and random-start for fertility preservation.Preliminary promising clinical data stimulated a deeper investigation of these strategies

Study design, size, duration: Multicenter prospective study performed between January2015-October2016. 208 patients(mean female age=39.7 ± 3.2 range 30.0-44.0)with reduced ovarian reserve(AMH≤1,5 ng/ml,antral follicular count ≤6,and/or ≤ 5oocytes retrieved in a previous cycle)underwent oocyte retrieval after FPS and LPS.The primary outcomes were MII oocytes' intrinsic quality defined as fertilization,blastulation,euploidy rates and ongoing implantation after eSET of blastocyst obtained in the LPS versus FPS from the same patients.Secondary outcomes were the number of MII oocytes,blastocysts, euploid blastocysts and ongoing pregnancies obtained in LPS versus FPS.

Participants/materials, setting, methods: Both FPS and LPS were performed with rFSH in an antagonist protocol. After the first oocyte retrieval from FPS we waited five days before starting LPS. All embryos obtained were cultured to blastocyst, underwent trophectoderm biopsy and vitrification. A single chromosomal analysis was performed through qPCR on all the biopsies

obtained after both FPS and LPS. eSETs were performed in a subsequent natural or artificial cycle

Main results and the role of chance: The number of MII oocytes after FPS and LPS were 763 (3.6 ± 2.3;1-16) and 960 (4.5 ± 2.9;1-15), respectively (p < 0.001). The fertilized oocytes were 509 (2.4 ± 2.0;0-15) and 707 (3.3 ± 2.0;0-13), (p < 0.001). The fertilization rate was 66.7% versus 73.6% (NS). The blastocyst obtained after FPS and LPS were 234 (1.1 ± 1.0;0-4) and 364 (1.7 ± 1.6;0-9) (p < 0.001). The blastulation rate was 46.0% versus 51.5% (NS). The euploid blastocysts obtained after FPS and LPS were 99 (0.5 ± 0.7;0-3) and 154 (0.7 ± 1.0,0-6), respectively (p = 0.005). The euploidy rate was 42.3% (n = 99/234;95%CI:35.9%-48.9%) versus 42.3% (n = 154/364;95% CI:37.1%-47.5%) in FPS and LPS and 12.9% (n = 99/763; 95%CI:10.7%-15.6%) and 16.0% (n = 154/960; 95%CI=13.8%-18.5%) in FPS and LPS, per biopsied blastocyst and MII oocytes, respectively (NS). Overall, the rate of cycles with at least one euploid blastocyst increased from 34.4% (n = 74/215; 95%CI:28.1%-41.1%) in the FPS-only to 57.7% (n = 124/215; 95%CI=48.4%-61.7%) after Duostim (p < 0.001). Thirty-four eSETs of blastocysts from the FPS and 37 from the LPS were performed up to date and no difference was shown in terms of ongoing pregnancy rate: 41.2% (n = 14/34; 95%CI=24.7%-59.3%) versus 45.9% (n = 17/37; 95%CI=29.5%-63.1%) (NS).

Limitations, reasons for caution: A more thorough assessment of oocyte quality after LPS versus FPS in terms of gene expression, metabolism and dynamic developmental parameters is still eagerly needed. Moreover, the neonatal outcomes and the cost-effectiveness especially of Duostim need yet to be evaluated.

Wider implications of the findings: The evidence of multiple follicular waves during a single menstrual cycle in women opened important implications for the treatment of infertility. Here, we report that LPS allows higher yields without affecting the developmental and reproductive potential of the oocytes obtained.Thus, Duostim and random-start ovarian stimulation may be considered clinically-valuable strategies.

Trial registration number: none.

O-276 In Vitro Maturation (IVM) culture conditions: the effect of oxygen tension and medium volume

I. Segers[1], S. Santos-Ribeiro[1], F. Lolicato[2], J. Smitz[2], G. Verheyen[1], R. Gilchrist[3], J. Thompson[4], M. De Vos[1]

[1]UZ Brussel, Centre for Reproductive Medicine CRG, Jette- Brussels, Belgium
[2]Vrije Universiteit Brussel - UZ Brussel, Follicle Biology Unit FOBI, Jette- Brussels, Belgium
[3]University of New South Wales Sydney, School of Women's and Children's Health, Sydney, Australia
[4]The University of Adelaide, Robinson Research Institute, Adelaide, Australia

Study question: Does modulation of oxygen tension and culture medium volume during human IVM influence maturation efficiency and embryo development?

Summary answer: Reduction in oxygen tension (5%) and culture medium volume (1 Cumulus Oocyte Complex (COC)/20 µl) in a 30 h grouped culture IVM system significantly impaired blastocyst development.

What is known already: Low (5%) oxygen tension improves embryo development in vitro (Nastri et al., 2016). However, the optimal oxygen tension during IVM of human oocytes has not been established. Differential oxygen tension during IVM in mice induced differences in developmental potential (Banwell et al., 2007) and cumulus cell gene expression (Kind et al., 2015). Oocytes and cumulus cells in antral follicles have different oxygen requirements, with oocytes dependent on oxidative phosphorylation (Cinco et al. 2016). Dissolved oxygen available to the oocyte depends on both oxygen tension and IVM medium volume. Grouped IVM culture may have a beneficial effect on IVM outcome.

Study design, size, duration: A RCT on sibling oocytes was performed in 29 consecutive PCOS patients who had at least 11 immature oocytes retrieved after non-hCG triggered IVM. COC were randomly divided into either groups of 8-10 COC/500 µl in IVM medium at atmospheric oxygen tension (20% O_2; 'High O_2-IVM') or groups of 3-5 COC in 60-100 µl medium at 5% O_2 ('Low O_2-IVM' with a strict ratio of 1 COC/20 µl).

Participants/materials, setting, methods: IVM was performed in Origio IVM System: COC were washed in LAG medium and incubated for 30 h in IVM medium supplemented with 75 mIU/ml HP-hMG, 100 mIU/ml hCG and

10 mg/ml HSA in four-well dishes with 500 μl or macrodroplets of 60-100 μl under oil. IVM was performed in incubators containing 6% CO_2 at 37°C under either 20% O_2 or 5% O_2. After IVM and ICSI, embryos were cultured individually in 25 μl Cleav™ and Blast™ medium (Origio).

Main results and the role of chance: In total, 169 COC were randomly allocated to 'High O_2-IVM', 137 COC to 'Low O_2-IVM'. Using mixed-effects regression analysis (to account for the fact that multiple oocytes derived from the same patient), comparable maturation rates (49% vs 48%; p = 0.36), fertilization rates (73% vs 73%; p = 0.92) and embryo quality scores on day 3 (top quality: 40% vs 39%; good quality: 29% vs 29%; p = 0.9) were obtained in 'High O_2-IVM' vs 'Low O_2-IVM' respectively. For 14 patients, ≥4 good-quality embryos were available on day 3 and cultured to day 5/6. On day 5/6 a utilization rate (embryos of sufficient quality for transfer or cryopreservation per fertilized oocyte) of 44% was obtained in 'High O_2-IVM', 18% in 'Low O_2-IVM' (p = 0.002).

The combined reduction of oxygen tension and COC/volume ratio during the IVM phase only specifically affected blastocyst formation, with fewer top quality blastocysts and more arrested embryos after extended culture. This finding was unexpected considering good blastocyst development by others when culturing individual COC in 5% O2 during IVM (Walls et al., 2015). Although fewer good quality blastocysts were produced in our 'Low O2-IVM' system, clinical pregnancies were obtained in both 'Low O2-IVM' and 'High O2-IVM' culture conditions.

Limitations, reasons for caution: Since oxygen tension conditions and COC/volume ratio during IVM were investigated in parallel, we could not identify whether blastocyst development was impaired by oxygen tension, COC/volume ratio or both. The results are based on a small number of IVM cycles.

Wider implications of the findings: Every specific in vitro culture system, including human IVM, requires fine-tuning of physico-chemical parameters. Seemingly small adjustments in culture conditions can have profound, unexpected effects on embryonic development. Extended culture to day 5 provides important additional information on IVM-derived embryo development under differential IVM culture conditions.

Trial registration number: not applicable.

O-277   Liver X Receptors in granulosa cells regulate human oocyte meiosis resumption

A. Vega[1], S. Dollet[1], L. Janny[1,2], S. Vorilhon[1,2], S. Maqdasy[1], C. Bouche[2], S. Baron[1], F. Brugnon[1,2]

[1]Laboratoire GRED, CNRS 6293- INSERM U1103- Université Clermont Auvergne, Clermont-Ferrand, France
[2]CHU Clermont Ferrand- CHU Estaing Hospital, Laboratory of Developmental Biology and Reproduction- CECOS, Clermont-Ferrand, France

Study question: Do Liver X Receptors (LXRs) pathway in granulosa cells regulate the human oocyte meiosis resumption?

Summary answer: Our results show an increase of LXR activity in the activation of human oocyte meiosis resumption.

What is known already: Previous studies in animal model showed clearly that lipid homeostasis influences the oocyte meiosis. However, the signaling pathway is not clearly identified. Oxysterols are molecules derived from the cholesterol synthesis pathway. They are the ligands of the liver X receptors (LXRs). In mice deficient of LXR genes, the oocytes are unable to resume meiosis. In human, The LXR signaling pathway has never been investigated in this process.

Study design, size, duration: From 73 oocytes of 15 women (35 ± 3 years) with tubal infertility, Granulosa cells surrounding oocytes were isolated during in vitro fertilization (IVF) process and analyzed. The oocyte meiosis resumption was considered as positive (GC+) when two pronuclei and two polar bodies were observed at zygote stage and negative (GC-) when the oocyte remained blocked at metaphase II stage (at day 1). The embryos derived from CG+ oocytes were all top quality.

Participants/materials, setting, methods: The lipid accumulation in granulosa cells was assessed after oil red O staining. The expression levels of key enzymes of oxysterol synthesis, LXRs and their downstream genes were measured by qPCR.

Main results and the role of chance: Lipid accumulation, measured by oil red O staining, was higher in GC- (66 ± 4.9%) compared with CG+ (43 ± 17.8%; p = 0.02). We showed that the accumulations of HMGCoS, SQLE, LSS and Cyp51 (genes involved in oxysterols synthesis) were upregulated in GC+ versus GC- respectively at 102 ± 14.1, 60 ± 9.9, 56 ± 17 % and 48 ± 10.9% (p < 0.05). Although LXRs genes expression was not affected, we observed an increased level of some direct target genes such as LDLr (58 ± 16.2 %) involved in cholesterol uptake (p < 0,05).

Limitations, reasons for caution: These results should be confirmed by measurements of oxysterols levels in granulosa cells. In addition, LXRs protein levels and its target genes should be quantified by western blot and immunofluorescent experiments.

Wider implications of the findings: The analysis of LXR pathway could be used to detect in reliable way the oocytes with high potential of resumption meiosis in a IVF program. Moreover, these novel findings may help to better understand the physiopathology of oocyte meiosis failures.

Trial registration number: None.

O-278   The motility and number of mitochondria in the advanced age embryos

H.R. Lee[1], S.H. Hong[2], S.J. Lee[2], M. Kim[1], K.H. Choi[1], J.H. Lee[1,3]

[1]CHA fertility center- Seoul station, embryology, SEOUL, Korea- South
[2]Sahmyook University, Department of Animal biotechnology, Seoul, Korea- South
[3]CHA University, College of life science, Pochen, Korea- South

Study question: What is difference of mitochondria between advanced age embryo and young embryo?

Summary answer: The mitochondria movement dramatically decreases in the advanced age embryo.

What is known already: Mitochondrial functionality is important for oogenesis and embryo development. However, the motility of mitochondria has not yet been clearly identified for embryo development. Mitochondria are unique cellular organelles that have their own genome, the mitochondrial DNA (mtDNA). The mtDNA encodes proteins involved in oxidative phosphorylation and ATP synthesis. Therefore, it is important for maintaining life via modulating metabolic pathways. The specific mitochondrial localization and movement are important for their function and activity. Mitochondrial activity affects the quality of oocytes and embryos directly. Low-quality oocytes show mitochondrial dysfunction, such as altered mitochondrial morphology and decreased number of mitochondria.

Study design, size, duration: set-up of functional activation of mitochondria for advanced age female infertility model study. Sixty-head female mouse (30 weeks old) during1years study.

Participants/materials, setting, methods: All procedures for animal breeding and care were approved by the IACUC of Sahmyook University, Seoul, Republic of Korea. Superovulation was induced in 30-weeks-old female mice and in a 2~4weeks female mice as controls. We then performed the mitochondria analysis by PCR and image analysis in embryos with the mitotracker-RFP stained /tubulin-GFP injected embryo. Then we measured the mitochondria's moving speed in young and old mouse embryos by the ZESS 2016 program.

Main results and the role of chance: Young age embryos showed hyperactive motility of the mitochondria from one-cell to a blastocyst. However, advanced age embryos had no mitochondrial motility from all pre-implantation development. Specifically, young embryos presented one nm per one second of the speed ratio base on live imaging analysis. Mitochondria motility is important to profile for the functionality and the biogenesis support to cell behavior. The process for embryo development requires amount of energy from mitochondria at a specific location like the nuclear and the endoplasmic reticulum region. However, the loss in movement of the mitochondria means that it cannot support well-conducted biogenesis for specific regions for cellular processing. Therefore, it needs to improve mitochondrial functional activity by enhancing movement to specific localization. We need to further study for the enhancement of mitochondrial motility and the functional activity for the advanced age embryo.

Limitations, reasons for caution: This study is limited animal study for pre-clinical application.

Wider implications of the findings: The oocyte and embryo needs the functional activity of the mitochondria for high quality embryo. Our findings will probably contribute to finding ways to restore the function of mitochondria in advanced age embryos. Furthermore, it shows the possibility of overcoming infertility due to aging in humans.

Trial registration number: This is not a critical trial

[4]St Antonius hospital, Obstetrics and gynecology, Nieuwegein, The Netherlands
[5]Robinson Research Institute- University of Adelaide, School of Paediatrics and Reproductive Health, Adelaide, Australia
[6]Maastricht University Medical Centre, Obstetrics and gynecology, Maastricht, The Netherlands
[7]Maxima medical center, Obstetrics and gynecology, Veldhoven, The Netherlands

Study question: What is the diagnostic accuracy and acceptability of transvaginal hydrolaparoscopy (THL) compared to hysterosalpingography (HSG) as a primary tool to assess tubal patency?

Summary answer: THL and HSG are safe and well-tolerated. The number of women diagnosed with tubal pathology is comparable. THL gives more information about adhesions and endometriosis.

What is known already: Tubal pathology is found in 10-20% of infertile women. To assess tubal function in these women, various diagnostic tests are available, among which HSG has been around for over a century. THL is a relatively new technique, that allows direct visualisation of the pelvic cavity and tubes in an outpatient setting. Here, we compare THL and HSG as a first line tubal patency test in a randomised clinical trial (RCT).

Study design, size, duration: We performed a multicenter RCT (NTR3462) in 4 teaching hospitals in the Netherlands. We included subfertile women. The primary outcome of the trial was cumulative live birth rate at 24 months. In this abstract we present findings at THL and HSG, as well as complication rates and VAS scores for pain and acceptability. To exclude a difference in live birth rate larger than 6%, we needed to randomize 1,330 women (alpha .05, beta .80).

Participants/materials, setting, methods: Subfertile women scheduled for tubal patency testing were eligible. Women with a positive Chlamydia PCR, prior tubal testing or tubal surgery, retroverted uterus, masses/or cysts in the pouch of Douglas, or allergies to iodine or methylene blue were excluded. After written informed consent, women were randomized to THL or HSG. Pain and acceptability were measured on a visual analogue scale (VAS). Here, we compare the findings at THL and HSG.

Main results and the role of chance: Between May 2013 and October 2016, we allocated 152 women to THL and 151 to HSG, of whom 17 and 12 women conceived naturally before the scheduled procedure, respectively. In seven women allocated to THL (5%) the procedure was not possible, either due to preperitoneal placement of the trocar or due to pain, while in one women allocated to HSG the procedure was stopped due to pain (RR 6.9, 95% CI 0.87 to 56).

In women undergoing THL we found no abnormalities in 86%, endometriosis in 8%, adhesions in 4%, unilateral tubal occlusion in 6%, and bilateral tubal occlusion in 1% of women. In women undergoing HSG, we found no abnormalities in 90%, unilateral tubal occlusion in 8% and bilateral tubal occlusion in 2%. The risk of detecting an abnormality was 13.2% versus 10.1% (RR 1.3 95% CI 0.69 to 1.5).

In the THL group one woman had a bowel perforation which was handled conservatively, while two women had a bleeding of the posterior vaginal wall that needed stitching. In the HSG group one woman had a bleeding after the procedure. Pain scores (4.9 versus 5.4, p = 0.17) and acceptability scores (1.9 versus 2.3, p = 0.30) did not differ significantly.

Limitations, reasons for caution: Our original sample size was set at 1,330 women. Since attempts to fund the study were not successful, the original sample size could not be reached and the study was halted after 3 years and randomization of 303 women.

Wider implications of the findings: Both THL and HSG are in terms of safety and pain acceptable methods to test tubal patency. THL gives more information about endometriosis and adhesions than HSG, but the clinical implication of these findings is unclear.

Trial registration number: NTR3462.

O-280   Multivariate Meta-analysis is required for partially reported multiple endpoints and demonstrates the benefit of rh-LH supplementation on live birth for Poor Ovarian responders

P. Lehert[1], P. Humaidan[2], C. Alviggi[3]

[1]The University of Melbourne and Melbourne IVF, Faculty of Medicine- Psychiatry Department, East Melbourne VIC, Australia
[2]Fertilitetsklinikken- Skive, Department of Clinical Medicine -, Skive, Denmark
[3]University of Naples, Medicina della Riproduzione ed Endocrinologia Ginecologica, Naples, Italy

Study question: Compared with clinical or ongoing pregnancy, Live Birth is much less reported in trials. How to correct important biases and inconsistencies observed on the separate results of these endpoints?

Summary answer: Compared with separate meta-analysis of each endpoint, the multivariate meta-analysis model provides consistent estimates, better precision, and minimizes biases and paradoxical results.

What is known already: In ART, almost all the meta-analyses report results of multiple endpoints, although these endpoints were partially reported. When analyzing separately and independently each endpoint, results cannot be compared as there are based on different studies and number of studies. Necessitating a longer follow-up, live birth (LB) is the less reported endpoint, other measurements such as biochemical (BP), clinical (CP), On-going pregnancies (OP) being more often reported. Reporting independent analyses of these endpoints generates inconsistent results essentially caused by power difference, and because the correlation between these endpoints is not accounted for. No appropriate technique was used as yet.

Study design, size, duration: We illustrate this problem on the widely debated question of the benefit of LH-supplementation in ART cycles. We conducted a meta-analysis based on the largest possible selection of randomized controlled trials having compared LH supplementation added to FSH with FSH Alone. 54 RCTs (n = 7702, 36 and 18 studies on Poor(POR) and Normal (NOR) Ovarian responders). Pregnancy was partially reported by 26, 47, 16 and 8 studies for BP, CP, OP and LB endpoints, respectively.

Participants/materials, setting, methods: We compared the results obtained by separate and independent analyses with those found with a random multivariate model based on BP, CP, OP and LB, their sequential occurrence modeled following an ARMA hetero-scedastic autoregressive AR(1). Intent to treat analysis was only considered. The risk ratio RR (rh-LH+FSH/FSH) on POR compared with NOR constituted the main endpoint and was tested by using the binary moderator POR-NOR as fixed meta-regressor.

Main results and the role of chance: Strong correlations were found between the four endpoints and in particular between sequential endpoints confirming our autoregressive hypothesis. We compared the Risk Ratio RR (95%CI and Pvalue) between the univariate separate model and the multivariate model (table 1).

Table 1 Comparison of the results of the univariate separate analyses with the multivariate result for Biochemical (BP), clinical (CP) and ongoing (OP) pregnancies and Live birth (LB).

	Univariate				Multivariate			
	RR	95%CI		P	RR	95%CI		P
BP (22)	1.36	.58	2.19	.29	1.19	.81	1.73	.23
CP (39)	1.29	1.02	1.64	.003	1.27	1.03	1.59	.04
OP(13)	1.22	.78	2.05	.18	1.36	1.02	1.88	.03
LB (8)	1.68	.64	3.96	.21	1.41	1.06	2.07	.01

The precision of univariate estimates was poor, heterogeneous, and inconsistent among sequential endpoints: Univariate model found a strong although non-significant RR=1.68 for LB poorly consistent with a significant RR=1.29 for CP. In contrast, multivariate estimates and related p-values were more consistent and stable with respect to sensitivity analyses: A non significant effect is identified for the first pregnancy measurement (BP) followed by a continuous increase of the observed benefit until final endpoint (LB) characterized by a significant effect.

Limitations, reasons for caution: This never used approach in ART considerably improves the consistency of the results, however, results remain dependent of some hypothesis underlying the correlations between pregnancy measurements. The multivariate model is also more complex which may limit its use in clinical applications.

Wider implications of the findings: Life Birth constitutes the ultimate and paradoxically the less reported endpoint in controlled trials and caused important biases in previous meta-analyses. Multivariate meta-analysis based on the between-endpoint correlation provides consistent, unique and comparable estimates during the luteal phase, providing evidence of a significant benefit of rh-LH supplementation on live birth.

Trial registration number: not applicable.

O-281 Follicle developmental inhibition at the primordial stage without increasing apoptosis, by the combination of everolimus and verapamil: a preclinical randomized study

I. Kosmas[1], M. Pargianas[2], C. Kitsou[3], A. Dalkalitsis[4], S. Markoula[5], E. Kolibianakis[6], B. Tarlatzis[6], I. Georgiou[7]

[1]Ioannina State General Hospital G. Chatzikosta, Obstetrics and Gynecology, Ioannina, Greece
[2]Mpodosakeio General Hospital, Obstetrics and Gynecology, Ptolemaida, Greece
[3]Medical School University of Ioannina, Obstetrics and Gynecology - Genetics and IVF Unit, Ioannina, Greece
[4]Medical School University of Ioannina, Obstetrics and Gynecology, Ioannina, Greece
[5]Medical School- University of Ioannina, Genetics and IVF Unit, Ioannina, Greece
[6]Medical School- Aristotle University of Thessaloniki, Unit for Human Reproduction-1st Department of Obstetrics & Gynecology, Thessaloniki, Greece
[7]Medical School- University of Ioannina, Department of Obstetrics and Gynecology - Genetics and IVF Unit, Ioannina, Greece

Study question: The aim of this study was to test whether follicular stop and reactivation can be achieved and at what extend.

Summary answer: There is significant increase in the primordial follicles after the inhibitory effect of Everolimus plus verapamil.In parallel, atresia was reduced at the control levels.

What is known already: TSC/Mtor pathway manipulation has a profound effect in rapid follicular activation and Tsc1 and Tsc2 proteins play the major role in this over-activation (Adhikari et al 2009, 2010). Both Mtor complexes (Tsc1 /Raptor and Tsc2 /Rictor) will be inhibited alone or in combination, with Everolimus and Fisetin respectively. The combination of Everolimus plus Verapamil (an CYP3A inhibitor and everolimus enhancer) will be used, in order to lower the dose of everolimus and increase the effect. It is not known yet whether after follicular inhibition, activation could be achieved. Therefore, an effort to activate follicles afterwards, with FSH, will take place.

Study design, size, duration: 45 female immature Wistar rats were divided, after randomization, in five groups.All animals received the intervention from 9th week and for 8 weeks in total.Control group received 0.2 ml of intra-peritoneal saline. Next group received everolimus (1,5mgr/Kg daily). The third group received Fisetin (10 mg/kg daily).The fourth group received Everolimus (1,5mgr/Kg daily) plus Fisetin (10 mg/kg daily) every other day. Fifth group received Everolimus (0,75mgr/kg daily) plus (Verapamil 2,5mgr/kg every other day).

Participants/materials, setting, methods: Following to, left ovary of each animal was removed and primordial, primary, secondary, antral, atretic follicles and Corpora Lutea measured.After three weeks, animals received 35 IU FSH for 4 days and 35 IU of hCG on the 5th day. After that, right ovary examined for the same parameters. AMH, estradiol and progesterone measurements took place at the end of the first and second intervention.

Main results and the role of chance: Significant difference has been observed at the primordial stage of development (P=0, 0159) (33, 3 ± 15,6) at the Everolimus plus Verapamil group compared with Everolimus alone (28 ± 13,7) and the control group (25,2 ± 16,4). This group, had the less number of atretic follicles (12, 16 ± 6, 26) (P=0, 0001) followed by the control group (15, 66 ± 6, 68).After ovarian stimulation, no significant difference has been observed between the five groups for the primordial (P=0,214), primary (P=0,435) follicles and corpus lutem (P=0,201). From the other side, significant difference has been observed in the pre-antral follicles (P=0,022), antral follicles (P=0,0001), Graafian (secondary) follicles (P=0,044) and atretic follicles (P=0,0001). Especially in the atretic follicles, control and everolimus plus verapamil group showed the lowest number (7, 7 ± 2,1 and 18,7 ± 7,8) respectively.

Limitations, reasons for caution: A randomized study that assigns pharmaceutical interventions to all animal groups. Both ovaries serve as internal control for each animal. Both pathologists, performed the histological analysis were blinded for the intervention examined on each slide.

Wider implications of the findings: Patients that wish to withhold their fertility for a long time or patients that must undergo cytotoxic therapies should have the option of keeping their ovarian follicles in a dormant state. Such pharmaceutical schemes may have position in POF and fertility preservation.

Trial registration number: None.

O-282 Assessment of the reliability of the Bologna criteria in predicting ovarian response and live birth rates in subsequent IVF attempts: An external validity study

K. Yakin[1,2], O. Oktem[1,2], S. Yildiz Oguz[2], A. Isiklar[1], B. Balaban[1], B. Urman[1,2]

[1]American Hospital, Women's Health Center- Assisted Reproduction Unit, Istanbul, Turkey
[2]Koc University School Of Medicine, Department of obstetrics and gynecology- the division of reproductive endocrinology and infertility, Istanbul, Turkey

Study question: Are the Bologna criteria reliable in predicting ovarian response and live birth rate in subsequent IVF cycles?

Summary answer: The Bologna criteria based on age and oocyte yield in the first IVF cycle successfully predict ovarian response and clinical outcome in subsequent IVF attempts.

What is known already: The ESHRE Working Group on Poor Ovarian Response defined a set of variables to standardize the definition of poor responders. Several concerns have been raised regarding their prognostic significance and their external validity, which have not been vigorously tested.

Study design, size, duration: This retrospective study included 2047 women who had undergone two (n= 1370) and three (n = 667) consecutive IVF cycles between April 2010 and December 2013.

Participants/materials, setting, methods: We analyzed the ovarian response and live birth rates in subsequent IVF attempts of patients who were defined as poor responders according to the Bologna criteria based on a history of collection of ≤ 3 oocytes in two prior IVF cycles for women aged <40 years or; in a single cycle for women aged ≥40 years.

Main results and the role of chance: Age and ovarian response in the first IVF cycle were closely related with the prospects in the subsequent stimulation cycles. The Bologna criteria defined poor responders were more likely to show recurrent poor ovarian response both in the second (72.4% vs. 17% respectively, p < 0.0001; OR(95%CI): 0.07 (0.047-0.13)) and the third IVF cycle (85.4% vs. 18.5% respectively, p < 0.0001; OR(95%CI): 0.03 (0.02-0.07)) compared to women who did not fulfil the criteria. Likewise, Bologna criteria defined poor responders had significantly lower live birth rates in their 2nd (6.9% vs. 29.9% respectively, p < 0.0001; OR(95%CI): 5.76 (2.63-12.4)) and 3rd IVF attempts (11.5% vs. 18.5% respectively, p < 0.001; OR(95%CI): 2.81 (1.51-5.3)). In the 3rd IVF cycle, younger Bologna criteria defined poor responders had significantly lower live birth rate compared to younger optimal responders (13.5% vs 28.6% respectively, p < 0.05; OR(95%CI): 0.38 (0.17-0.87)) whereas live birth rate of older patients who were defined as poor responder according to the Bologna criteria was not any different from those who do not fulfill the criteria (9.1% vs. 13.7% respectively, p = 0.56; OR(95%CI): 0.63 (0.20-2.1)).

Limitations, reasons for caution: The retrospective design and inability to evaluate all of the Bologna criteria due to unavailability of ovarian reserve tests are the major limitations of the study.

Wider implications of the findings: The Bologna criteria are the best available tool for the definition of poor responders and should be adopted universally into clinical practice. Given the heterogeneity of the population covered by the criteria, their descriptive or prognostic validity might be increased by detailed description of patient characteristics in future clinical trials.

Trial registration number: None.

O-283   Low serum Progesterone the day of embryo transfer is associated with diminished ongoing pregnancy rate in artificial endometrial preparation cycles. A prospective study

E. Labarta, G. Mariani, N. Holtmann, P. Celada, J. Remohí, E. Bosch

Instituto Universitario IVI Valencia, Human Reproduction, Valencia, Spain

Study question: Is there a relationship between serum Progesterone (P) and endometrial volume the day of transfer with the ongoing pregnancy rate in artificial endometrium preparation cycles?

Summary answer: Patients with serum P <9.2 ng/ml the day of embryo transfer had significantly lower ongoing pregnancy rate than the rest of patients.

What is known already: A window of optimal serum P levels during the embryo implantation period (e.g. after 7 days of P administration) has been described in artificial endometrium preparation cycles. This interval of P concentration has been defined to be between 70 and 99 nmol/L (22.0-31.1 ng/mL), while serum P levels < 50 nmol/L (15.7 ng/mL) and > 100 nmol/L (31.4 ng/mL) are related to significantly lower pregnancy rates. Also, it has been shown that an endometrial volume <2.5 ml is related to a poorer outcome, and that a volume < 1 ml is associated with a null pregnancy rate.

Study design, size, duration: Prospective cohort study including 244 patients undergoing embryo transfer after an artificial endometrial preparation cycle with estradiol valerianate and vaginal micronized progesterone (400 mg/12 hours). The study was performed between February 22nd, 2016 and October 25th, 2016 (8 months). Sample size was calculated to detect a 20% difference (35-55%) between 2 groups according to serum P levels, in a two sided test with a statistical power of 80% and a confidence level of 95%.

Participants/materials, setting, methods: Patients undergoing their 1st/2nd oocyte donation cycle, aged <50, BMI <30 Kg/m^2, with a normal uterine cavity in 3D ultrasound, a triple layer endometrium >6.5 mm, and being transferred 1-2 good quality blastocysts; in a private infertility centre. Serum P determination and 3D ultrasound of the uterine cavity were performed the day of embryo transfer. Endometrial volume measurements were done using VOCAL system. Primary endpoint was ongoing pregnancy rate beyond the 12th week of pregnancy.

Main results and the role of chance: Of 244 patients recruited, 211 fulfilled all the inclusion/exclusion criteria. In 27 patients a Müllerian abnormality was diagnosed with the 3D ultrasound (19 T-shaped, 6 septate partial/complete, 1 hemiuterus and 1 bicorporeal uterus). In 6 cases there was a protocol violation.

The mean age of the included women was 41.3 ± 4.4; BMI: 22.3 ± 2.6; Endometrial thickness: 8.9 ± 1.7 mm. Serum P the day of embryo transfer was 12.7 ± 5.4 ng/mL. (p25: 9.2; p50:11.8; p75:15.8).

The ongoing pregnancy rates according to serum P levels were: <p25: 32.7%; p25-p50: 49.1%; p50-p75: 58.5%; >p75: 50.9%. Women with serum P <p25 (<9.2 ng/mL) had a significantly lower ongoing pregnancy rate compared to the rest of patients: 32.7% vs. 52.8%; p = 0.016; RR (95% CI): 0.62 (0.41-0.94).

Endometrial volume was 3.2 ± 1.3 ml. Serum P the day of embryo transfer did not correlate with the endometrial volume. Only women with a very low endometrial volume (n = 10), (<p5 = 1.4 ml) were associated with a poor ongoing pregnancy rate (22.2% vs. 48.3%).

A logistic regression analysis adjusting for all potential confounders showed a statistically significant relationship between serum P the day of embryo transfer and the likelihood of ongoing pregnancy (OR: 1.10: 95%CI: 1.02-1.19), p = 0.01.

Limitations, reasons for caution: Only women with a normal uterine cavity, an appropriate endometrial thickness and good quality blastocysts transfer were included. Extrapolation to an unselected population needs to be validated. The role of endometrial volume could not be fully defined, as only a few patients presented a very low volume.

Wider implications of the findings: The present study suggests that there is a minimal threshold of serum P values the day of embryo transfer that needs to be reached in artificial endometrial preparation cycles to optimize the outcome. An upper threshold could not be defined.

Trial registration number: The www.clinicaltrials.gov registration number is NCT02696694

O-284   Prospective comparison of vitrification in two different devices and slow freezing techniques for cryopreservation of small numbers of human spermatozoa

S. Mnallah[1], C. Herbemont[1], M. Grynberg[2], C. Sifer[1]

[1]*Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, Bondy, France*
[2]*Hôpital Jean verdier, Médecine de la Reproduction, Bondy, France*

Study question: When cryopreservation of small numbers of human spermatozoa is needed, is vitrification more efficient than the slow freezing (SF) method? If yes, in which device?

Summary answer: Sperm vitrification in the Cell Sleeper as device enables higher recovery and survival rates, while requiring less time than vitrification in stripper tip or SF.

What is known already: Sperm cryoconservation is widely used in combination with ART (Assisted Reproductive Technology) techniques. Currently, the reference method remains the conventional SF protocol. However, despite many years of research, significant numbers of spermatozoa still do not survive cryopreservation or cannot be retrieved because of the large volumes commonly contained in straws (30-500 µL). Hence, the SF procedure is not suitable for single spermatozoa. Vitrification, using different devices, is a novel technique that has been widely used for embryo storage, but it has not been applied yet to routine sperm cryopreservation.

Study design, size, duration: Prospective study, conducted between June and December 2016, in a university hospital. Two sperm vitrification devices, the ready-to use Cell Sleeper (Nipro, Japan) (n = 12) (group 1) and the stripper tip (Origio, Denmark) (n = 11) (group 2) were tested, and compared to the SF method, using a classical straw (CBS, France) (n = 14) (group 3). Selected sperm from ejaculates were obtained from the same fertile man after written consent.

Participants/materials, setting, methods: Ten motile spermatozoa per device were isolated with an ICSI pipette and frozen with Spermfreeze (Fertipro, Belgium). Vitrification devices were cooled in liquid nitrogen (LN2) vapor for 2 minutes, plunged and stored in LN2. For SF, a programmable freezer was used. Samples were warmed at room temperature for 1 minute. Frozen-thawed spermatozoa were searched within 20 minutes per device. Motility, recovery and survival rates, using the hypo-osmotic test if needed, and recovery time were compared.

Main results and the role of chance: Briefly, vitrification in Cell Sleeper (group 1) provided higher recovery rate, motility and survival rate (98.5%; 13,0%; 76.4%, respectively) than the SF procedure (group 3) (37.8% [p < 0.0001]; 2.3% [p = 0.05]; 28.7% [p < 0.001]). Only recovery rate was higher in group 1 than when using vitrification in stripper tip (group 2) (84.5% [p = 0.03]). Moreover, recovery time per spermatozoa was faster in group 1 (1.3 minute) than in both groups 2 and 3 (2.2 minutes and 6.6 minutes, respectively [p < 0.01]). Furthermore, statistical significance was also achieved when comparing the four above parameters between groups 2 and 3 concluding to the superiority of vitrification in stripper tip over SF method.

Limitations, reasons for caution: Sample size must be increased and further studies are required to assess if ART outcome could be improved using our vitrification procedures in case of severe male factor infertility.

Wider implications of the findings: We conclude that the vitrification of small numbers of human spermatozoa especially using Cell Sleeper device should be applied to patients with a limited sperm resource.

Trial registration number: Not applicable.

O-285 The outcomes of intracytoplasmic sperm injection (ICSI) using sperm of Japanese men with Y chromosome microdeletion

[15]Aino Hospital, male infertility, Osaka, Japan

Study question: To clarify the results of microdissection testicular sperm extraction (micro TESE) of Japanese with Y chromosome microdeletion and ICSI outcomes using sperm from those men

Summary answer: Sperm was retrieved from over 70% patients with azoospermia factor (AZF) c deletions, however, fertilization rate was fairly-low in ICSI using sperm from those men.

What is known already: Microdeletions of Y chromosome, especially in the AZF, are the most common known genetic cause involving spermatogenesis. Deletion frequencies are 2-10% reflecting the composition of study population. Although these deletions are associated with disruption of spermatogenesis, some previous reports revealed the tendency to retrieve spermatozoa by micro TESE from patients with AZFc deletion rather than azoospermic men without Y chromosome microdeletions. When compared with ICSI outcomes for oligozoospermic men without Y chromosome microdeletions or controls, some authors described that ICSI using sperm from men with those deletions resulted in significant low fertilization rates, and high percentage of aneuploidies of embryos.

Study design, size, duration: This study was retrospectively examined a total of 1934 azoospermic or severe oligozoospermic patinets who undergone

genetic testing for AZF deletions in 18 Japanese medical centers from April 2007 to June 2016.

Participants/materials, setting, methods: A total of 1934 azoospermic or sever oligozoospermic patinets were examined genetic testing for AZF deletions by Promega Y Chromosome AZF Analysis System (version 2.0). We firstly investigated each type of AZF deletions frequencies, and sperm retrieval rate (SRR) by micro TESE of the azoospermic patients with AZF deletions. In addition, we analyzed the ICSI results using testicular or ejaculatory sperm of men with AZF deletions.

Main results and the role of chance: AZF microdeletions were found in 189 cases (9.8%): 20 AZFa, 15 AZFb, 72 AZFc, 1 AZF a+b, 58 AZFb+c, and 23 AZFa+b+c. Of men with isolated AZFc deletion, spermatozoa were retrieved in 71.4% (30/42) by micro TESE. We could not find spermatozoa from patients with other AZF deletions.

Twenty-nine couples underwent ICSI using testicular sperm retrieved by micro-TESE, and 3 couples underwent ICSI using ejaculatory sperm. In totally, 572 metaphase 2 oocytes were retrieved by 62 oocyte retrieval cycles. Fertilization rate was 46.1% (220/477). We performed 62 embryo transfer (ET) cycles, mean replaced embryos were 1.39 per ET. Implantation rate per total transfer embryos were 19.8% (17/86), and clinical pregnancy rate per ET cycles were 27.4% (17/62). Abortion rate was 23.5% (4/17). Although we could not detect significant differences, the results of ICSI using ejaculatory sperm had better propensity in fertilization rate, implantation rate, and clinical pregnancy rate compared with the results of ICSI using testicular sperm (72.7% vs 44.1%, 50.0% vs 17.5%, 75.0% vs 24.1%, respectively).

Limitations, reasons for caution: The cohort size is relatively low and the study is still ongoing at our institution.

Wider implications of the findings: This is the first relatively large Japanese study to clarify the outcomes of ICSI using sperm of patients with AZFc deletions. The results of this study provide useful actual clinical information for Japanese infertile couples with AZF deletions concerning the adoption of the treatment.

Trial registration number: none.

O-286 Is thyroid hormone evaluation of clinical value in the work-up of males of infertile couples?

F. Lotti[1], E. Maseroli[1], N. Fralassi[1], S. Degl'Innocenti[1], L. Boni[2], E. Baldi[1], M. Maggi[1]

[1]Sexual Medicine and Andrology Unit, Experimental and Clinical Biomedical Sciences, Florence, Italy
[2]Istituto Toscano Tumori/AOU Careggi, Department of Oncology, Florence, Italy

Study question: Is thyroid hormone (TH) evaluation of clinical value in the work-up of males of infertile couples?

Summary answer: Our results suggest that TH evaluation is not mandatory in the work-up of male infertility.

What is known already: A few previous studies performed on a limited series of subjects reported a negative impact of hyper- and hypo-thyroidism on semen volume, sperm density, progressive motility and normal morphology. No previous study has systematically evaluated associations between TH variation, semen parameters and ultrasound characteristics of the male genital tract.

Study design, size, duration: Cross-sectional analysis of a consecutive series of 172 subjects seeking medical care for couple infertility from September 2010 to November 2014.

Participants/materials, setting, methods: Of the entire cohort,163 men (age 38.7 ± 7.6 years) free of genetic abnormalities were studied. All subjects underwent a complete andrological and physical examination, biochemical and hormonal assessment, scrotal and transrectal colour-Doppler ultrasound (CDUS) and semen analysis (including seminal interleukin 8 levels, sIL-8) evaluation within the same day.

Main results and the role of chance: Among the patients studied, 145 (88.9%) showed euthyroidism, 6 (3.7%) subclinical hyper- and 12 (7.4%) subclinical hypo-thyroidism. No subjects showed overt hyper- or hypo-thyroidism. In a multivariate model, after adjusting for confounders such as age, BMI, smoking habit, sexual abstinence, calculated free testosterone, prolactin and sIL-8

levels, we observed a positive association between fT3 levels, ejaculate volume and seminal fructose levels. When CDUS features were investigated, using the same multivariate model, we found positive associations between fT3 levels and seminal vesicles (SV) volume, both before and after ejaculation (adj. r = 0.354 and adj.r = 0.318, both p < 0.0001), as well as with SV emptying (Δ SV volume; adj.r = 0.346, p < 0.0001) and echo-texture inhomogeneity. In addition, negative associations between fT4 levels and epididymal body and tail diameters were found. No significant associations between TSH or TH levels and CDUS features of other organs of the male genital tract were found. Finally, when the features of subjects with euthyroidism, subclinical hypo- and hyperthyroidism were compared, no significant differences in seminal or hormonal parameters were found. Conversely, subjects with subclinical hyperthyroidism showed a higher difference between the SV longitudinal diameters measured before and after ejaculation as compared to that of subclinical hypothyroid men, even after adjusting for confounders (p < 0.007).

Limitations, reasons for caution: First, due to the cross-sectional nature of the study, neither a causality hypothesis nor mechanistic models can be inferred. In addition, present results are derived from patients consulting an Andrology Clinic for couple infertility, and could have different characteristics from the male general population.

Wider implications of the findings: Although no associations between TH and sperm parameters were observed, this is the first study supporting a positive effect of TH on SV size and a permissive role on the ejaculatory machinery. However, our results do not support a systematic evaluation of thyroid function in males of infertile couples.

Trial registration number: not applicable.

O-287   Seminal carnitine and DNA fragmentation index (DFI) impact progressive sperm motility in oligoasthenospermic men treated with metabolic and essential nutrients, with moderate accuracy

S. Micic[1], N. Lalic[1], D. Djordjevic[2], N. Bogavac-Stanojevic[3], A. Virmani[4], A. Agarwal[5]

[1]Uromedica Polyclinic, Andrology department, Belgrade, Serbia
[2]Clinical Center of Serbia, Urologic Clinic, Belgrade, Serbia
[3]Faculty of Pharmacy, Institute of Biochemistry, Belgrade, Serbia
[4]Sigma-tau-ml, Inovation-Research and Development at Sigma-tau Health Science, Utrecht, The Netherlands
[5]American Center for reproductive Medicine, Andrology Center, Cleveland, U.S.A.

Study question: The aim of the study was to correlate sperm motility with seminal carnitine level and DFI, after 3 and 6 months therapy of oligoasthenozoospermic men

Summary answer: Study showed significant improvement in progressive motility, lower DFI and high seminal carnitine level after 6 months therapy with metabolic and essential nutrients.(

What is known already: L –carnitine (L-C) plays an essential role in long – chain fatty acids oxidation, by providing a shuttle system for free fatty acids. It is taken up by the epididymal cells and realised into the epididymal lumen by difusion. Many nutrients and metabolic compounds affect mitochondrial function. Both L-C and acetyl-L-carnitine(ALC) also have important roles in the postgonadal maturation of spermatozoa

It has been showen that sperm DNA fragmentation is associated with male infertility. Intact sperm DNA is essential for fertilization and genetic trasmission. Abnormal fragmented sperm DNA can be found in 25% of men with abnormal semen parameters.

Study design, size, duration: This study was randomized, double blind, placebo controlled and it examined the effect of test formulation, Proxeed Plus, L-C 2 g and ALC 1 g, as well as vitamins and minerals, in men with oligo- or asthenoteratozoospermia. The protocol was 2 months "wash out" and 6 months therapy (125 patients) or placebo (50 patients) and 2 months follow up (T-2, T0, T+3,T+6). The control group (placebo) 50 patients were administered in a similar way with the placebo

Participants/materials, setting, methods: Men (age group 18 – 50 years), with idiopathic oligospermia, with history of difficulty conceiving > 12 months were randomized to receive treatment or placebo in a double blind protocol.

Compliance was assessed at visits. Analysis of ejaculate was done according to WHO 5th guideline. Progressive sperm motility (A+B grade of rapid, progressive) was done manually. DFI was evaluated by Halosperm kit (Halotech DNA, S.L,) and seminal carnitine by enzymatic UV test

Main results and the role of chance: In the treated group there was statistically significant difference, p = 0.004 by McNemar-Boweker test, in the values of progressive sperm motility in 3 different time periods: T0=28.50% (12.00 ± 38.00), T3 = 30.00% (12.00 ± 39.00) and T6=31.00% (20.00 ± 41.00). The seminal plasma carnitine at T0 was 700.50 μmol/L (625.50 ± 800.00) and at T6=751.50 μmol/L (671.10 ± 896.80), and this difference was significant (p = 0.014, by Wilcoxon signed-rank test). DFI (%): T0=38,50 (32,00-48,75), T3=35,50 (25,50-44,00) andT6=31,00 (25,00-41,00) (Friedman test, p < 0.001). The Spearman's rank-order correlation test showed that the increase of seminal carnitine level influenced the progressive sperm motility (R = 0.274; p = 0.023). Thus the correlation of seminal plasma carnitine and progressive sperm motility showed that in man, an increase of seminal carnitine of 7.7%, after 6 months therapy, would impact progressive sperm motility >10% with moderate accuracy (AUC=0.713). The other point, if DFI drops by more than 3%, after 6 months of therapy, it can be expected, with moderate accuracy, that men have sperm motility greater than 10% (AUC=0.793; p < 0.001). DF reduction (odds ratios = 1.106 with 95% confidence intervals) independently of elevation carnitine, increases the likelihood that sperm motility is >10%.

There was no significant difference in placebo group, in sperm motility, seminal carnitine level and DFI, between T0 and T6

Limitations, reasons for caution: no technical limitations

Wider implications of the findings: This study showed, after six months therapy, that increase of seminal carnitine positively impacted upon the patient progressive sperm motility. On the other hand, the percentage of change in DFI with moderate accuracy can be used in detection of men with better sperm motility after therapy.

Trial registration number: PXP-001-B

O-288   Sperm telomere length is not related to reproductive outcomes up to live birth when analyzed independently from female variables

M. Torra[1], M. Barragán[1], E. Bellu[1], A. Rodríguez[1], R. Oliva[2], R. Vassena[1]

[1]Clínica EUGIN, EUGIN, Barcelona, Spain
[2]Universidad de Barcelona, Barcelona, Spain

Study question: What is the relationship between sperm telomere length (STL) and embryo quality and reproductive outcomes, independently of the oocyte characteristics?

Summary answer: STL of normozoospermic men has no effect on embryo quality, pregnancy rates and live birth rates in IVF/ICSI.

What is known already: Telomeres are non-coding hexameric tandem repeats of DNA located at the ends of eukaryotic chromosomes. STL has been proposed as novel biomarker of sperm fitness as its variations are associated to altered sperm parameters, increased DNA fragmentation, poor embryo quality, and lower pregnancy rates. However, in all studies reported so far, each man's STL was necessarily linked to his female partner characteristics, and an assessment of STL independently form these variables was impossible. Studying STL in sperm donor samples, each used for multiple female patients, allows to isolate and determine the effect of STL alone on reproductive outcomes.

Study design, size, duration: Basic study including 36 sperm donor samples used each for at least 10 fresh ET cycles. Study outcomes were embryo quality, biochemical, clinical, and rates ongoing pregnancy, and live birth (LB). Genomic DNA was isolated from each sample and the relative amount of telomere DNA was determined by quantitative PCR (qPCR). STL was calculated as the ratio between telomere DNA and a single copy gene (RPLP0).

Participants/materials, setting, methods: Univariate analysis was used to evaluate the correlation between STL and embryo quality, and to determine STL differences between leading or not to LB. The probability of pregnancy and LB across STLs was evaluated by LOWESS regression. The effect of STL on

reproductive outcomes was analyzed by multilevel regression adjusted for sperm concentration and motility, woman age and BMI, number, stage and morphological score of transferred embryos, and addressing the hierarchical data structure.

Main results and the role of chance: The average STL was 4.23 (SD 3.9; range 2.6-9.6, arbitrary units). Reproductive outcomes were 48.6%, 38.4% and 31.3% for biochemical, clinical and ongoing pregnancy rates, respectively, while LB rate was 24.2%. LOWESS regression did not return relevant correlations between STL and reproductive outcomes. However, there was a significant correlation (Rho-spearman coefficient –0.069; p = 0.029) between STL and mean morphological embryo score, albeit the magnitude of the correlation is not clinically relevant. STL was not different between cycles ending or not in LB (Mann Whitney U-test p>0.05) and no significant effect of STL on the reproductive outcomes was found, with OR for each unit increase in STL of 0.98 (95%CI 0.87-1.1), 1.04 (95%CI 0.93-1.18), 1.03 (95%CI 0.91-1.17) and 1.04 (95%CI 0.93-1.18) for biochemical, clinical, ongoing pregnancy and LB, respectively. The multilevel analysis confirmed that the effect of STL on embryo morphological score, biochemical, clinical, ongoing pregnancy and LB was not significant (p>0.05).

Limitations, reasons for caution: Only normozoospermic men were included in this study, caution should be exerted when generalizing these results to non-normozoospermic men.

Wider implications of the findings: This is the largest study of STL to date, and the only one addressing STL independently from female variables. STL was not related to any of the reproductive outcomes analyzed and, regardless of its relationship to other sperm parameters, might be of little relevance as a predictor of ART success.

O-289　Feto-placental discrepancies in the analysis of products of conception in clinical miscarriages reveals that mosaicism is not restricted to trophoblast cells

S. Garcia_Herrero[1], J. Ferro[2], I. Campos-Galindo[3], E. Mateu[3], M. Milán[3], V. Peinado[3], L. Rodrigo[3], C. Rubio[3], C. Simón[2,3,4]

[1]IGENOMIX, PGS, Paterna Valencia, Spain
[2]Instituto Valenciano de Infertilidad IVI Valencia, Medical, Valencia, Spain
[3]Igenomix. Paterna- Valencia- SPAIN, PGS, Paterna Valencia, Spain
[4]Adjunct Clinical Professor- Department of Ob/Gyn- Stanford University School of Medicine- CA- USA Professor of Obstetrics & Gynecology. Adjunct Professor- Department of Ob/Gyn- Baylor College of Medicine- TX- USA, Ob/Gyn, Palo Alto, U.S.A.

Study question: In Feto-Placental Discrepancies (FPD), is mosaicism always confined to placenta (MCP)?

Summary answer: Hysteroembryoscopy allow us to detect accurately FPD (2%), with the presence of the aneuploid cell line in the fetal tissue.

What is known already: During pregnancy, feto-placental discrepancies (FPD) are due the presence of two different chromosomal cell content usually presenting the fetus a normal karyotype and the placenta an abnormal one that is known as mosaicism confined to placenta (MCP). Despite that MCP is described in normal pregnancies, chromosomal abnormality present in the placenta could lead to clinical miscarriage or even a poor perinatal outcome. Nevertheless, if these abnormalities were present in the fetus, the consequences for the perinatal outcome could be even worse, furthermore a prenatal non-invasive test could lead to false negatives.

Study design, size, duration: The objective of the study was to determine the incidence of FPD in products of conception (POC) from first trimester clinical miscarriages (n = 46) carefully sampled separately from embryo and

trophoblast guided by hysteroembryoscopy. We include 46 first trimester miscarriages in which two tissue types (fetal and extraembryonic) were successfully collected by hysteroembryoscopy from January 2014 to September 2016.

Participants/materials, setting, methods: POC specimens were collected in sterile tubes containing saline solution. Direct DNA extraction was performed without the previous cell culture required for classical cytogenetic studies. Chromosome status was determined by genetic molecular methods: genome hybridization (CGH array) (Illumina, San Diego, USA) or Next Generation sequencing (NGS) (Thermofisher, MA USA). STRs analysis of maternal and POC DNA were included to fully discard maternal cell contamination (AmpFlSTR Identifiler Plus (Applied Biosystems, CA, USA).

Main results and the role of chance: In 45 out of the 46 cases, the results were concordant between trophoblastic tissue and its corresponding embryonic tissue. Only in one case a discrepancy was reported, trophoblast show an euploid result (46,XX), and fetal sample was aneuploid (47,XY,+4), discarding maternal contamination. This case corresponded to a 30 years old patient with recurrent pregnancy loss that underwent preimplantation genetic screening by aCGH with transfer of an euploid blastocyst previously biopsied at day-3.

Limitations, reasons for caution: Limitations for the present study are the reduced number of samples included and the fact that not the whole tissue sample could be analyzed.

Wider implications of the findings: In FPD, abnormalities are frequently confined to placenta, but aneuploid cells can be also found exclusively in the fetus (2.1%). This FPD might be the reason for previous unknown PGS false negatives.

Trial registration number: CEIC201120007.

O-290　Clinical results following the transfer of mosaic blastocysts-impact of different aneuploidy types to ongoing implantation rates

S. Munné[1], J. Blazek[2], M. Large[2], P. Martin[3], E. Liu[4], N. Tarozzi[5], A. Baker[6], J. Zhang[6], S. Maxwell[7], J. Grifo[7], D. Wells[8], E. Fragouli[8]

[8]Reprogenetics UK, Research, Oxford, United Kingdom

Study question: Does the type of mitotic chromosome abnormality present in a trophectoderm (TE) biopsy affect the implantation potential of mosaic blastocysts?

Summary answer: Complex mosaics had lower implantation rates, but % of abnormality, monosomy vs. trisomy, full or segmental chromosome mosaicism had no significant effect on pregnancy rates.

What is known already: Next Generation Sequencing (NGS) can detect mosaicism, and approximately 15-20% of blastocysts are then classified as such. Mosaic blastocysts miscarry more and implant less than euploid blastocysts, resulting to lower ongoing implantation rates. However, some mosaic blastocysts can become normal live births. It is therefore paramount to determine which mosaic embryos have a higher chance to reach term. Recent guidelines recommend that in the absence of euploid embryos to prioritize replacing mosaic ones with low % of abnormal cells in the TE biopsy, monosomies over trisomies, and certain aneuploidies over others. However, there is little evidence to support this position.

Study design, size, duration: Retrospective study comparing concurrent PGS cycles during which either mosaic (n = 143) or euploid embryos (n = 1045) were replaced in four fertility centers. Implantation, miscarriage rates and ongoing implantation rates were compared between euploid and mosaic blastocysts, and among different mosaic subgroups. These included: presence of 20-40% and >40% mosaicism, with 1, 2 or 3 chromosomes affected, monosomy, trisomy, complex or segmental mosaics, and mosaics involving large (1-10, X) or small chromosomes (11-22, Y).

Participants/materials, setting, methods: Blastocysts from PGS cycles were biopsied and send to three PGD Laboratories to be processed by NGS

using the same protocol and equipment (MiSeq, Illumina). Embryos were classified as mosaic if they had the equivalent of between 20-80% abnormal cells. This was calculated from mixing experiments using cell lines (euploid: trisomies X, 13, 18, or 21) in 20% increments. All euploid and mosaic embryos were replaced after thawing, mostly as SETs.

Main results and the role of chance: Of the four centers, two had significant differences in ongoing implantation rates (OIR) between mosaic and euploid transfers. However, these differences or lack of them were attributed to the different composition of sub-groups of mosaics replaced per center, with one of them replacing only <40% mosaic embryos. Overall, implantation rates were higher (70% vs 53%, p < 0.001), miscarriage rates lower (10% vs 25%, p < 0.001) and OIR higher (63% vs 40%, p < 0.001) after euploid embryo transfers. Regarding sub-types of mosaics, those involving 3 or more chromosomes (Complex mosaics) had a 10% OIR compared to the rest of the group (45%, p < 0.005). There was a tendency for mosaics with many abnormal cells (40-80% in the TE sample) to have lower OIR than those with <40% (22% vs 56%, p < 0.06) but few 40-80% embryos were replaced. There was no difference between mosaic monosomy and mosaic trisomy outcomes (OIR of 47% vs. 55%), or between entire chromosome mosaicism or segmental mosaicism (OIR of 50% vs. 41%). Large chromosomes (1-10, X) implanted equally well with smaller ones (11-22, Y) (45% vs. 41%), but with significantly more segmental mosaic abnormalities occurring in larger than smaller chromosomes (47 vs. 13, p < 0.001).

Limitations, reasons for caution: Different fertility centers replaced different types of mosaic embryos. Overall few mosaic blastocysts with 40-80% abnormal cells in the TE sample were replaced precluding finding differences with those with <40% abnormal cells. A randomized controlled trial (RCT) would be impractical, but the current study is nonetheless retrospective in nature.

Wider implications of the findings: We concluded that complex mosaic blastocysts have lower OIR than other mosaics, and hypothesize that those with 40-80% abnormal cells in the TE sample also will. However, mosaic monosomies perform as well as mosaic trisomies and mosaic segmental aneuploidies. Guidelines should therefore be revised accordingly.

Trial registration number: Not Applicable.

O-291 Comparative analysis between endometrial stromal proteomes of repeated implantation failure (RIF), recurrent pregnancy loss (RPL) and normal fertile (NF) women

L. Dhaenens[1], S. Lierman[2], D. Deforce[3], K. Tilleman[2], P. De Sutter[2]

[1]Ghent University Hospital, Ghent Fertility And Stem cell Team G-FAST- Dept. for Reproductive Medicine, Gent, Belgium
[2]Ghent University Hospital, Ghent Fertility And Stem cell Team G-FAST- Dept. for Reproductive Medicine, Ghent, Belgium
[3]Ghent University, Laboratory for Pharmaceutical Biotechnology- Faculty of Pharmaceutical Sciences, Ghent, Belgium

Study question: Are there any proteomic differences between endometrial stromal cells of RIF, RPL and NF women, and is there differential protein expression upon decidualization?

Summary answer: The main proteomic difference was observed in decidualized stromal cells of RPL, where serotransferrin was expressed 1.5-fold higher than in decidualized stromal cells of NF.

What is known already: A successful pregnancy requires the endometrium to obtain structural and functional competence during the midluteal phase. Failure of the endometrium to express this receptive phenotype is thought to be a major cause of RIF, and is also considered to be linked to RPL. Insight in the biological mechanisms underlying this receptive phenotype is crucial if we wish to improve embryo implantation. While a few studies have attempted to profile the endometrial proteome, current innovative high-throughput mass spectrometry approaches allow the analysis of a substantially higher number of proteins, not only predominantly high abundant proteins (Altmäe S et al., 2014).

Study design, size, duration: We performed an exploratory study investigating the proteome of *in vitro* cultured endometrial stromal cells of in total 11 women (included in the period from March 2014 until May 2016). The aim was

to compare the proteome between women with repeated implantation failure (RIF; n = 4), women with recurrent pregnancy loss (RPL; n = 3) and normal fertile women (NF; n = 4). Moreover, the differentially expressed proteins (DEPs) upon decidualization were also studied between these groups.

Participants/materials, setting, methods: Endometrial biopsies were processed for primary cultures of endometrial stromal cells and were collected at day 0 or after 5 days of decidualization. Total proteins were extracted from cell lysates using phenol/ethanol extraction, trypsin digested and analyzed by label-free quantitative High Definition Mass Spectrometry (HDMSE) using a nanoscale UPLC system coupled to a Synapt G2-Si mass spectrometer. Data analysis was performed using ANOVA (p < 0.05) in Progenesis QI, and SAM (p < 0.05; FDR 10%) in R.

Main results and the role of chance: A total of 1424 proteins were identified across all samples. For the RIF group 127 DEPs were upregulated and 138 DEPs were downregulated in the decidualized versus the non-decidualized condition, in the RPL group 39 DEPs were upregulated and 42 DEPs were downregulated and in the NF group 183 and 134 DEPs respectively (p < 0.05). SAM analysis comparing ratios of expression of decidualized over non-decidualized samples, revealed 6 DEPs when comparing the different groups (FDR 10%, p < 0.05): DUX4L2, CNPY4, PDE7A, CTSK, PCBP2 and PSMD4. Comparison of expression profiles of RPL samples versus NF samples in the non-decidualized condition showed no DEPs (FDR 92%). But comparison of expression profiles of RPL samples versus NF samples in the decidualized condition revealed TF to be differentially expressed (p < 0.001; FDR 3%). However, comparing expression profiles of RIF samples versus NF samples in the non-decidualized, as well as in the decidualized condition did not yield statistically significant DEPs (FDR 50% and 61% resp.).Comparison of the expression profiles in the non-decidualized or the decidualized condition between these three groups of patients could in principle identify proteins that predict differences in clinical outcome. However, this SAM analysis did not yield statistically significant DEPs (FDR=89%).

Limitations, reasons for caution: This was an exploratory study using a label free high throughput proteomics platform, ona limited number of samples. Furthermore, the proteomics data need to be validated.

Wider implications of the findings: With this innovative label-free quantitative HDMSE study, a total of 1424 proteins were identified and quantified, presenting an overview of the endometrial stromal proteome of women with RIF, RPL and NF women. These results provide a window into the mechanisms of endometrial receptivity and possible mechanisms of its impairment.

Trial registration number: Ethical approval was obtained from the Ghent University Hospital Institutional Review Board under reference EC2013/887.

O-292 Cytoskeleton and exosome trafficking proteins of epithelial endometrial cells during secretory phase interact with trophoblast proteins

A. Reyes Palomares[1], A. Castillo-Dominguez[2], A. Reyes-Engel[3], A. Reyes-Palomares[4]

[1]Instituto de Fertilidad Clinica Rincon, Reproduction Unit, Málaga, Spain
[2]Instituto de Fertilidad Clínica Rincon, Reproduction Unit, Málaga, Spain
[3]University of Málaga, Biochemistry- Molecular Biology and Inmunology, Malaga, Spain
[4]European Molecular Biology Laboratory EMBL Heidelberg, SCB Unit, Heidelberg, Germany

Study question: Which proteins and molecular mechanisms are involved in epithelial endometrial and trophoblastic cells crosstalk during the secretory phase?

Summary answer: Extracellular proteins of epithelial endometrial cells related to cytoskeleton organization and exosome trafficking potentially interact with trophoblast during implantation.

What is known already: Endometrium is receptive for blastocyst during a limited period within mid-secretory phase coinciding with the maximal differentiation state of epithelial endometrial cells (EECs). In this phase a complex and not well-understood crosstalk between EECs and trophoblast cells (TCs) is established for initiating embryo implantation. Recent studies provided the EECs proteome during secretory phase (Hood et al 2015) and TCs

transcriptome derived from blastocysts (Yan et al 2013) that enable the study of their putative and functional protein interactions. The identification and characterization of these biomolecular interactions will provide new insights into cellular mechanism during embryo implantation.

Study design, size, duration: Here we show an integrative approach to study and characterize the biomolecular interactions between expressed genes in EECs and TCs respectively. This analysis was carried out using network methods on the human interactome (Rolland et al. 2014) in combination with 1.216 proteins from EECs mass spectrometry proteomic data during secretory phase (Hood et al 2015) and 14.230 transcripts from TCs (RNAseq, Yan et al 2013).

Participants/materials, setting, methods: Combined network approaches were used to characterize the resulting subnetwork of the human interactome based on subsets of genes expressed in TCs and EECs. Different biocomputational tools were used for data integration and network building (Bioconductor) and also for network representation and data curation (Cytoscape). The resulting cluster of genes from EECs physically interacting to TCs genes were used for functional enrichment analysis (GProfiler) and for detecting cellular mechanisms overrepresented during the early embryo-maternal interaction.

Main results and the role of chance: A Protein-Protein Interaction (PPI) network was built based on the direct interactions between EECs and TCs genes. The resulting subnetwork –which contains a total of 91 and 33 genes of TCs and EECs respectively– represents the core interactions between both cell types based on putative direct PPIs. Subsequent functional analysis of resulting clusters extracted from the curated network revealed an overrepresentation of biological processes such as; cytoskeleton organization (13 genes), Fructose metabolism (3 genes) and Intermediate filament organization (3 genes). We also found proteins of different cellular components related to extracellular regions such as exosomes that involved (17 genes), cytoskeleton intermediate filament (7 genes) and the supramolecular complex fibers (12 genes).

The network analysis showed two EECs proteins KRT13 and KRT15 that are part of the cytoskeleton and were connected with a high number of genes of TCs, 28 and 45 respectively. Other genes related to cytoskeleton organization were found moderately interconnected in the subnetwork such as GFAP (9 connections), KRT6A (7), EMD (7), PPL(6), KRT5 and DES (1).

Limitations, reasons for caution: The present study is based on published data and represents an approach to interrogate features of the interactome between expressed EECs proteins and TCs genes. The absence of a functionally validated protein representation of TCs could lead to decrease accuracy of assumptions compared with validated *in vivo* PPIs

Wider implications of the findings: EECs proteins that potentially interact with TCs have been revealed and put light over specific biological process during implantation. Our findings suggest a representative role of cytoskeleton and intermediate filament organization as well as exosome in the extracellular region, where could have a direct contact with the implanting blastocyst.

O-293   Does application of auto-cross linker hyaluronic acid in women following D&;C for miscarriage with at least one D&C in history improve reproductive outcome?

A. Hooker[1,2], **R. Leeuw de**[2], **H. Brolmann**[2], **J. Huirne**[2]

[1]*Zaans Medical Center ZMC, Department of Obstetrics and Gynaecology, ZAANDAM, The Netherlands*
[2]*VU University Medical Center, Department of Obstetrics and Gynaecology, Amsterdam, The Netherlands*

Study question: Does intrauterine application of auto-crosslinked hyaluronic acid (ACP) gel following dilatation and curettage (D&C) for miscarriage, in women with at least one previous D&C in history improve reproductive performance?

Summary answer: Application of ACP gel following D&C for miscarriage in women with at least one previous D&C seems to have a favourable effect on reproductive performance.

What is known already: IUAs are reported in 19% of women after miscarriage; women with more than one D&C had statistical significant more IUAs

compared to women with one D&C, OR 2.05. IUAs is asocciated with menstrual disturbances, cyclis pain and infertiliy. In the Prevention of Adhesion Post Abortion (PAPA-study), intrauterine application of ACP gel following D&C for miscarriage in women with at least one previous D&C significantly reduced the incidence and severity of IUAs. Athough, the process of adhesion formation is not completely eliminated. It remains unclear if application of ACP gel improves fertility and reproductive performance.

Study design, size, duration: The present prospective, non-interventional long-term follow-up study was conducted in the Netherlands. 149 women with a (incomplete) miscarriage of less than 14 weeks with at least one D&Cin history were preoperatively randomised to D&C plus ACP gel (intervention group) or D&C alone (control group) in the PAPA-study. The participants received questionnaires three, six and twelve months after the D&C-procedure. The aim of the current study was to evaluate reproductive performance after the D&C-procedure

Participants/materials, setting, methods: All women who participated in the PAPA-study were eligible to participate. Questionnaires were send to 149 women, 77 women assigned to the intervention group and 72 to the control group, three, six and twelve months after the D&C-procedure, The questionnaires consisted of questions concerning demographics, complication, treatment received, menstrual pattern, contraceptive use, conception and reproductive performance. In women willingly to conceive, conception, miscarriage and ongoing pregnancy rates were assessed.

Main results and the role of chance: Of the 149 women elligible to participate, six women were lost to follow-up after three months and nine women after six and twelve months. The overall response rate for the questionnaires was 96% at three months and 94% at six and twelve months. The response rate in the intervention group was 94.8% after three, six and twelve months and respectively 97.2%, 93.1% and 93.1% after three, six and twelve months in the control group, there were no diference between the groups. In both groups 62 women attempted to conceive. After twelve months 44 women (71%) conceived in the intervention group compared to 40 women (64.5%) in the control group (Fisher exact test, p = 0.56). One pregnancy was terminated on social indication in the control group on social grounds and in the intervention group a woman had a extra uterine pregnancy, requiring surgical management.The cumulative miscarriage rate in the intervention group was 14.5% compared to 22.5% in the control group (Fisher exact test, p = 0.79). The cumulative ongoing pregnancy rates were respectively 71.0% and 64.5% (Fisher exact test, p = 0.79).

Limitations, reasons for caution: The sample size was of the current follow-up study is small and was not powered for reprodcutive outcomes. The result are based of the ansers provided by the participants, making it not possible to drawn solid conclusions. It remains unclear whether known and unknwon factors could have influenced the results.

Wider implications of the findings: Application of ACP gel following D&C for miscarriage reduces the incidence and severity of IUAs in women with at least one D&C in history. Prevention of IUAs is essential because of the association between IUAs and complications while application of ACP gel seems to improve reproductive performance.

Trial registration number: NTR3120 (Dutch Clinical Trail Registry).

O-294   Personalised scheduling of embryo transfer at the moment of highest endometrial receptivity according to ER Map® test significantly improves clinical outcomes

J. Sarasa[1], **J. Aizpurua**[2], **I. Jurado**[1], **B. Rodriguez-Estrada**[1], **M.C. Garcia-Poyo**[1], **A.B. Climent**[3], **P. Martínez-Ortiz**[3], **M. Enciso**[1]

[1]*iGLS, Genetics, Alicante, Spain*
[2]*IVF Spain, Reproductive Medicine, Alicante, Spain*
[3]*IVF Spain, Statistics, Alicante, Spain*

Study question: Does identifying the window of implantation using the molecular tool ER Map® improve ART outcomes on patients with previous IVF failed cycles?

Summary answer: The use of ER Map® test for endometrial receptivity evaluation and personalised scheduling of embryo transfer during the moment of highest receptivity improves ART outcomes.

What is known already: The endometrium reaches a receptive status for embryonic implantation around day 19-21 of the menstrual cycle. During this period, known as the window of implantation (WOI), the endometrium shows a specific gene expression profile suitable for endometrial function evaluation. ER Map® is a molecular diagnostic tool able to accurately predict endometrial receptivity status by analysing this gene expression profile on an endometrial biopsy by high-throughput RT-qPCR. In this study the experience of the application of ER Map® for WOI identification and personalised scheduling of embryo transfer is studied for the first time.

Study design, size, duration: This is a retrospective study comparing pregnancy rates of patients with and without displaced WOI when embryo transfer was scheduled on the moment of highest endometrial receptivity (WOI timeframe) as recommended by ER Map® (group A), or according to standard endometrial evaluation and deviating more than 12 h from ER Map® recommendation (group B). ER Map® clinical results comparison was performed on 204 couples undergoing egg donation treatment between March and November 2016.

Participants/materials, setting, methods: Women with 2 or more previously failed IVF cycles were included in the study. Endometrial biopsy samples were obtained in an HRT cycle at $P_4+5.5$. Samples were classified by ER Map® into 'Receptive", 'Pre-receptive' or 'Post-receptive". In cases where a WOI displacement was detected, a second biopsy to confirm the displacement and to schedule embryo transfer on the moment of highest endometrial receptivity was performed. Once the WOI was confirmed, embryo transfer was recommended accordingly.

Main results and the role of chance: Preliminary results indicate that a total of 57 out of 204 patients (27.95%) with previous failed cycles were found to have a displaced WOI. Within this group of patients, a significantly higher pregnancy rate was achieved when embryo transfer was scheduled according to ER Map® prediction compared to transfers that followed traditional endometrial evaluation methods and deviated more than 12 h from ER Map® recommendation (75.51% vs 33.33%, X^2 Test with Yates' correction p < 0.01). More than double pregnancy rates were achieved when these patients' WOI displacement is identified and managed adequately.

No difference in pregnancy rates was observed in patients whose WOI was not displaced (i.e. patients whose endometria were classified as 'Receptive" at $P_4+5.5$) when embryo transfer schedule was guided by either ER Map® or traditional evaluation methods (73.20% vs 70.00%). No positive nor negative effect of the application of ER Map® was observed on these patients. The effectiveness of ER Map® strategy depends on patient endometrial receptivity diagnosis.

Limitations, reasons for caution: The retrospective and non-randomised design of the study may be a reason for caution. A wider spectrum of infertility conditions and patient characteristics is desirable to define more precisely the group of patients that could potentially benefit from the assessment of endometrial receptivity and personalised embryo transfer using ER Map®.

Wider implications of the findings: The application of ER Map® as a routine tool for the identification of cases of WOI displacement and personalised embryo transfer scheduling is an effective strategy for improving ART outcomes and achieving pregnancies on challenging repeated IVF failure cases.

Trial registration number: Not applicable.

O-295   Endometrial preparation: Impact of estrogen duration of administration before frozen-thawed blastocyst transfer on live birth rate

F. Kefelian[1], P. Santulli[1], M. Bourdon[1], L. Vienet-Legue[1], C. Maignien[1], V. Gayet[1], K. Pocate-Cheriet[2], L. Marcellin[1], J. Gonnot[1], C. Cervantes[1], V. Blanchet[1], C. Chapron[1]

[1]Université Paris Descartes- Faculté de Médecine- Assistance Publique—Hôpitaux de Paris AP- HP, Service de Gynécologie Obstétrique II and Reproductive Médicine Professor Chapron, Paris, France

[2]Université Paris Descartes- Faculté de Médecine- Assistance Publique – Hôpitaux de Paris AP- HP, Service d'Histologie-Embryologie-Biologie de la Reproduction, Paris, France

Study question: To investigate the impact of estrogen (E2) duration of administration before frozen –thawed blastocysts transfer on life birth rate.

Summary answer: Live birth rate significantly decreases as estrogen duration of administration increases before frozen-thawed blastocyst transfer.

What is known already: Different cycle regimens for endometrial preparation are used prior to frozen embryo transfer. Currently, one effective method is the hormonal replacement therapy with a sequential regimen with estrogen (E2) and progesterone, which aims to mimic the endocrine exposure of the endometrium in the normal cycle. There nonetheless remains a lack of knowledge concerning the optimal duration of exogenous E2 administration before transfer.

Study design, size, duration: This cohort study was conducted in a tertiary care university hospital between 01/01/2012 and 31/12/2015. Main inclusion criteria's were having a single frozen-thawed blastocyst transfer with an artificial endometrial preparation using exogenous estrogen (E2).

Participants/materials, setting, methods: A total of 1377 frozen – thawed blastocysts transfer were allocated to 4 groups according to the duration of E2 administration: ≤ 21days (Group A, n = 330), 22-28 days (Group B, n = 665), 29-35 days (Group C, n= 289) and 36-48 days (Group D, n= 93). The main outcome measured was the live birth rate following frozen – thawed blastocysts transfer. Statistical analysis were conducted using univariate and multivariate logistic regression models.

Main results and the role of chance: Live birth rates significantly decrease with the increase of E2 duration before frozen –thawed blastocysts transfer (group A: n= 98 (29.70%), OR 1; Group B: n= 185 (27.82%), OR 0.91 CI95% 0.68-1.22; Group C: n= 63 (21.80%), OR 0.66 CI95% 0.46-0.95 and Group D: n = 16 (17.20%), OR 0.49 IC95% 0.27-0.89). In contrast, early pregnancy loss rate significantly increase with the increase of E2 duration before frozen – thawed blastocysts transfer (group A: n= 41(28.47%), OR 1; Group B: n= 89 (31.79%), OR 1.17 CI95% 0.75-1.82; Group C: n = 35 (34.31%), OR 1.31 CI95% 0.76-2.27 and Group D: n= 17(48.57%), OR 2.37 IC95% 1.12-5.05).

Obstetrical and neonatal outcomes were not significantly different among groups. After multivariate logistic regression, E2 duration of administration longer than 28 days before frozen-thawed blastocyst transfer was found to be an independent predictive factor of life birth rate (29-35 days versus ≤21days: OR 0.68 95%CI 0.460-0.989; 36-48 days versus ≤21days: OR 0.51 95%CI 0.269-0.953).

Limitations, reasons for caution: One limitation is linked to the observational design of this study: randomized clinical trials are needed to confirm these results.

Wider implications of the findings: In order to give patients the best chance to obtain a live birth after frozen –thawed blastocysts transfer, it seems important to limit estradiol duration of administration before ET. This study brings new insight to endometrial preparation using hormonal replacement therapy before frozen blastocysts transfer.

Trial registration number: NA.

O-296   Antioxidant Gene Expression of Peroxiredoxin (PRDX) decreases in granulose cells from oocytes of young women with low ovarian reserve

L. Ortega López[1], S. Cortés Gallego[1], L. Rancan[2], E.M. Vara Ameigeiras[2], P. Lopez Domínguez[1], J. Fernández Tresguerres[3], P. Caballero Peregrín[4], R. Núñez Calonge[1]

[1]Clínica Tambre, Embriology Lab, Madrid, Spain
[2]Universidad complutense de Madrid, Department of Biochemistry and Molecular Biology, Madrid, Spain
[3]Universidad complutense de Madrid, Department of phisiology, Madrid, Spain
[4]Clínica Tambre, Clinician, Madrid, Spain

Study question: Is gene expression of antioxidant peroxiredoxin altered in cumulus (CCs) and granulose cells (GCs) from young women with reduced ovarian reserve compared with oocyte donors?

Summary answer: Our results show that the expression of PRDXs was higher in donors' GCs suggesting that these are important oxidative stress regulators in low responder patients.

What is known already: Oxidative stress has been implicated in various aspects of female infertility. Our previous studies have shown that the initiation of apoptotic cell death in cumulus and granulosa cells is initiated by increased reactive oxygen species.

Peroxiredoxin (PRDX), a family of peroxidases, are associated with various biological processes such as protection against DNA damage, oxidative stress and cell apoptosis. On the other side, the upregulation of some PRDX in cells and tissues by various stress agents is considered an important biological response to prevent oxidative damages. Nevertheless, little attention has been given to the role of PRDX on female infertility.

Study design, size, duration: This observational, prospective study compared the mRNA expression of PRDX1, PRDX2, PRDX3, PRDX4, PRDX5, PRDX6 and caspase 3 in 56 oocyte-cumulus and 62 oocyte-granulose complexes retrieved from 4 healthy fertile oocyte donors <35 years old and 4 patients <35 years old who had a low response ($\leq$ 5 oocytes retrieved) after gonadotropic stimulation from July to December 2016. Only donors with at least a previous cycle with pregnancy were included.

Participants/materials, setting, methods: All patients were stimulated with the same protocol (FSHr and triggering with GnRH analogues). GCs and CCs were collected from each patient and immediately fresh-frozen. mRNA was extracted using commercial kits. mRNA expression of PRDXs genes and endogenous controls was measured by qRT-PCR using TaqMan probes. Relative changes in gene expression were calculated using the $2\text{-}\Delta\Delta CT$ method. No parametric tests were used to identify any significant difference between groups. Statistical significance was set at $p < 0.05$.

Main results and the role of chance: We found that PRDX2, PRDX3, PRDX4, PRDX5 and PRDX6 are expressed in CGs and CCs. Results obtained from comparative RT-PCR analysis revealed that the mean relative levels of mRNA coding for PRDX2, PRDX3, PRDX4, PRDX5 and PRDX6 were significantly decreased in GCs from young women with low response compared with oocyte donors: (PRDX2 p= 0.03; PRDX3 p= 0.022; PRDX4 p= 0.014; PRDX5 p= 0.02; PRDX6 p= 0.014). No significant differences were found in the levels of mRNA coding for PRDX2, PRDX3, PRDX4, PRDX5 and PRDX6 in CCs from young women with low response compared with oocyte donors.

The levels of caspase 3 mRNA in GCs were also significantly increased in patients compared with donors (p<0,001) whereas there were not differences in CCs between groups.

Limitations, reasons for caution: The main limitation of our study is the small number of replicates. The results observed in this study should be confirmed on a larger sample number.

Wider implications of the findings: These results suggest that cellular antioxidant defense capabilities are diminished during low ovarian response, leading to an increase in oxidative damage in the ovary in a similar way as in age-related oxidative damage. These findings could open up to new therapeutic strategies for the treatment of low ovarian reserve.

Trial registration number: 2.

O-297 Zika virus infects the female reproductive tract of mice via subcutaneous route

D. Broughton[1], E. Caine[2], V. Salazar[2], S. Scheaffer[3], J. Govero[2], T. Owuor[3], M. Diamond[2], K. Moley[3]

[1]St. Louis, U.S.A.,
[2]Washington University in St. Louis, Medicine, Saint Louis, U.S.A.
[3]Washington University in St. Louis, Obstetrics and Gynecology, Saint Louis, U.S.A.

Study question: Does Zika virus (ZIKV) infect the female reproductive tract and are there any damaging effects?

Summary answer: After inoculation with ZIKV, viral RNA is found in the ovary, oviduct, uterus, cervix, and vagina and inflammatory cells invade the ovary and follicular compartment.

What is known already: Since its emergence in the Americas, Zika virus (ZIKV) has been linked to the development of congenital birth defects and viral persistence for extended periods of time in semen, urine, and vaginal washes of

humans. Mouse models have been used to confirm ZIKV infection in the male reproductive tract including testes, epididymis, and sperm. However, the effects of infection on the female reproductive tract is poorly understood.

Study design, size, duration: This was an observational, basic science experiment with inbred mice

Participants/materials, setting, methods: Using a mouse adapted ZIKV strain, we evaluated tissue tropism in the female reproductive tract in C57Bl/6 mice after subcutaneous inoculation. Hematoxylin and eosin staining was performed as was in situ hybridization looking for viral RNA expression. qRT-PCR was conducted on all tissues to detect the titers of the virus in the tissues. Immunohistochemistry was performed to locate CD45 positive leukocytes in the tissues. The infection studies were repeated in ovariectomized mice vs shams.

Main results and the role of chance: ZIKV was detected in the ovary, oviduct, uterus, cervix, and vagina. The highest titers were close to 10^6 FFU equivalents/gram in the cervix and vagina of mice on day 7 post infection. This was confirmed through in situ hybridization. Preliminary results suggest that the presence of estrogen enhances Zika infectivity. Bilateral oophorectomy reduced viral titers, however, these titers increased with add back estradiol. We further investigated the effect of ZIKV on the ovary and found no significant differences in ovarian weight or in primary or secondary follicular development at 14, 21 or 90 days post infection. ZIKV infected mice, however, did demonstrated significant infiltration of CD45 cells at all time points. This was localized to the follicular compartment, specifically antral fluid and the zona pellucida. Robust CD45 follicular staining was seen in 3/7 (43%) mice at the day 14 time point and 4/4 (100%) mice at the day 21 time point. This could represent evidence of systemic ZIKV infection in the follicular fluid, or could be indicative of a tissue-specific effect of ZIKV on the ovary.

Limitations, reasons for caution: This is a mouse study however woman to man transmission of ZIKV has been reports and would be predicted by the results of these studies.

Wider implications of the findings: ZIKV can infect all female reproductive tract tissues by the subcutaneous route, which includes mosquito bites.This infection leads to inflammatory infiltration of the ovary and could potentially lead to later tissue destruction. Women may be more sensitive to ZIKV during different times in the menstrual cycle due to estrogen.

Trial registration number: Not Applicable.

O-298 Infection with high-risk Human Papillomavirus (HPV) and the risk of female infertility

B. Nøhr[1], S. Krüger Kjær[2], L. Soylu[2], A. Jensen[2]

[1]Herlev University Hospital, Department of Obstetrics- Gynaecology and Reproductive Medicine, Copenhagen, Denmark
[2]Danish Cancer Society, Virus- Lifestyle and Genes, Copenhagen, Denmark

Study question: Does known infection with high-risk HPV, both registered as a single HPV positive test or HPV persistence, increase the risk of female infertility?

Summary answer: Infection with high-risk HPV does not seem to increase the risk of female infertility in later reproductive life.

What is known already: HPV positivity at the time of fertility-treatment has been associated with a decreased success-rate in both IVF and IUI outcomes, but the role of high-risk HPV as a cause of female infertility is unclear. No previous studies have investigated the risk of infertility subsequent to infection with high-risk HPV.

Study design, size, duration: This study was based on a large national population-based cohort study, including 10.898 women (20-29 years of age) randomly drawn from the general female population living in Copenhagen, Denmark and enrolled during 1991-93. All women were tested for cervical high-risk HPV and again after 2 years. The study cohort was linked to the Danish Infertility Cohort, which consists of all Danish women referred for fertility problems to private or public fertility clinics.

Participants/materials, setting, methods: Follow-up for each study participant was the period from the date of enrollment until diagnosis of infertility, first conception, death, emigration, disappearance, or end of study period (Dec 2010). Data were analyzed by means of a Cox proportional hazards regression model estimating hazard ratios (HRs) and its corresponding confidence intervals (CIs). Potential confounders such as maternal age, smoking, educational level

and previous genital infections were selected a priori according to existing literature and availability.

Main results and the role of chance: Of the 10.898 women eligible for study, 1.863 (17.0%) were high-risk HPV positive at the first visit, 2802 (25.7%) were positive at either or both first and the next visit, and 324 (3.0%) were high-risk HPV positive for a specific subtype at both the first and the second visit. In all, 1.282 women (11.8%) were diagnosed with infertility in the cohort.

Neither one (HR 0.87, 95% CI 0.75-1.02), or two following positive tests for high risk HPV (HR 1.00, 95% CI 0.88-1.13), or two tests positive for the same subtype of high risk HPV (persistence) (HR 0.90, 95% CI 0.64-1.26) was associated with an increased risk of infertility later in reproductive life. Adjusting for potential confounding factors did not change the estimates.

Limitations, reasons for caution: A limitation of the study is that an unknown number of the unexposed women in our study could have had a high-risk HPV infection before or after the test at enrolment and follow up.

Wider implications of the findings: Our results are reassuring since infection with high-risk HPV is widespread and female infertility is increasing in the industrialized countries.

Trial registration number: Not applicable

POSTER VIEWING SESSION
ANDROLOGY

P-001   Choosing the appropriate insemination method in assisted reproductive treatments based on sperm chromatin fragmentation

D. Keating, N. Pereira, S. Chow, A. Parrella, M. Goldstein,
Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We question if sperm chromatin fragmentation (SCF) can guide couples with unexplained infertility and poor intrauterine insemination (IUI) outcomes to the appropriate subsequent reproductive treatments.

Summary answer: Couples with prior IUI failures can be offered a SCF-based treatment algorithm comprising of conventional IVF or ICSI with ejaculated or surgically retrieved spermatozoa.

What is known already: Ovulation induction (OI) with IUI is the mainstay of treating couples with unexplained infertility. However, some couples may have poor IUI outcomes despite an adequate number of treatments attempts and normal semen parameters. Recent evidence has suggested that sperm DNA integrity is closely associated with fertility potential. During the later stages of spermiogenesis, breakage of a sizable amount of single- or double-stranded DNA occurs to allow tight chromatin compaction and, in ideal conditions, only those spermatozoa with fully repaired chromatin would reach the ejaculate. Thus, high SCF in the ejaculate, may have an inverse relationship with IUI success.

Study design, size, duration: Over a 36-month period, couples diagnosed with unexplained infertility, based on normal female infertility screening and semen analysis, underwent treatment with ovulation induction and IUI. Those with a history of 2-4 failed IUI attempts underwent SCF assessment of the ejaculate. The couples were then allocated to conventional IVF or ICSI with ejaculated or surgically retrieved sperm according to the level of SCF. The clinical pregnancy rate (CPR) was stratified according to the SCF-based insemination method.

Participants/materials, setting, methods: Infertile couples with unexplained infertility underwent SCF assessment by the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay or sperm chromatin structure assay (SCSA). In-house TUNEL assessment evaluated at least 500 spermatozoa under fluorescent microscopy and the SCF was deemed abnormal above a threshold of >15%. SCSA assessment was also performed by an external laboratory, which analyzed at least 5000 spermatozoa. The SCSA was considered abnormal above a threshold of >25%.

Main results and the role of chance: A total of 631 couples underwent 1464 IUI cycles. The female and male age in the study cohort was 37.6 ± 4 years and 39.8 ± 5 years, respectively. The overall average sperm concentration was $50.4 \pm 32 \times 10^{6}$/mL, with a motility of 46.6 ± 12% and morphology of 3.1 ± 2%. The CPR with IUI at our center in an age-matched cohort is 17.9%; however, the study cohort had CPR of 5.1%. The mean TUNEL and SCSA values of the men in study cohort was 21.7 ± 8% and 39.5 ± 26%, respectively. Couples with failed IUI attempts but normal SCF in the male partner underwent conventional IVF, resulting in a CPR of 24.4%. In women <35 years undergoing conventional IVF, the CPR increased to 38.2% (P < 0.001). Couples with abnormal SCF underwent ICSI with ejaculated sperm, leading to an overall CPR of 24.1% (P < 0.001); when controlling for female age <35 years, the CPR rose to 27.8%. Couples who failed to conceive with ICSI using ejaculated sperm were offered testicular sampling. Eighty-six men consented for the surgical retrieval of testicular sperm and were found to a have a SCF of 9.28 ± 6%, which was significantly lower than the SCF of the ejaculate (P < 0.001). The CPR in couples undergoing ICSI with surgically retrieved sperm was 29.8%.

Limitations, reasons for caution: Surgical sampling of the vas deferens, epididymis, or testis in men with high SCF in their ejaculates samples or those with poor IUI outcomes should only be performed after extensive individualized counseling. Moreover, such an approach is preliminary and requires further prospective analysis.

Wider implications of the findings: IVF is successful in men with intact sperm chromatin. When sperm SCF is compromised in the ejaculate, ICSI is the most suitable insemination method. In men with high SCF in their ejaculate who fail ICSI treatment, surgical sampling yields spermatozoa with lower SCF and higher changes of pregnancy.

Trial registration number: Not Applicable.

P-002   Impact of intracytoplasmic morphologically selected sperm injection (IMSI) on blastocyst quality: a prospective blinded randomized sibling oocyte study of IMSI vs. intracytoplasmic sperm injection (ICSI)

G. Westlander[1], K. Borg[1], C. Persson[2], L. Rogberg[1], P. Saldeen[3],
S. Wennerström[1], T. Hardarson[1]

[1]*Fertility Center Scandinavia, Carlanderska Hospital, Göteborg, Sweden*
[2]*IVF Clinic CuraÖresund, Per Albin Hanssons väg, Malmö, Sweden*
[3]*Nordic IVF Center, Malmö, Limhamn, Sweden*

Study question: To evaluate the impact of IMSI on blastocyst development.

Summary answer: No difference in number of good quality blastocysts on day 5/6 was found between IMSI and ICSI.

What is known already: Motile sperm organelle morphology examination (MSOME) at magnification up to 6600x enables assessment of sperm nuclear morphology. Spermatozoa with as few vacuoles as possible can then be selected for microinjection (IMSI). However, a decade after its introduction the clinical implication of MSOME is unclear.

Study design, size, duration: The study was a prospective oocyte sibling study performed at 3 IVF centers, where the patients were blinded to randomization of treatment. When 8 or more oocytes were retrieved the oocytes were individually and randomly 1:1 allocated to either ICSI or IMSI.

Participants/materials, setting, methods: Infertile couples for ART treatment with severe male infertility (sperm concentration < 1 million sperm/ml and/or sperm motility grade less than 2.5 after gradient centrifugation), previously at least two failed ICSI attempts and at least 8 retrieved oocytes were selected for the study. All couples gave their signed informed consent.

Main results and the role of chance: A total of 58 patients were enrolled in the study with a total of 644 oocytes randomized to ICSI or IMSI. No statistical difference was found between the treatments in day 5/6 good quality blastocysts per injected oocyte or fertilized oocyte (2PN): the percent of good quality blastocysts was 19.6% (SD 27.7%) and 21.1% (SD 28.2%) in the IMSI and ICSI groups, respectively (Wilcoxon signed ranks test, P = 0.71). The fertilization rate was significantly lower in the IMSI group (54.0%; SD 23.7%) compared to the ICSI group (65.3; SD 28.5) (P = 0.004).

Limitations, reasons for caution: Time for selecting an optimal sperm could affect the quality of the embryos, which might explain the impaired fertilization rate in the IMSI group. Furthermore, many men enrolled in the study

suffered from severe oligozoospermia and the IMSI technique cannot guarantee that spermatozoa with normal morphology were selected for microinjection.

Wider implications of the findings: In literature, IMSI is not considered "state of the art" for treating male infertility. The current study included couples with male infertility and at least two previous failed ICSI cycles, which is only one of several potential indications for IMSI. Further studies are needed to elucidate the role of IMSI.

Trial registration number: Not applicable when study was commenced in 2012.

P-003 Superior clinical pregnancy rates after microsurgical epididymal sperm aspiration

H. Hibi[1], T. Ohori[2], M. Sumitomo[3], M. Sonohara[4], N. Fukunaga[4], Y. Asada[4]

[1]Kyoritsu General Hospital, Urology, Nagoya, Japan
[2]Kyoritsu General Hopital, Urology, Nagoya, Japan
[3]Aichi Medical University, Urology, Nagakute, Japan
[4]Asada Ladies Clinic, Gynecology, Nagoya, Japan

Study question: Since reports on the use of microscopic epididymal sperm aspiration (MESA) are limited, we assessed normal fertilization and live birth rates after use of MESA.

Summary answer: MESA is a beneficial procedure and should be given priority over TESE.

What is known already: Testicular sperm extraction (TESE) is now widely applied as a method of sperm retrieval surgery owing to its technical simplicity. Nevertheless, testicular sperm retrieval requires surgical intervention and hence carries associated risks such as bleeding, infection, and impaired testicular function.

Study design, size, duration: Of 438 subjects who underwent surgical sperm retrieval in our clinic between April 2004 and January 2016, 160 who underwent MESA were evaluated.

Participants/materials, setting, methods: MESA was performed under local anesthesia by using a micropuncture method with a micropipette. In cases where motile sperm were not obtained after repeated bilateral puncturing of the epididymis, conventional or micro TESE was used.

Main results and the role of chance: Adequate motile sperm were retrieved in 71 subjects by using MESA, and in 59 subjects by using TESE. Of the patients, 123 underwent intracytoplasmic sperm injection (ICSI). After MESA, the normal fertilization rate was 73.5%, and the clinical pregnancy rate per cycle was in 43%. Healthy deliveries resulted after MESA in 65 cases and after TESE in 38.

Limitations, reasons for caution: small number of subjects

Wider implications of the findings: MESA specimen collection dose not have any special requirement such as mincing tissue disposition. MESA can also reduce the laboratory work such as that required for cryopreseravation. Moreover, a MESA specimen is easily applied for ICSI in both cases where the sperm is fresh or frozen-thawed.

Trial registration number: none.

P-004 Influence of dietary patterns on semen quality among patients undergoing infertility treatment

M.J. Soriano[1], S. Sadeghi[2], A. Gascón[1], A. Palomar[1], J.V. Martínez[1], S. Balasch[3], I. Molina[1]

[1]Hospital Universitari i Politècnic La Fe, Reproducción Humana Asistida, Valencia, Spain
[2]Universidad de Valencia, Departamento de Biología Celular- Biología Funcional y Antropología Física, Valencia, Spain
[3]Universitat Politècnica de València, Departamento de Estadística e Investigación Operativa Aplicadas y Calidad, Valencia, Spain

Study question: Are there any associations between food intake and semen quality in male patients undergoing an assisted reproductive technology (ART) treatment?

Summary answer: Higher antioxidant intake was associated with higher semen quality and ART success.

What is known already: Around 40% of infertility cases are caused by male factor due to significant declines in semen quality. While genetic, endocrine, congenital and demographic factors such as age, smoking and heavy alcohol use are risk factors for decreased sperm quality, there is increasing evidence that nutritional status could be a critical determinant of normal reproductive function. Dietary intake of antioxidants, such as vitamins C and E, β-carotene, and micronutrients such folate and zinc, have been demonstrated to be critically important for normal semen quality and reproductive function in humans.

Study design, size, duration: Cross-selectional study. 28 normozoospermic, 73 asthenozoospemic, 62 oligoasthenozoospermic and 33 oligoasthenoteratozoospermic patients involved in ART were recruited between March 2015 and October 2016 at Hospital Universitari i Politècnic La Fe of Valencia (Spain). 33 cycles were underground by intrauterine insemination (IUI) and the rest, by *in vitro* fecundation (IVF) or intracytoplasmic sperm injection (ICSI).

Participants/materials, setting, methods: A total of 196 men of subfertile couples undergoing IUI and IVF/ICSI treatment were studied. Semen samples were analysed according WHO 2010 criteria. Semen parameters including sperm concentration (SC), total sperm motility (TSM), progressive motility (PRM) and normal sperm morphology (NSM) were recorded. All them were analysed by an Integrated Sperm Analysis System (ISAS). Diet was assessed using food frequency questionnaire. Lineal regression models analysed associations between dietary patterns, sperm parameters and pregnancy rate (PR).

Main results and the role of chance: Attending to dietary patterns of patients it is possibly to differentiate two ones: Western and Mediterranean diet. While the Mediterranean diet is high in whole grains, fruits and vegetables, the Western diet is high in refined carbohydrates, sugars and red meats. SC, TSM and PRM are positively influenced by the consumption of vegetables, fruits, cereals and polyunsaturated fats (*P*-value <0.05). However, a high intake of saturated fatty acids declines SC and TSM (r = -0.32 and r = -0.47, respectively). Higher intake of selenium, omega-3 and omega-6 polyunsaturated fats was associated with higher normal sperm morphology. Men in the highest tertile of selenium intake had a 1.4 (95% CI: 0.9 to 2.8) higher percentage of morphologically sperm than men in the lowest tertile of intake. Men in the highest third of omega-3 fatty acids had 3.2% (95% CI: 1.1 to 3.9) higher normal morphology than men in the lowest third (P_{trend} = 0.01). The Mediterranean diet was associated with a significant higher PR (*P*-value = 0.02).

Limitations, reasons for caution: This was a cross-sectional and observational study, which limited our ability to determine causality of diet on semen quality parameters.

Wider implications of the findings: There are many studies that analyse the relationship between dietary patterns and semen quality but only a few of them study its influence on pregnancy rates. Our findings suggest that a diet rich in antioxidants, like Mediterranean diet, may improve semen quality and increases the chance of getting pregnant.

Trial registration number: This is a basic science.

P-005 Sperm preparation after freezing improves sperm count, motility, viability and morphology in frozen-thawed sperm compared with sperm preparation before freezing-thawing process

A. Palomar[1], A. Gascon Sanchez[1], J.V. Martinez Sanchis[1], S. Balasch Parisi[2], I. Molina Botella[1]

[1]Hospital Universitari i Politecnic La Fe, Assisted Reproduction Unit, Valencia, Spain
[2]Universitat Politecnica de Valencia, Department of Statistics, Valencia, Spain

Study question: The purpose of this study is to evaluate which cryopreservation protocol, semen preparation before or after freezing, improved sperm count, motility, viability and morphology results

Summary answer: Semen preparation after cryopreservation resulted in higher total motile sperm count, viability and morphology, so it is recommended in patients with poor sperm baseline

What is known already: Indications for sperm cryopreservation include donor insemination, cryopreservation prior to surgical infertility treatment and malignancies and avoiding additional surgery in couples undergoing repeated IVF/ICSI cycles. However, dramatic changes during cryopreservation have

detrimental effects on the sperm membrane, resulting in a large increase in the percentage of poorly motile sperm or sperm with abnormal morphology. The negative effects related to rapid temperature decrease, such as osmotic injury, cellular dehydration, intra-cellular ice crystal formation, and oxidative stress can also lead to damage the sperm function affecting the reproductive outcome. Seminal plasma could perform a protective function during the freezing-thawing process

Study design, size, duration: Comparative study between two cryopreservation protocols performed since January 2016 until August 2016 in the Assisted Reproduction United (La Fe Hospital). Semen samples from 40 normozoospermic men and 40 men presenting abnormal sperm parameters according the 2010 WHO were equally divided into two aliquots, one of which was processed by swim-up before cryopreservation (SF) while the other was prepared following cryopreservation (FS). Sperm count, motility, viability and morphology were evaluated in each group

Participants/materials, setting, methods: Semen samples presenting more than 4 ml of volume were considered. A 0.5 ml aliquot of the same semen sample was used for each protocol. Sperm count, progressive and total motility and morphology were performed using CASA system. Sperm vitality was assessed by HOS-test. Slow freezing was used for sperm cryopreservation. Sperm preparation was performed by swim-up. Multivariate linear regressions and T-test of dependent samples were performed. P-values<0.05 were considered significant

Main results and the role of chance: The progressive (PM) and total motility (TM), the total motile sperm count (TMS) and the percentage of viable sperm (VS) in the semen samples prepared after cryopreservation (FS) were higher than that in the pre-freezing preparation group (SF) (PM: 37.38% vs7.64%; TM: 38.71vs13.97%; TMS: $5.41 \cdot 10^6$vs$1.61 \cdot 10^6$; VS: 38.93%vs14.93%, in all cases P < 0.01). Regarding the morphology (M), percentage of normal sperm in fresh samples seemed to decrease when semen preparation was performed prior cryopreservation (4.05%vs3.05%, P = 0.079). The semen samples behavior after freezing-thawing process was not influenced by the initial semen quality since no differences were observed between samples presenting normal or abnormal initial seminal parameters. Total motility in both, prepared and non-prepared samples, is more related to HOS-test results than progressive motility: HOS=0.38+0.97•TM

Limitations, reasons for caution: Future studies should include more patients in order to validate these results testing other storage devices apart from straws and other freezing techniques should be investigated. Fertility potential of the spermatozoa could not be assessed since ICSI outcomes had not been followed

Wider implications of the findings: FS protocol resulted in better sperm quality than SF. Therefore, it is demonstrated that sperm preparation after freezing should be considered to increase the available sperm number, especially in patients with poor sperm baseline undergoing repeated ICSI cycles. TM could assess sperm viability in a simpler way than HOS-test

Trial registration number: .

P-006   Zinc nanoparticles prevents freeze-thaw-induced DNA damage in human spermatozoa

G. Kalthur, A. V Isaac, S. Kumari, R. Nair, S. Adiga

Kasturba Medical College, Clinical Embryology, Manipal, India

Study question: To assess the beneficial role of Zinc Oxide nanoparticles (ZnO NP) in preserving the genetic and functional characteristics of human spermatozoa during cryopreservation

Summary answer: ZnO nanoparticles stabilizes the DNA of human spermatozoa and decreases the freeze-thaw-induced damage

What is known already: Semen cryopreservation is an integral part of the assisted reproductive technology and reproductive medicine field. Despite the importance of semen cryopreservation importance in infertility treatment, even today we do not have an ideal semen cryopreservation medium which can preserve the structural and functional characteristics of the spermatozoa. A recent study conducted in our laboratory has demonstrated that addition of Zinc to fresh human ejaculate before cryopreservation can be an efficient approach to prevent the DNA damage during freeze- thaw process.

Study design, size, duration: This is a prospective study involving 30 normozoospermic semen samples. The semen samples were stored in liquid nitrogen with commercial freezing medium containing ZnONPs (100 μg/mL). After 7 days of storage in liquid nitrogen, the semen samples were thawed and assessed for sperm functional parameters.

Participants/materials, setting, methods: Men attending Manipal Assisted reproduction center, Kasturba Medical College, Manipal University, Manipal for routine semen evaluation were recruited for the study. The motility was assessed manually, DNA integrity of the spermatozoa was assessed by TUNEL assay, acrosome intactness was studied by using PSA-FITC staining method and lipid peroxidation in the spermatozoa was assessed by estimating Malonedialdehyde level.

Main results and the role of chance: A significantly higher progressive motility (p < 0.05) was observed in ejaculates cryopreserved with ZnONP's at 1 and 24 h. In addition, the sperm DNA damage was significantly lower (p < 0.01) and number of spermatozoa with intact acrosome were non-significantly higher in this group. The sperm pellet had significantly lower (p < 0.01) level of lipid peroxidation as indicated by decrease in malondialdehyde level in ZnONP group. However, the transmission electron microscopic (TEM) imaging of the spermatozoa cryopreserved with ZnONP's revealed that these nanoparticles do not permeate across the membrane which was also confirmed by fluorescence imaging with fluorescent ZnONP's.

Limitations, reasons for caution: The sample size used in the study is relatively small. The beneficial effect of ZnONP on cryopreservation of poor quality ejaculates and fertilization outcome of spermatozoa needs to be studied further to assess its clinical application.

Wider implications of the findings: This is a novel approach to stabilize the DNA of spermatozoa which may help us in extracting superior quality spermatozoa for ART and thus help in improving the fertilization outcome with frozen-thawed spermatozoa.

Trial registration number: Not applicable.

P-007   Structural modification of pentoxifylline to improve the sperm function and reduce embryo toxicity

S. Kumari[1], J.P. Dasappa[2], G. Kalthur[1], S.K. Adiga[1]

[1]*Kasturba Medical College- Manipal University, Clinical Embryology, Manipal, India*
[2]*Mangalore University, Chemistry, Mangalore, India*

Study question: Is it possible to modify the structure of pentoxifylline (PTF) to lower its adverse effects on oocyte and embryos without compromising with its efficacy on enhancing the motility in spermatozoa?

Summary answer: We synthesized two safe and potent modified pentoxifyline (mPTF) compounds which significantly improved the survival and functional competence of human spermatozoa *in vitro*

What is known already: Poor sperm motility is the common cause for fertilization failure in assisted reproductive technology (ART). Various strategies have been implemented in improving the success in IVF fertilization rate by chemical stimulation of spermatozoa such as treating spermatozoa with non-specific inhibitors of phosphodiesterase (PDEIs). Even though pentoxifylline is used as a potent sperm motility enhancer in ART, due to its adverse effect on fertilization and embryonic development, search for alternate molecules is of great clinical significance.

Study design, size, duration: This is a prospective study. We first synthesized four mPTF compounds (mPTF1, mPTF2, mPTF3, mPTF4) and characterized them by infrared and mass spectroscopy. These compounds were assessed for beneficial effect on human sperm motility by using fresh normozoospermic samples (n = 12). The selected mPTF compounds were further assessed for sperm function tests (n = 12). Cytotoxicity and genotoxicity of the selected compounds were assessed *in vivo* by injecting Swiss albino mice (n = 7) with PTF and mPTF compounds.

Participants/materials, setting, methods: Ejaculates were collected from men attending for routine semen analysis at the Manipal Assisted reproduction center, Kasturba Medical College, Manipal University, Manipal. Manual motility assessment, computer- assisted sperm analysis (CASA), mitochondrial function using rhodamine 123 staining, DNA integrity by TUNEL assay and ionophore-induced acrosome reaction was studied in human spermatozoa. Cytotoxicity

and genotoxicity of these compounds were assessed in mouse bone marrow by assessing micronucleus incidence.

Main results and the role of chance: We have successfully synthesized four derivatives of pentoxifylline, mPTF1, mPTF2, mPTF3, and mPTF4 by adding 6 methoxy naphtholdehyde, 5 bromobenzaldehyde, 4 nitrobenzaldehyde, 2 and 4 dichlorobenzaldehyde to methoxy group of pentoxifylline. Pentoxifylline, mPTF1 and mPTF4 increased the progressive motility in comparison to control at all intervals. At 24 h intervals, the motility dropped in all the groups which was more predominant in control and PTF groups. However, in mPTF1 (0.25 mM) and mPTF4 (0.3 mM), significantly higher percentage of motile spermatozoa was observed (P < 0.01). In addition, the mPTF had slower acrosome reaction rate compared to PTF. Prolonged incubation of processed spermatozoa up to 24 h did not result in any increase in chromatin instability compared to control or PTF group. mPTF1 and mPTF4 had lower percentage of micronucleated cells in mouse bone marrow cells compared to PTF suggesting that their lower genotoxic effect.

Limitations, reasons for caution: This study involves *in vitro* assessment of the modified compounds to improve sperm motility. The effect of these mPTF compound on ART outcome is yet to be tested. The motility enhancement property of these agents in asthenozoospermic or testicular samples is not studied.

Wider implications of the findings: This experiment confirms the structural modification and synthesis of pentoxifylline compounds that are able to enhance sperm. The present study helped us in identifying novel compounds with lower toxicity and higher motility enhancement property compared to PTF. This will have potential clinical application in ART set up in future.

Trial registration number: Not applicable.

P-008 The influence of the storage temperature on the semen parameter: storage at 37°C might not be suitable

K. Suzuki, T. Shin, Y. Shimomura, T. Iwahata, S. Onota, Y. Kobori, A. Miyata, H. Okada

Dokkyo Medical University Koshigaya Hospital, Reproduction Center, Koshigaya, Japan

Study question: What is the most suitable temperature for sperm storage?

Summary answer: The most suitable temperature to preserve sperm may be 25°C.

What is known already: In the assisted reproduction technologies, oocyte are stored in the suitable condition by controlling temperature and gas using equipment such as incubators. Meanwhile, the sperm are stored at room temperature or 37 °C in incubators, but the suitable conditions of the storage of sperm are undetermined and not standardized among the facilities. Therefore, we investigated the most suitable condition of the storage of semen by focusing on the storage temperature.

Study design, size, duration: In this study, 5 men who fathered within 2 were included.

Participants/materials, setting, methods: The standard semen analysis tests, the sperm vitality test, and the measurements of static oxidation-reduction potential (sORP) of sperm and sperm DNA fragmentation index (DFI) were conducted immediately after ejaculation. Then, 700 μl of semen were divided into 2 ml tubes, and incubated in the water bath whose temperatures were set at 4, 25, or 37 °C. The examinations described above were conducted after incubations for 6, 12, and 24 hours.

Main results and the role of chance: Sperm concentration were not significantly different among 4, 25 and 37 °C groups at any time point. Sperm total motility of 25 and 37 °C groups were significantly higher compared with 4 °C group after 3 hours incubation, and that of 25 °C group was significantly higher than those of 4 and 37 °C groups after 6, 12 and 24 hours incubation. Progressive sperm motility of 25 and 37 °C groups were significantly higher compared with 4 °C groups after 3 hours incubation, and that of 25 °C group was significantly higher than those of 4 and 37 °C groups after 6 and 12 hours incubation although those of each group were not significantly different after 24 hours incubations. As for the sperm vitality tests, that of 25 °C group was significantly higher than those of 4 and 37 °C groups after 6, 12 and 24 hours incubations. The sORP of 25 °C group was significantly lower than that of 37 °C

group after 12 and 24 hours incubations and higher than that of 4 °C group after 6, 12 and 24 hours incubations. DFI was not significantly different among groups at any time point.

Limitations, reasons for caution: Small sample size Included only fertile males

Wider implications of the findings: The storage at 25°C lead to keeping sperm quality, it is improving treatment outcome of reproductive therapy.

Trial registration number: none.

P-009 Correlation of Sperm DNA fragmentation and Seminal oxidation reduction potential in infertile men

M. Arafa[1], H. ElBardisi[1], A. Majzoub[1], S. Alsaid[1], H. AlNawasra[1], K. Khalafalla[1], K. AlRumaihi[1], A. Agarwal[2]

[1]*Hamad Medical Corporation, Urology, Doha, Qatar*
[2]*Cleveland Clinic, American Center for reproductive medicine, Cleveland- Ohio, U.S.A.*

Study question: Is Sperm DNA fragmentation really correlated to seminal oxidative stress?

Summary answer: Sperm DNA fragmentation is positively correlated with seminal oxidative stress measured by Seminal oxidation reduction potential

What is known already: Oxidative stress is a proposed cause for sperm DNA fragmentation. Oxidation reduction potential is a new accurate measure for oxidative stress as it measures the balance between oxidants and reductants

Study design, size, duration: This is a prospective study performed on 312 patients attending the male infertility clinic at a tertiary medical center between February and August, 2016.

Participants/materials, setting, methods: Patients receiving medical or surgical treatment for infertility prior to their presentation or who had a sperm concentration less than 5 millions/ml sperm were excluded. Patients were subjected to history taking, clinical examination as well as semen analysis and SDF assessment using Halosperm kit (cut off value <30%) and static oxidation reduction potential (sORP) using MiOXSYS system. Patients were divided according to SDF result (normal/ high) and to age (<40 years / > 40 years).

Main results and the role of chance: A total number of 312 patients were included in the study. Patients with high SDF had significantly higher age than those with normal SDF. The mean total and progressive motility was significantly higher in the normal SDF group while sORP was significantly lower in the normal SDF group compared with the high SDF group. Presence of varicocele did not significantly affect SDF level (Table 1). SDF was negatively correlated with total (-0.526, p < 0.001) and progressive motility (-0.415, p < 0.001) and positively correlated with abnormal morphology, sORP and age (0.351, 0.222 and 0.192 respectively, p < 0.001 for all). SDF was significantly lower while total motility was significantly higher in patients <40 years compared with patients > 40 years of age.

Table 1 Comparison between normal and abnormal sperm DNA% result.

	Normal DNA%	High DNA%	p Value
Age	**35.11 ± 0.47**	**38.14 ± 0.95**	**0.01***
Count	35.45 ± 1.71	30.99 ± 2.62	0.14
Total motility	**57.53 ± 0.89**	**40.92 ± 1.78**	**0.00***
Prog.	**13.8 ± 0.73**	**5.56 ± 0.83**	**0.00***
Abnormality	92.94 ± 0.69	95.86 ± 0.78	0.12
sORP	**2.14 ± 0.14**	**4.03 ± 0.61**	**0.00***
Varicocele	77 (68.1%)	36 (31.9%)	0.56

Limitations, reasons for caution: The main limitation of the study is absence of normal fertile controls.

Wider implications of the findings: Sperm DNA fragmentation and seminal oxidation reduction potential should be included in assessment of male infertility. Using ORP testing can help in detecting the target patients for antioxidant therapy.

Trial registration number: This is not a clinical trial.

P-010 Indices of global DNA methylation status of sperm from smokers and non-smokers men

M. Hamad[1], M. Montenarh[2], M.E. Hammadeh[3]

[1]King Saud Bin Abdulaziz University for Health Sciences, Basic Sciences- College of Science and Health Professions-, Jeddah, Saudi Arabia
[2]Saarland University, Medical Biochemistry and Molecular Biology, Homburg, Germany
[3]Saarland University, IVF & Andrology Laboratory- Department of Obstetrics and Gynecology, Homburg, Germany

Study question: Are there Global DNA methylation variations in sperms of smokers that negatively affect sperm quality and male fertility?

Summary answer: Cigarette smoking significantly correlated with sperm global DNA methylation and sperm quality.

What is known already: Abnormal sperm DNA methylation was connected with male infertility in patients with poor sperm quality.

Study design, size, duration: A prospective study compares sperms from 109 men; 55 smokers and 54 non-smokers whose female partners attended an assisted reproduction and andrology laboratory were evaluated.

Participants/materials, setting, methods: A total of 109 sperm samples collected from 55 smokers and 54 non-smokers patients were involved in this study. DNA was extracted from purified sperms. A colorimetric quantification of global DNA methylation measures specifically the levels of 5-methylcytosine (5-mC) with an Enzyme Link Immunosorbent Assay (ELISA)-like method. Sperm's chromatin condensation, vitality and membrane integrity were evaluated according to the World Health Organization guidelines.

Main results and the role of chance: Results are showing highly and significantly (p = 0.000) lower levels of global DNA methylation in non-smokers than smokers (4.85 ± 2.72 and 7.08 ± 1.77 ng/ μL, respectively). Also, global DNA methylation levels are found to be significantly (r = 0.220; P = 0.021) correlated with non-condensed chromatin (CMA3 positive). In addition, global sperm DNA methylation are correlated negatively and highly significantly (p < 0.010) with sperm count (r=-0.273), motility(r=-0.301), and vitality (r=-0.265).

Limitations, reasons for caution: The results of this study were created from males whose wives attended the IVF and Andrology laboratory pursuing fertilization. However, comparison between smokers and non-smokers supports the idea that smoking negatively affects sperm, but additional studies are required to reveal the impacts of DNA methylation on male fertility.

Wider implications of the findings: The study results may act as an evidence for the negative effect of smoking on male fertility. Furthermore, DNA methylation from smokers may serve as a marker for male fertility.

Trial registration number: NA.

P-011 Management of infertility in men with spinal cord injury: an educational program for practitioners

N.L. Brackett[1], C. Lynne[2], E. Ibrahim[3], T. Aballa[3]

[1]University of Miami Miller School of Medicine, Neurological Surgery, Miami, U.S.A.
[2]University of Miami Miller School of Medicine, Department of Urology, Miami-Florida, U.S.A.
[3]University of Miami Miller School of Medicine, The Miami Project to Cure Paralysis, Miami- Florida, U.S.A.

Study question: Can practitioners obtain formal training in the management of infertility in men with spinal cord injury?

Summary answer: Training is provided at University of Miami, Florida. Trainees' travel to Miami supplemented by grant from Craig Neilsen Foundation. Course approved for Continuing Education Credit

What is known already: Spinal cord injury (SCI) occurs most often to young men. Infertility is a major sequela of SCI. Anejaculation and abnormal semen

parameters are seen in 90% of cases. Currently, there is no established standard of care for the management of infertility in these men, largely due to a lack of education of healthcare providers at all levels. Consequently, couples with SCI male partners are often over-treated with expensive and unnecessary procedures. A three-year educational program funded by the Craig Neilsen Foundation has been developed to train practitioners in methods and techniques for managing infertility in this population.

Study design, size, duration: A teaching curriculum was developed based on our 27 years of experience in the management of infertility in men with SCI. The training is performed at our center at the University of Miami Miller School of Medicine in Miami, Florida. Training can also be provided at outside centers, if requested. The program offers Continuing Medical Education (CME) credits for physicians (7.5 AMA PRA Category 1 Credits™). Certificates of training are provided to all participants.

Participants/materials, setting, methods: The 1.5 day course includes:

(1) A half-day of lectures and videos.
(2) Two half-days of hands-on training in the techniques of penile vibratory stimulation (PVS) and electroejaculation (EEJ) as well as management of autonomic dysreflexia, and retrograde ejaculation.
(3) Syllabus, PowerPoint presentation, and instructional videos are given to trainees for incorporation into their own teaching.
(4) Limited travel reimbursement (up to $2,250) is available for professionals who train at our center in Miami.

Main results and the role of chance: During the first 5 months of this program (January to May 2016), educational materials (syllabus and comprehensive 30 minute instructional video) were developed. Training began in June 2016. A total of 9 physicians from the USA, Canada, Spain, Brazil, and Israel have been trained to date at our center. An additional 20 practitioners have been trained at the San Antonio Veterans Administration Hospital. Requests for training are ongoing, and scheduling is in progress. Training sessions scheduled at our center in February, March and April, 2017 are full. The curriculum was presented to 150 professionals at the 2016 Academy of Spinal Cord Injury Professionals meeting in Nashville. The curriculum has been selected for presentation at the 2017 meetings of the Barrow Neurological Institute in Phoenix, the American Spinal Injuries Association meeting in Albuquerque, the American Society of Andrology meeting in Miami, and the 2017 American Urological Association meeting in Boston. This program is open to trainees from outside the United States, including physicians and allied health personnel. At the conclusion of the funded training period, (2018), a communication network of providers will be established. A website will be created providing information to professionals and patients.

Limitations, reasons for caution:

(1) The 1.5 day training course is comprehensive, but cannot address every possible case that a practitioner may encounter.
(2) Training is available only in the English language.

Wider implications of the findings: This educational program addresses a gap in knowledge among health care professionals on the topic of management of infertility in men with SCI. Interested professionals are encouraged to take advantage of this training opportunity, which will be available through December 2018.

Trial registration number: Not applicable.

P-012 Effect of antioxidant supplementation on sperm parameters in oligo-astheno-teratozoospermia, with and without varicocele: a double blind place controlled (dbpc) study

G.M. Busetto[1], A. Virmani[2], G. Antonini[1], G. Ragonesi[1], F. Del Giudice[1], A. Agarwal[3], V. Gentile[1]

[1]Sapienza University, Urology, Roma, Italy
[2]Sigma-tau HealthScience, Nutraceuticals, Utrecht, The Netherlands
[3]American Center for Reproductive Medicine, Andrology, Cleveland, U.S.A.

Study question: Is effective an antioxidant supplementation on sperm quality of patients suffering oligo-astheno-teratozoospermia? Is there any difference in the effect between those with varicocele and those without?

Summary answer: Antioxidant supplementation is effective and safe when used for treating patients with oligo-astheno-teratozoospermia. The effect is stronger when patients are affected by varicocele.

What is known already: The male factor in worldwide infertility incidence is 20-30%. Sperm has high energy requirement for maturation, capacitation and motility. Many factors affecting sperm quality act through decreasing energy and increasing reactive oxygen species (ROS) by causing mitochondrial dysfunction. Sperm is vulnerable to ROS causing sperm immobilization, impairment of acrosomal reaction, abnormal morphology, DNA fragmentation and cell death.

Study design, size, duration: To determine the effect of antioxidant supplementation containing L-carnitine, acetyl-L-carnitine, fructose, citric acid, selenium, coenzyme Q10, vitamin C, vitamin B12 and zinc on sperm quality in subjects with oligo- or astheno-teratozoospermia, with and without varicocele and history of difficulty conceiving.

Participants/materials, setting, methods: This was a monocentric, randomized, DBPC with a total of 104 patients, 52 in the supplementation and 52 in the placebo arm, that were recruited in 6 months. The enrollment was divided in 52 patients with varicocele and 52 patients without. We evaluated efficacy of 6 months of supplementation versus placebo. Spermogram evaluation, according to the WHO guidelines, was done at the beginning of treatment and at the end of the 6 month treatment.

Main results and the role of chance: Sperm count (number $\times 10^6$/mL) in patients with varicocele was 39.3 +/- SD 16.8 in placebo group and 49.4 +/- 18.9 in supplementation group (percentage change 25.7% t=2.04 p < 0.05 Student test); in patients without varicocele 47.5 +/- 7.9 in placebo group and 52.3 +/- 9.1 in supplementation group (percentage change 9.9% t = 2.01 p < 0.05). Total sperm motility in patients with varicocele was 33.9+/- 6.9 in placebo group and 38.3+/- 8.0 in supplementation group (percentage change 18.6% t = 2.10 p < 0.05); in patients without varicocele was 35.0 +/- 7.5 in placebo group and 39.9 +/- 8.0 in supplementation group (percentage change 13.8% t=2.19 p < 0.05). Progressive sperm motility in patients with varicocele was 23.1 +/- SD 6.7 in placebo group and 27.4 +/- 7.9 in supplementation group (percentage change 18.6% t=2.10 p < 0.05); in patients without varicocele was 25.1 +/- 7.0 in placebo group and 29.7 +/- 9.1 in supplementation group (percentage change 18.6% t=2.07 p < 0.05).

Limitations, reasons for caution: We didn't compare the effect of this treatment with varicocele surgical treatment and we didn't evaluated DNA fragmentation. Furthermore latest evidences report that evaluating oxidative-stress can help in better understanding the best strategy for male infertility treatment.

Wider implications of the findings: In our study, at the end of the treatment we observed a marked increase in quality parameters of sperm especially in varicocele patients. The supplementation was safe without adverse events. On this basis it can be established that functional substances can form part of an efficacious strategy to handle infertility.

Trial registration number: PXP-001 A.

P-013 Perspectival study about Testicular sperm aspiration as easy, outpatient procedure in support to Assisted Reproduction Technique in Obstructive Azoospermia: confrontation with Testicular Sperm Extraction

N. Arrighi[1], D. Zani[2], A. Musesti[3], J. Bilali[4], S. Bonetti[4], G. Loda[4], P. Telò[4], M. Moretti[4], L. Farinelli[4], C. Gastaldi[4]

[1]Istituto Clinico "Città di Brescia", Urology -ART Centre, Brescia, Italy
[2]Istituto Clinico "Città di Brescia"- University of Brescia, Urology- Chair of Urology, Brescia, Italy
[3]Catholic University, Chair of Mathematics and Physics, Brescia, Italy
[4]Istituto Clinico "Città di Brescia", Unit of Gynecology- ART Centre, Brescia, Italy

Study question: Is Testicular Sperm Aspiration (TeSA) a suitable technique for "fresh" sperm retrieving in ART, with the same results (or better) than cryopreservation from TESE?

Summary answer: TeSA has shown to be an easy, cheap and feasible technique to retrieve fresh spermatozoa with same results (possibly better) than cryopreservation from TESE.

What is known already: TESE and cryopreservation is most used technique before ART in OA, for sperm retrieving. TeSA is an alternative, costless, outpatient procedure, providing fresh spermatozoa.

Study design, size, duration: Since September 2013,all OA cases underwent TeSA contextually to ovuli pick-up for partners (group A, n= 33, data perspectively stored, TESE and cryopreservation had been carried on during previous months, to avoid impossibility of fertilization in hypothesis of absence of spermatozoa from TeSA). Control group were couples that previously underwent ICSI (B, n= 31, only TESE). Average age was 41 and 35; 37,5 and 34 (respectively group A and B, patients and partners, p>010).

Participants/materials, setting, methods: During TeSA, the aspiration has been repeated until an adequate amount of spermatozoa has been obtained (range 1-4 aspirations, average 2.03) for ICSI procedure.

Main results and the role of chance: In all cases of group A, spermatozoa have been found. No complication of procedures has been reported. Average fertilization rate for single couple has been 56% of obtained ovuli. In only one couple, no fertilization occurred in group A (4%). In group B, fertilization rate has been 34%. In 4 cases we didn't obtain fertilization (19,5%), 2 complications occurred. In particular one patients reported pain for 10 days (grade 1), one patients has been recovered for orchyepididimitis (grade 2). TeSA demonstrated in all cases to provide an adequate amount of spermatozoa by a very low number of aspirations and low pain (average 2, VAS during procedure 1-7, average 1.66). TeSA associated to use of fresh spermatozoa showed much higher fertilization rate than TESE (56% vs 34%, p = 0.001, MannWhytney test). In addition, in only one case TeSA didn't show fertilization (embryo-transfer carried on in 96% of procedure), TESE with cryopreservation in 4 cases (80,5%).

Limitations, reasons for caution: The sample is not big, results are only preliminary.

Wider implications of the findings: By now, considering the higher fertilization rate, we are suggesting and using it in II and III level ART, also with aim to reduce costs of these procedures. In EAU guideline, TeSA is considered a second choice in confrontation to TESE. We think in future this could be changed.

Trial registration number: No registration number.

P-014 Influence of cigarette smoking on DNA methylation levels of sperm from the current smokers

M. Laqqan[1], Y. Alkhaled[2], E.F. Solomayer[3], M. Hammadeh[4]

[1]University of Saarland, Obstetrics & Gynecology, Homburg/Saar, Germany
[2]University of Saarland, Obstetrics & Gynecology, Homburg./Saar, Germany
[3]University Clinic of the Saarland and the Medical Faculty of the University of Saarland, Obstetrics & Gynecology, Homburg/Saar, Germany
[4]University of Saarland, Department of Obstetrics & Gynecology-, Homburg/Saar, Germany

Study question: Are there an influence of cigarette smoking on DNA methylation patterns of sperm from the current smokers males.

Summary answer: Cigarette smoking causes alterations in sperm DNA methylation level at CpGs in MAPK8IP and TKR gene-related amplicon. Besides its impact on some semen parameters.

What is known already: Sperm DNA methylation can be influenced by several factors including environment/lifestyle like chemicals known as mutagens and carcinogens found in cigarettes and cigarette smoke.

Study design, size, duration: A prospective cohort study. A total of 108 human semen samples were collected during the period of February 2016 to May 2016. 57 samples were obtained from never smokers, and 51 from current smoker's males.

Participants/materials, setting, methods: As a screening study, 450 K BeadChip arrays were used, to identify genomic regions that show differences in DNA methylation patterns between 15 current smokers and 15 never smokers males. Subsequently, local deep bisulfite sequencing was used to validate two differentially methylated CpGs (cg07869343 and cg19169023), which have the highest difference in the methylation level, and directly linked to MAPK8IP3 and TKR genes, respectively; on 78 sperm DNA samples (42 never-smokers versus 36 current smokers).

Main results and the role of chance: The results of 450 K BeadChip arrays identified 8 CpGs have an alteration in DNA methylation patterns, and only 5 of those CpG do not overlap common annotated SNPs. According to the

results of validation, the variation in methylation levels was found in more than one CpGs: The results of *MAPK8IP* amplicon showed a significant difference at six from twenty-two CpGs was tested (CpG3, CpG5, CpG6, CpG7, CpG8, and CpG21) in cases compared to controls group (P ≤ 0.043; P ≤ 0.005; P ≤ 0.002; P ≤ 0.003; P ≤ 0.045 and P ≤ 0.040, respectively). Besides, one from four CpG tested in the *TKR* amplicon (CpG4, P ≤ 0.002). On the other hand, the results of this study indicate the presence of a significant correlation between methylation levels at CpG4, CpG8, CpG9, CpG10, CpG15 and CpG22 in the *MAPK8IP* gene-related amplicon and percentage of total motility (P ≤ 0.005, P ≤ 0.001, P ≤ 0.013, P ≤ 0.0001, P ≤ 0.021, and P ≤ 0.003, respectively). Furthermore, a significant correlation between the methylation level at CpG13 and CpG16 and CpG18 in the *MAPK8IP* gene-related amplicon and the sperm count (P ≤ 0.014, P ≤ 0.032, and P ≤ 0.030, respectively).

Limitations, reasons for caution: The number of samples is small to obtain a strong conclusion, so more samples is needed to elucidate the effects of these alterations in sperm DNA methylation pattern on male fertility.

Wider implications of the findings: The results of the present study suggest that the cigarette smoking affects sperm DNA methylation patterns. Besides, this finding may explain some causes of male infertility.

Trial registration number: No.

P-015 The effect of BMI on semen quality with an assessment of the new 2010 WHO Laboratory Manual for the Examination of Human Semen- a meta-analysis

R. Sharma[1], S. Esteves[2], A. Harlev[3,4], A. Agarwal[4]

[1]*Saint Joseph's University, Department of Health Services, Philadelphia, U.S.A.*
[2]*ANDROFERT- Andrology and Human Reproduction Clinic, Referral Center for Male Reproduction, Campinas- SP, Brazil*
[3]*Fertility and IVF unit, Soroka University Medical Center- Ben Gurion University of the Negev, Beer Sheva, Israel*
[4]*American Center for Reproductive medicine, Cleveland Clinic, Cleveland, U.S.A.*

Study question: To assess the effect of body mass index (BMI) on semen quality based on the new World Health Organization (WHO) manual for laboratory examination of human semen.

Summary answer: Men who are overweight (OW) or obese (OB) show decline in all semen parameters and clinical pregnancy rate achieved through ART cycles.

What is known already: Obesity is considered as a risk factor for male infertility. Its prevalence has doubled worldwide since 1980. Recent studies have suggested an increased risk of abnormal semen parameters, including concentration, motility, and morphology among overweight and obese men. However, the evidence is not unequivocal, and some studies have found no effect of obesity/overweight on sperm quality. Therefore, this study sought to assess the effect of BMI on semen parameters according to the new WHO criteria for the laboratory examination of human semen.

Study design, size, duration: A systematic search was conducted using MEDLINE/PubMed, SJU discover and Google Scholar to identify all relevant studies published from 2010 to 2017 (January) corresponding to the release of the 2010 WHO manual. Participants were from fertility/urological clinics and general population. The outcome measures were semen volume, sperm count, motility, and morphology. Clinical pregnancy rate (CPR) assessed in couples following ART was used as an outcome measure to evaluate fecundity.

Participants/materials, setting, methods: Participants were males aged 13 years and older regardless of population size and origin. Each semen parameter was evaluated separately and independently. The study groups were stratified and compared according to BMI categories based on WHO classification - Normal, Overweight, and Obese. Subgroup analysis included the comparison of WHO 2010 manual (Fifth Edition) versus 4 previous editions.

Main results and the role of chance: We used 18 studies in the meta-analysis, involving 21,011 subjects. Semen volume (MD -0.11 mL, [95% CI -0.17, -0.04], P = 0.001), and morphology (MD -1.55%, [95%CI -2.54, -0.55], P = 0.002) were significantly reduced in OW group when compared to men with normal BMI. Sperm concentration, motility, total progressive motile sperm count and CPR achieved through ART were also reduced in OW men. Obese men as compared to men with normal BMI showed a

significant decline in semen volume (MD -0.22 mL, [95% CI -0.34, -0.11], P < 0.001), sperm count (MD -8.26 × 10^6/mL, [95% CI -13.42, -3.10], P = 0.002), motility (MD -4.89% [95% CI -6.74, -3.04], P < 0.001), morphology (MD -1.91%, [95%CI -3.16, -0.65], P = 0.003), total progressive motile sperm count (MD -20.27 × 10^6 [95% CI -38.26, -2.29], P = 0.03) and CPR achieved through ART (OR 0.78% [95% CI 0.62, 0.98], P = 0.04). The recent changes in the 2010 WHO reference values for semen parameters had no observed negative effect on an association between BMI and sperm quality in overweight and obese men, but motility results in obese men were equivocal. Subgroup analyses based on the study participant type did not affect heterogeneity estimates

Limitations, reasons for caution: The meta-analysis did not include any randomized trials since a randomized trial to assess the impact of BMI is not possible. We conducted a thorough bias evaluation of the included studies.

Wider implications of the findings: Pooled results from evaluated studies suggest that BMI negatively affects sperm quality and fecundity. The full clinical implications of the 2010 WHO criteria on the association between BMI and human semen quality deserves further investigation as does the effect of BMI on natural fecundity rates.

Trial registration number: Not applicable.

P-016 The downstream signaling pathways of perfluorooctanesulfonate (PFOS)-induced disruption of blood-testis barrier – disorganization of F-actin-based and microtubule-based cytoskeleton in Sertoli cells

W. Lee, Y. Gao, C.Y. Cheng

University of Hong Kong, School of Biological Sciences, Pokfulam, Hong Kong

Study question: We sought to investigate the involvement of Akt (Ak strain transforming) pathway in the PFOS-induced Sertoli cell injury and to explore the rescue process.

Summary answer: PFOS exerts its disruptive effects on Sertoli cell function downstream through Akt1/2. The PFOS-induced male dysfunction can be managed through an intervention on Akt1/2 expression.

What is known already: Earlier study in our laboratory has shown that the PFOS-mediated Sertoli cell injury that impedes blood-testis barrier (BTB) function is through a disruption of actin-based cytoskeleton in Sertoli cells involving an activated form of FAK (p-FAK-Y407). This notion was further confirmed by using an endogenous miRNA specific for FAK, miR-135b, which was found not only perturbed the Sertoli TJ-permeability barrier alone, but also worsened PFOS-induced TJ-barrier disruption. Studies in other mammalian cells have shown that FAK is the upstream signaling protein of Akt, and these two signaling proteins often work as close partners to modulate a number of cellular functions.

Study design, size, duration: In order to better understand the signaling pathway of FAK-mediated rescue function during PFOS-induced Sertoli cell injury, we sought to examine the involvement of Akt in PFOS-mediated Sertoli cell injury, and its functional relationship with p-FAK-Y407 using an in vitro model of Sertoli cell blood-testis barrier.

Participants/materials, setting, methods: Sertoli cells isolated from 20-day-old rat testes were cultured in vitro for 3 days to form a cell epithelium with an established functional TJ-barrier. Thereafter, these cells were treated with PFOS at 10, 20 or 50 μM for 24 hr.

Main results and the role of chance: PFOS was found to induce Sertoli cell injury by perturbing actin cytoskeleton through changes in the spatial expression of actin regulatory proteins. Specifically, PFOS caused mis-localization of Arp3 (actin-related protein 3, a branched actin polymerization protein) and palladin (an actin bundling protein). These disruptive changes thus led to a disorganization of F-actin across Sertoli cell cytosol, causing truncation of actin microfilament, thereby failing to support the Sertoli cell morphology and adhesion protein complexes (e.g., occludin-ZO-1, CAR-ZO-1, and N-cadherin-ß-catenin), through a down-regulation of p-Akt1-S473 and p-Akt2-S474. The use of SC79, an Akt1/2 inhibitor, was found to block the PFOS-induced Sertoli cell injury by rescuing the PFOS-induced F-actin dis-organization. These findings thus illustrated that PFOS-mediated Sertoli cell BTB disruption can be rescued by the use of an Akt activator SC79, which apparently exerts its effects by re-

establishing the underlying actin- and MT-based cytoskeletons, restoring the localization of BTB-associated adhesion protein complexes. This thus reseals the disrupted Sertoli cell TJ-permeability barrier induced by PFOS.

Limitations, reasons for caution: In summary, we have demonstrated that PFOS exerts its disruptive effects on Sertoli cell function downstream through Akt1/2. As such, PFOS-induced male reproductive dysfunction can possibly be managed through an intervention on Akt1/2 expression.

Wider implications of the findings: Supported by General Research Fund 771513 of Hong Kong Research Grants Council and NSFC/RGC Joint Research Scheme N_HKU717/12.

Trial registration number: N.A.

P-017   Assessment of sperm ploidy status by flow cytommetry correlates to embryo quality

M. Sánchez[1], A. Pacheco[1], M. Cruz[2], A. Requena[3]

[1]IVI Madrid, Andrology Lab, Madrid, Spain
[2]IVI Madrid, IVF Lab, Madrid, Spain
[3]IVI Madrid, Reproductive Medicine, Madrid, Spain

Study question: To assess, by using flow cytometry, the effect of sperm ploidy status on embryo quality following an *in vitro* fertilization treatment

Summary answer: Sperm ploidy condition constitutes a critical parameter for the evaluation of semen samples before an assisted reproductive treatment

What is known already: Male infertility is a contributing factor in up to 50% of all infertility cases. New and improved diagnostic methods that reduce inter/intra variability should be evaluated. Flow cytometry has been an outstanding tool to evaluate sperm cells for achieving a better reproductive condition. The implementation of this technique in order to evaluate sperm ploidy, is contributing to the discrimination of spermatozoa from subfertile men in an objective way, leading to a reproducible assessment of male infertility, especially in candidates for an assisted reproductive treatment

Study design, size, duration: Prospective and observational study. Sixty seminal samples coming from sperm donors (n = 30) and subfertile patients (n = 30) were analyzed by flow cytometry in IVI Madrid from June to December 2016. Furthermore, in order to analyze if there were any correlation between sperm ploidy and embryo quality, we evaluated clinical outcomes from 30 couples included in our oocyte donation program; all these couples underwent an ICSI procedure and a fresh embryo transfer

Participants/materials, setting, methods: Semen analysis was performed according to World Health Organization guidelines. Ploidy determination was performed by using propidium iodide (PI) staining in combination with sperm flow cytometry; the resulting cell suspension (n = 20000 cells/sample) was examined. For describing the correlation between ploidy and other sperm and embryo parameters, linear functions were approximated and the Pearson's correlation coefficient (r) was determined. Differences were considered to be significant if the probability of their occurrence by chance was <0.05.

Main results and the role of chance: We found significant differences in some of the analyzed variables between patients and donors respectively. From semen analysis, data were as follows: ejaculation volume (ml) 2.8 vs. 3.5, p = 0.027; sperm concentration (million/ml) 43.6 vs. 70.9, p < 0.001; total sperm number (million) 122.4 vs. 234.6, p < 0.001; progressive motility (%) 36.7 vs. 58.5, p < 0.001; total motility (%) 47.8 vs.139.0 p = 0.001. Data derived from sperm ploidy showed significant differences in the percentage of subploid cells between patients (20.4%) and donors (8.1%), p < 0.001; similar results were obtained for haploid cells (75.6 % vs. 84.3%, p = 0.011)

According the correlation between sperm ploidy and some embryo features, we observed a positive correlation in the fertilization rate (r = 0.398) and in the number of viable embryos (r = 0.454) as well as the percentage of haploid cells increased in the seminal sample. On its behalf, seminal samples with a higher rate of subploid cells were significant negative correlated with both variables, r = 0.265 and r = 0.459 for the fertilization rate and viable embryos respectively.

Limitations, reasons for caution: Flow cytometry is a screening method in which is not possible to perform a precise determination of aneuploidies of specific chromosomes; moreover, we cannot quantify the degree of DNA damage within a single cell

Wider implications of the findings: Although conventional semen analysis maintain its central role in assessing male fertility, is often insufficient to provide definitive diagnosis. Implementing flow cytometry in the daily's practice due to its higher sensibility and lower cost could help many couples undergoing unexplained infertility to improve clinical outcomes within an assisted reproductive treatment.

Trial registration number: Does not apply.

P-018   Loss of both OSR1 and SPAK in Sertoli cells manifest Sertoli cell-only-like syndrome in mice

Y.L. Liu[1,2], S.S. Yang[3,4], F.W. Chang[1], H.K. Sytwu[3,5,6], G.J. Wu[1,3]

[1]Department of Obstetrics and Gynecology, Tri-Service General Hospital, National Defense Medical Center
[2]Department of Obstetrics and Gynecology, Tri-Service General Hospital Penghu Branch, Penghu 880, Taiwan
[3]Graduate Institute of Medical Sciences, National Defense Medical Center, Taipei 114, Taiwan
[4]Division of Nephrology, Department of Medicine, Tri-Service General Hospital
[5]Department and Graduate Institute of Microbiology and Immunology, National Defense Medical Center, Taipei 114, Taiwan
[6]Graduate Institute of Life Sciences, National Defense Medical Center, Taipei 114, Taiwan

Study question: What is the modulatory role of oxidative stress-responsive kinase-1 (OSR1) and STE20 (sterile 20)/SPS1-related proline/alanine-rich kinase (SPAK) in Sertoli cells?

Summary answer: The OSR1 and SPAK are vital in Sertoli cell support spermatogenesis. Loss of both OSR1 and SPAK in Sertoli cells caused spermatogenesis arrest.

What is known already: OSR1 and SPAK are upstream regulators of Na^+-K^+-2Cl$^-$ cotransporters. Most studies have revealed their roles in the regulation of blood pressure and cell volume. We previously generated Sertoli cell-specific OSR1 combined with global SPAK double knockout mice. These male mice are infertile with defective spermatogenesis, indicating that Sertoli cell function is impaired.

Study design, size, duration: This time, we generated Sertoli cell-specific OSR1 and SPAK double knockout mice to further elucidate the physiological roles of OSR1 and SPAK in Sertoli cells.

Participants/materials, setting, methods: We assessed male fertility in these tissue-specific double knockout mice. Testes of adult mice were evaluated by histology. Immunofluorescence staining and RT-qPCR were performed to further identify the cellular composition of these double knockout mice. Moreover, the first wave of spermatogenesis was analyzed to evaluate key time points for germ cell development.

Main results and the role of chance: These male Sertoli cell-specific double knockout mice were infertile. The adult testicular histology revealed Sertoli cell-only-like syndrome. Immunofluorescence staining supported that most cells within seminiferous tubules showed Sertoli cell-specific markers, GATA-1 and SOX9. Moreover, most germ cell-specific genes were barely detected in RT-qPCR. Furthermore, no obviously round spermatids were found in these mice during the first wave of spermatogenesis, indicating that absence of OSR1 and SPAK in Sertoli cells caused spermatogenesis arrest.

Limitations, reasons for caution: This study is mainly performed in the mouse model. Application of this mutant model in the patients with Sertoli cell-only syndrome needs further studies.

Wider implications of the findings: This study provides that OSR1 and SPAK are potential biomarkers for the assessment of human male infertility.

Trial registration number: All animal experiments were approved by the Institutional Animal Care and Use Committees (IACUC) in Taiwan.

P-019   Differential sperm DNA fragmentation of X- and Y-chromosome bearing human spermatozoa

X. Shi, T.C. Li, C.P.S. Chan, L. Chi, J. Huang, D.Y.L. Chan

The Chinese University of Hong Kong, Department of Obstetrics and Gyneacology, Hong Kong, Hong Kong

Study question: Do X- and Y- chromosome bearing spermatozoa have different levels of DNA fragmentation?

Summary answer: Sperm DNA fragmentation level of Y- chromosome bearing spermatozoa was significantly higher than X- chromosome bearing spermatozoa in pathozoospermic subjects, but not in normozoospermic subjects.

What is known already: Sperm DNA fragmentation could be induced by suboptimal testicular and epididymis environment. The Y chromosome of sperm has been considered particularly vulnerable to DNA damage, partly because of its genetic structure and partly because it cannot correct double-stranded DNA fragments by homologous recombination. An early mice study demonstrated that X- chromosome bearing spermatozoa are more robust to irradiation induced DNA damage than Y- chromosome bearing spermatozoa. However, direct evidence is lacking regarding whether X- and Y- chromosome bearing sperm has different susceptibilities to DNA fragmentation.

Study design, size, duration: This is a cross sectional study, which included 100 men who underwent routine fertility assessment between November 2015 and June 2016.

Participants/materials, setting, methods: Fifty normozoospermic men (Group I) and fifty pathozoospermic men (Group II) were recruited in this study. All participants received routine semen analysis at the IVF unit of Prince of Wales Hospital, the Chinese University of Hong Kong. DNA fragmentation states and sex chromosome complement were assessed by a combined test of sperm chromatin dispersion (SCD) and fluorescence in situ hybridization (FISH), followed by an observation of at least 300 spermatozoa/sample under florescent microscope.

Main results and the role of chance: We found, for the first time, in our study that the median level of DNA fragmentation in Y- chromosome bearing spermatozoa was significantly ($P < 0.05$) higher than that of X- chromosome bearing spermatozoa when all subjects were considered together (23.5% and 20.4% respectively) or in Group II (25.9% and 22.5% respectively), but not ($P > 0.05$) in Group I (17.2% and 17.3% respectively). We also observed several findings which were in line with previous studies: (1) DNA fragmentation level is correlated with both sperm concentration [regression coefficient (RC) 95% confidence interval (CI): 0.08 (0.01 to -0.15); $P = 0.03$] and motility (RC (95% CI): -0.33 (-0.48 to -0.17); $P < 0.001$); (2) DFI and sex chromosome disomic rate of subjects in the pathozoospermic group [median(IQR): 4.81%(2.73%-8.98%)] was significantly higher ($P = 0.01$) than subjects in the normozoospermic group [median(IQR): 2.40%(1.79-4.78%)].

Limitations, reasons for caution: We did not assess the autosomes complement of spermatozoa in our study. As a result, we cannot determine the impact of autosomes aneuploidy on sperm DNA fragmentation.

Wider implications of the findings: Y- chromosome bearing spermatozoa are more susceptible to DNA damage under suboptimal testicular environment, especially in pathozoospermic subjects. The clinical relevance of the finding requires further investigation.

Trial registration number: N/A.

P-020 **The role of sperm surface galectin-3 on spermatozoa-zona pellucida binding in humans**

S. Mei, C.L. Lee, K.K.W. Lam, W.S.B. Yeung, P.C.N. Chiu

The University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Is galectin-3 involved in human spermatozoa-zona pellucida (ZP) interaction?

Summary answer: Is galectin-3 involved in human spermatozoa-zona pellucida (ZP) interaction?

What is known already: A spermatozoon acquires its fertilization capacity within the female reproductive tract by capacitation. Spermatozoa-ZP receptor is suggested to be a composite structure that are assembled into a functional complex during capacitation. In the male reproductive tract, galectin-3, a carbohydrate binding protein, has been identified in Sertoli cells, epididymis, seminal plasma and ejaculated spermatozoa.

Study design, size, duration: The origin and cellular localization of sperm galectin-3 were studied. The roles of galectin-3 on sperm functions were assessed by functional blocking anti-galectin-3 antibody and galectin-3 competitive carbohydrate substrate. Ejaculated sperm were obtained from semen

samples from normozoospermic men. For epididymal sperm samples, donated cryopreserved epididymal spermatozoa from men who have undergone assisted reproduction with microsurgical epididymal sperm aspiration and have completed their family were used. Human oocytes were obtained from an assisted reproduction program.

Participants/materials, setting, methods: Extracellular vesicles (EVs) in seminal plasma were purified by ultrafiltration. The expressions of galectin-3 in seminal plasma/EVs and spermatozoa were studied by transmission electron microscopy, western blotting or immunostaining. Sperm functions including motility, viability, acrosome reaction and ZP-binding capacity were assessed by standard assays.

Main results and the role of chance: The expression of galectin-3 on ejaculated spermatozoa (uncapacitated or capacitated) was much higher than that of epididymal spermatozoa, indicating that galectin-3 is acquired after leaving the testis. This possibility is supported by the presence of galectin-3 in the EVs of human seminal plasma, which are capable of transferring proteins to the sperm plasma membrane. Galectin-3 immunoactivity was further demonstrated to be localized in the post-acrosomal region of uncapacitated spermatozoa. It was translocated to the apical region of spermatozoa after capacitation, a region known to bind ZP. Blocking of galectin-3 function by specific antibody or competitive substrates against galectin-3 reduced the ZP-binding capacity of human spermatozoa.

Limitations, reasons for caution: The mechanisms by which EV-derived galectin-3 transfer to the sperm surface have not been depicted.

Wider implications of the findings: The results indicate the possible use of galectin-3 content in seminal plasma and sperm surface as test for prediction of fertilization potential of semen samples.

Trial registration number: NA.

P-021 **Sperm morphology and motility alterations do not predict bipolar spindle assembly defects in the egg cytoplasm**

F. Amargant[1], M. Barragán[1], A. Rodríguez[1], R. Vassena[1], I. Vernos[2]

[1]Clínica EUGIN, EUGIN, Barcelona, Spain
[2]Center for Genomic Regulation, CRG, Barcelona, Spain

Study question: Is there a relationship between sperm morphology/motility and their ability to support bipolar spindle assembly?

Summary answer: Spermatozoa were able to build bipolar spindles regardless of their morphology/motility.

What is known already: Despite significant advances in the in vitro culture of human embryos, around 30% of fertilized oocytes arrest their development during early cell divisions. This suggests that functional defects of the sperm cell, such as the failure to fuse the pronuclei or to build the bipolar spindle, could be partially responsible for these arrests. To test this possibility, we first established an ex-vivo system with *Xenopus laevis* egg extract (XEE) and then used it to obtain quantitative data on the ability of human sperm sample with different diagnosis to support bipolar spindle assembly.

Study design, size, duration: We analyzed 20 human sperm samples with different clinical outcomes, and different morphology and motility: normozoospermic (N, n = 11), astenozoospermic (A, n = 2), teratozoospermic (T, n = 4), astenoteratozoospermic (AT, n = 3). Each sperm sample was incubated in 4 different XEE preparations. The sperm capacity to build bipolar spindles in XEE was analyzed by immunofluorescence, and the contribution of the sperm centrosome was dissected by interfering with one of the microtubule assembly pathways.

Participants/materials, setting, methods: The cytoplasmic layer of MII *Xenopus* eggs were isolated and 3000 Xenopus or human spermatozoa, treated with Triton X-100 and DTT, were incubated in XEE at 20°C for up to 150 min. The presence and overall morphology of spindles formed upon incubation of 200 human spermatozoa were correlated with the corresponding clinical data. To study more specifically the chromosomal and the centrosomal microtubule assembly pathways, the system was perturbed by cold treatment or recombinant protein addition.

Main results and the role of chance: We established a quantitative ex-vivo experimental system based on the use of XEE and human spermatozoa for functional studies. A time-course analysis showed that the human sperm cells

incubated in XEE require a longer time (40 minutes) than the control *Xenopus* sperm nuclei (10 min) to promote microtubule assembly and this regardless of their clinical diagnosis. Complementation assays showed that the sperm centrosome become competent for nucleating microtubules. During interphase, the human sperm centrosome duplicates and the sperm DNA undergoes a partial and rapid decondensation during the first 10 minutes of XEE incubation (area from $17,3 \pm 5,40$ to $55,9 \pm 16,26 \, \mu m^2$ on average), followed by a 50 min of steady state, before undergoing full nuclear decondensation ($156,2 \pm 38,80 \, \mu m^2$ on average). Upon entry into mitosis, the duplicated centrosomes localize correctly to the spindle poles even for samples with low motility (*Xenopus*=41%, N = 42,6%, A=41,1). Moreover samples with a variety of diagnosis assemble bipolar spindles with similar efficiency (Bipolar spindles%: N = $62,4 \pm 8,64$; A=$58,1 \pm 3,01$; T=$52,0 \pm 16,34$; AT=$58,1 \pm 2,66$. Abnormal spindles%: N = $24,2 \pm 10,66$; A=$31,06 \pm 1,32$; T=$31,2 \pm 4,02$; AT = $29,0 \pm 6,50$, p>0,05).

Overall, our results suggest that human spermatozoa can drive bipolar spindle assembly when incubated in oocyte cytoplasm even when they present defects in morphology and motility.

Limitations, reasons for caution: In these experiments we did not address directly the functionality of the centrosome. Since during the early embryonic divisions spindle assembly is mainly dependent on the chromosomal dependent microtubule assembly pathway, defective centrosomes (reflected, for example, in defects in pronuclei apposition) may not be detected.

Wider implications of the findings: We established a heterologous system to obtain quantitative data on the human sperm functional capacity to support bipolar spindle assembly. Our data suggest that sperm morphology and motility defects do not interfere directly with the assembly of the bipolar spindle in the human embryo.

Trial registration number: NA.

P-022 Sperm affinity for hyaluronic acid relates to sedimentation properties in density gradients and to sperm chromatin integrity

F. Torabi, D. Miller

University of Leeds, Faculty of Medicine and Health, Leeds, United Kingdom

Study question: Is sperm selection by hyaluronic acid (HA) binding at least as good as selection by density gradient centrifugation (DGC, 90%:45%) in relation to chromatin integrity?

Summary answer: 90% and HA binding sperm have lower levels of DNA fragmentation and higher levels of chromatin compaction than 45% and HA non binding sperm.

What is known already: Many ART laboratories rely on differential density gradient centrifugation (DDGC) or swim-up to obtain sperm suitable for IVF or ICSI. Sperm preparation by hyaluronic acid (HA)-binding could be an appropriate alternative if it was shown to be as effective and had any advantages over these standard methods. HA binding proteins (HABPs) appear on the matured sperm plasma membrane and bind HA in the extracellular calyx surrounding the cumulus-oopherous complex. This phenomenon can be considered part of a 'capture' mechanism that may 'select' for higher quality sperm with lower levels of DNA fragmentation and high chromatin compaction.

Study design, size, duration: An investigation into DNA fragmentation, chromatin compaction and the location of HABPs in sperm obtained by DGC or after HA-binding of 16 washed semen. The study is part of a three year PhD programme sponsored by the EU Marie Curie Training network.

Participants/materials, setting, methods: DNA fragmentation and chromatin compaction were assessed using acridine orange (AO) and aniline blue (AB) staining, respectively in samples from males with unproven fertility (N = 16) resolved into 90% and 45% fractions or in samples binding or not to hyaluronic acid. HA binding affinity was assessed in pelleted and interface fractions and HABPs were evaluated by immunocytochemistry.

Main results and the role of chance: Higher capacity for sperm hyaluronic-acid-binding was shown to correspond with their DDGC sedimentation profiles.

Strong, statistically significant relationships between AO/AB staining and sperm sedimentation and hyaluronic-acid-binding were revealed. Sperm resolving in the 90% fraction or binding to HA had lower levels of DNA fragmentation and higher levels of chromatin compaction than sperm resolving in the 45% fraction or not binding to HA. Sperm capacitation enhanced HA binding of both 90% sperm and sperm washed free of seminal fluid that may reflect associated changes in the expression of HA-binding proteins.

Immunocytochemistry showed that the HABP CD44 was located mainly on the sperm acrosome and equatorial segment and became more restricted to the equatorial segment in capacitated spermatozoa. Hyaluronic acid-TRITC, a generic probe for detection of HABPs labelled the membrane and the neck region, and capacitation intensified the signal.

The results show that by measures of DNA fragmentation and chromatin compaction, standard, correctly done DGC is good at enriching for good quality sperm for IVF or ICSI or quid pro quo, excluding poor quality sperm from a sample. Under circumstances where sperm count is very low or DGC cannot be carried out, HA binding should be considered. Investigations into sperm HABPs are continuing.

Limitations, reasons for caution: The study used 16 normozoospermic men of unproven fertility. While not diminishing the study findings, future inclusion of men with proven fertility or idiopathic infertility would be helpful.

Wider implications of the findings: These data support the argument for further research into HA-based sperm selection, particularly for ICSI, where the choice of sperm is more critical.

Trial registration number: The study is not a clinical trial.

P-023 The beneficial role of CoQ10 supplementation in male infertility: fact or fiction?

A. Moazamian, P. Gharagozloo

CellOxess LLC, Research & Development, Ewing, U.S.A.

Study question: To evaluate if oral supplementation with CoQ_{10} improves semen parameters and male fertility potential.

Summary answer: The evidence supporting the use of CoQ10 in male infertility is inadequate, but its oral intake appears to augment mitochondrial α-tocopherol content.

What is known already: Men with high levels of oxidative stress (OS) may be subfertile or infertile, expose their female partners to higher risk of miscarriage, and pass on *de novo* genetic and epigenetic changes to their offspring. To combat OS, many natural antioxidants have found widespread use in the management of male infertility but often without sufficient scientific or clinical evidence. Naturally synthesized by all animals, Coenzyme CoQ_{10} (CoQ_{10}) is a critical component to the mitochondrial electron transport chain. The bioenergetic and antioxidant role of this molecule suggest possible involvement in sperm biochemistry and therefore the male fertility potential.

Study design, size, duration: This review focuses on the latest evidence from human clinical trials but also closely examines the evidence from biochemical studies documenting the importance of CoQ_{10} molecule to male reproductive health.

Participants/materials, setting, methods: A systematic and detailed review of the scientific literature including analysis of human clinical trials, *in vitro/vivo* studies and a stringent set of medicinal and pharmacological criteria were used to critically examine the role of CoQ_{10} in the management of male infertility.

Main results and the role of chance: The beneficial use of exogenous CoQ_{10} supplementation in the management of male infertility remains controversial. To date, 15 low-medium grade clinical trials have been performed. Only three trials were randomized, placebo-controlled, double-blind studies but only one reports minor improvement in sperm motility with no rise in pregnancy or live-birth rates. Additionally, the oral intake of CoQ_{10} is allied with a rise in mitochondrial concentration of α-tocopherol (common form of Vitamin E). Interestingly, as an antioxidant, CoQ_{10} only has $1/10^{th}$ the reactivity of α-tocopherol with much poorer oral bioavailability. These observations suggest that the minor, beneficial effect seen with CoQ_{10} supplementation reported in some trials may be incidental and attributable to an increase in cellular Vitamin E content.

Limitations, reasons for caution: Our findings are largely based on the results of many low quality clinical trials conducted with CoQ_{10} oral supplementation. To definitively determine the potential value of CoQ_{10} in the

management of male infertility, a large, placebo-controlled randomized clinical trial in a 2 × 2 factorial-blinded design with Vitamin E is required.

Wider implications of the findings: The evidence surrounding the beneficial use of CoQ10 supplementation in the management of male infertility is minor and circumstantial, so its widespread use among fertility experts should be deferred until data from high quality clinical trials becomes available.

Trial registration number: n/a.

P-024 Sperm DNA fragmentation and semen hyperviscosity in human samples

V. Zazzaro, F. Scarselli, M.G. Minasi, A. Ruberti, E. Cursio,
A. Colasante, V. Casciani, A. Pristerà, S. Muzzì, P. Greco,
M.T. Varricchio, A. Caragia, E. Greco

European Hospital Rome, Medicina della riproduzione, Rome, Italy

Study question: Is there a possible correlation between sperm DNA fragmentation and semen viscosity?

Summary answer: Semen hyperviscosity wouldn't seem to be related with higher DNA fragmentation values.

What is known already: It has been shown that semen hyperviscosity is associated with poor outcomes in Assisted Reproduction Techinques (ART). Moreover fertilization rate, positive β-HCG, clinical pregnancy and implantation rates after intra cytoplasmatic sperm injection (ICSI) are significantly lower in patients with hyperviscous semen. In literature hyperviscous samples are characterized by a significant lower percentage of sperm concentration and progressive motility. This could explain, at least in part, the lower fertilization rates. In addition, it has been reported that in hyperviscous samples, oxidative stress is increased, as well as chromatin integrity and packaging defects.

Study design, size, duration: From January 2009 to December 2016, data from 6846 semen samples were collected and retrospectively analyzed. Evaluated semen parameters were sperm viscosity, volume, concentration, motility and morphology according to WHO 2010. DNA fragmentation was detected by TUNEL, using the commercially available In situ Cell Death Detection Kit (Roche).

Participants/materials, setting, methods: Seminal viscosity was assessed by aspiration of the sample into a glass Pasteur pipette. Ejaculates with normal viscosity had a thread length of ≤ 2 cm. Sample's parameters were evaluated according to the WHO 2010 guidelines. A TUNEL positive semen was defined as a sample with DNA fragmentation > 20%. Correlations between seminal fluid viscosity and TUNEL value, sperm volume, concentration, motility and morphology were tested with t-student test (level of significance was P< 0.05).

Main results and the role of chance: Of the 6846 semen samples, 4951 showed normal viscosity (Normal Viscosity Group, NVG), whereas 1895 had high viscosity (High Viscosity Group, HVG). Mean men age was 40.1 ± 7.9 and 40.5 ± 7.9 in NVG and HVG, respectively (NS). Sperm concentration (million/ml) was statistically higher in NVG (30.7 ± 20.1) then in HVG (29.1 ± 19.2) (P < 0.05). Sperm motility was significantly higher in NVG (58.1 ± 16.7) then in HVG (53.9 ± 17.6), (P < 0.05). Sperm morphology was statistically different between the two groups (4.5 ± 3.4% in NVG and 4.2 ± 3.1% in HVG) (P < 0.05). In NVG, 472/4951 semen samples examined (9.5%) were TUNEL positive whereas, in HVG, 174/1895 (2.5%) semen samples examined were TUNEL positive (NS). According to our data, there is no correlation between hyperviscosity and fragmentation in examined semen samples. As for motility and morphology it is clear that hyperviscous samples present lower values of these parameters.

Limitations, reasons for caution: Tunel test is a diagnostical test and it is not applicable in the practical routine. In this study patients' medical history is not known; previous infections, prostatic affection or medical therapy may interfere with semen viscosity. Also age may affects sperm viscosity and sperm concentration, motility and morphology.

Wider implications of the findings: Since TUNEL detects only necrosis and final apoptosis effects, and not earlier ones, further studies are needed on sperm chromatin structure and oxidative stress in hyperviscous human semen such as Mitocondrial Membrane Potential Study (JC-1) or Magnetic Cells Sorting (MACS).

Trial registration number: Not applicable.

P-025 Ejaculate vs surgical spermatozoa in severe male factor: which is the best choice?

E. Cursio[1], F. Scarselli[2], M.G. Minasi[2], A. Ruberti[2], M.C. Greco[2],
G. Nastri[2], V. Zazzaro[2], M.T. Varricchio[2], A. Caragia[2], A. Biricik[3],
F. Spinella[3], F. Fiorentino[3], E. Greco[2]

[1]*European Hospital, Centre for reproductive medicine, Rome, Italy*
[2]*European Hospital, Centre for reproductive medicine, Roma, Italy*
[3]*genoma Molecular Genetics Laboratory, Genetics, ROMA, Italy*

Study question: Could conventional testicular sperm extraction (cTESE) be a good strategy after one or more previous cycles without implantation in couples with a severe male factor?

Summary answer: In couples where male-partner present severe oligoasthenoteratozoospermia (OAT), proceeding to intracytoplasmatic sperm injection with ejaculated or testicular sperm would seem to lead to similar outcomes.

What is known already: Severe male factor constitutes about 30% of the infertility causes. Couples undergoing ICSI with severe OAT, risk a failure of the treatment because of the low fertilization and cleavage rates. To reduce cycle cancellation rate, a cleavage stage embryo-transfer is usually performed. The reasons of the low success rate could be a DNA damaged by Reactive Oxygen Species (ROS), improper DNA-packaging, nuclear decondensation, varicocele, infections or iatrogenic causes. Testicular sperm in this patients could give a better outcome, since this spermatozoa present a shorter time of exposition to ROS compared to ejaculated, a lack of infection and better DNA-packaging.

Study design, size, duration: In this prospective study, performed from June 2013 to December 2016, 18 couples which underwent a second or third cycle of assisted reproduction with Pre-implantation genetic screening (PGS) after previous implantation failure, were enrolled. All male-partners were affected by severe OAT (WHO 2010). All blastocysts were frozen immediately after the biopsy and a frozen-thawed single embryo-transfer (sFET) were performed in a subsequent cycle. Mean female and male ages were 34.05 ± 3.52 and 34.77 ± 3.94 years old, respectively.

Participants/materials, setting, methods: Mature oocytes retrieved were injected and cultured individually until blastocyst stage at 37°C, 6%CO_2, 5%O_2. Male partners were asked a single or double semen collection. On the day of oocytes pick-up, males underwent cTESE. Both ejaculated and testicular sperm samples were processed by washing. After denudation, approximately half of mature eggs were injected with ejaculated sperm and half with testicular one. In all patients histological analysis was performed and they all resulted hypospermatogenesis.

Main results and the role of chance: A total of 207 mature oocytes were injected; 99 with ejaculated (EG) and 108 with testicular (TG) spermazoa. Fertilization rates were 62.6% (N = 62) and 57.4% (N = 62) in EG and TG, respectively (NS). An amount of 5.0% (N = 5) and of 3.7% (N = 4) of the injected oocytes presented an irregular fertilization (3PN) in EG and TG, respectively (NS). Degenerated eggs after ICSI were 4.0% (N = 4) and 3.7% (N = 4) in EG and TG, respectively (NS). Blastocyst formation rates were 46.8% (N = 29) and 53.2% (N = 33) in EG and TG, respectively (NS). After biopsy, 31.0% (N = 9) and 30.3% (N = 10) of the blastocysts resulted euploid in EG and TG, respectively (NS). In EG, 4 euploid blastocysts were transferred in 4 sFET resulting in a clinical pregnancy rate (CPR) of 75.0% (N = 3) and an implantation rate (IR) of 75% (N = 3). In TG, 5 sFET were performed transferring 5 euploid blastocysts obtaining the CPR and IR of 100%. One of the clinical pregnancies of this group resulted in an early abortion. The other pregnancies are still ongoing.

Limitations, reasons for caution: Sample size is still too low and it should be enlarged; furthermore a high number of mature oocytes available for the injection per patient is needed. Finally, most of the euploid obtained blastocysts have still to be transferred before drawing final conclusions.

Wider implications of the findings: In case of male with severe OAT it should be carefully evaluated if performing cTESE is an efficient strategy after previous implantation failure. Blastocysts obtained injecting ejaculated or testicular sperm would seem to have the same ploidy rate and the same implantation potential.

Trial registration number: Not applicable.

P-026 HYDROGEN TREATMENT IS SAFETY FOR HUMAN SPERM NUCLEI

K. Nakata[1], K. Yoshida[2], M. Yoshida[3], N. Yamashita[4]

[1]Yamashita shonan yume clinic, Reproductive Medicine Reserch Center, Kanagawa, Japan
[2]Toin University of Yokohama, Faculty of Biomedical Engineering, Yokohama, Japan
[3]The University of Tokyo, Misaki Marine Biological Station- Graduate School of Science, Kanagawa, Japan
[4]Yamashita shonan yume clinic, Doctor, Kanagawa, Japan

Study question: Is the hydrogen treatment safe on the nuclei of human sperm?

Summary answer: We found that the H_2 treatment does not cause nuclear DNA fragmentation or cell death of human sperm.

What is known already: H_2 treatment remarkably improved rate of forward motility of human spermatozoa, whereas N_2 treatment did not. H_2 treatment also increased the mitochondrial membrane potential of human sperm. The frozen-thawed sperm from patients that had low motility improved the rate of forward motility after being cultured in a 75% H_2-saturated medium.

The H_2 treatment increases ATP production in the human spermatozoa, and seems to act on the electron transport chain downstream of the action site A or directly acts on oxidative phosphorylation.

Study design, size, duration: We used 140 samples of human sperm with $>2.0 \times 10^6$ cells/mL and >60% motility. DNA Fragmentation of the sperm nuclei was evaluated by the TUNEL, EOSIN and Chromomycin A3 staining methods, and by the CASY cell counting system. At least 150 and 1,500 sperm per sample were examined in the staining methods and the CASY measurements, respectively.

Participants/materials, setting, methods: The sperm samples were from subjects who consented to have their samples used in research. The samples were mixed with TEST Yolk Buffer (TYB) at a ratio of 1:1 to create a suspension that was then frozen in liquid N_2. After thawing, sperm samples were separated into 2 groups; a H_2 group, which was washed in a culture medium containing 75%-saturated H_2, and a control group, which was washed in a culture medium without H_2.

Main results and the role of chance: DNA fragmentation of the sperm nuclei and survival rates were compared between the H_2 and control groups. TUNEL reactions were observed in 1.4% ± 1.9% sperm of the H_2 group and 2.5% ± 3.6% sperm of the control group. No significant difference was seen between the two groups (n = 30, P = 0.98). There was also no significant difference in EOSIN reactions (1.6% ± 4.3% in the H_2 group, and 2.3% ± 5.7% in the control group) (n = 30, P = 0.069). The rates of positive Chromomycin A3 reactions were 2.1% ± 3.6% in the H_2 group, and 4.0% ± 8.0% in the control group: the H_2 group were significantly lower than the control group (n = 50, P < 0.01). The rates of dead sperm found by CASY were 11.8% ± 2.6% in the H_2 group and 11.5% ± 2.7% in the control group, indicating no significant difference between the groups (n = 30, P = 0.69)

Limitations, reasons for caution: This is a basic study on a relatively small sample size with limited conditions. The confirmation using larger samples under various conditions may be required. Furthermore, we need to check the safety of H_2 treated sperm use in ART.

Wider implications of the findings: The findings of this study indicate that H_2 treatment is a safe method of increasing sperm motility and ATP content with minimal damage to cells and their nuclei. It may also be useful in the selection of good quality sperms for ICSI.

Trial registration number: No.

P-027 First case report of successful deliveries of an oligoasthenoteratozoospermia patient and of a repeated fertilization failure patient using ICSI sperm selected by hydrogen treatment

K. Hiroomi[1], K. Nakata[2], N. Yamashita[3]

[1]Yamashita shonan yume clinic, Reproductive Medicine Reserch Center, Fujisawa, Japan
[2]Yamashita shonan yume clinic, Reproductive Medicine Reserch Center, Fujisawa, Japan
[3]Yamashita shonan yume clinic, Doctor, Fujisawa, Japan

Study question: Can oligoasthnoteratozoospermia (OAT) patients and repeated fertilization failure patients take home healthy babies using ICSI sperm selected by hydrogen treatment?

Summary answer: We performed ICSI for patients using sperm selected by hydrogen treatment and transferred fertilized eggs. The patients conceived and delivered healthy babies.

What is known already: The selection of a good sperm is key to the success of ICSI, therefore the development of a safe method that ensures accurate selection is urgently needed.

Empiric treatments such as pentoxifylline have met with limited success and their efficacy and safety are yet to be verified. We have reported that hydrogen treatment elevates the mitochondrial membrane potential and increases the ATP production of OAT sperm. As a result, hydrogen treatment improves the motility of the OAT sperm which has no DNA damage.

Study design, size, duration: The first case involves a 36-year-old male with OAT. ICSI-ETs were performed several times with the couple but all treatments failed. The second case involves a 31-year-old male whose semen analysis showed normal. However, fertilization did not occur with IVF nor ICSI. After obtaining informed consents from these couples we performed ICSI using sperm selected by hydrogen treatment and transferred the egg to the female partner.

Participants/materials, setting, methods: The patients' semen were divided into two groups: the hydrogen treatment group and the control group. Each sample was mixed with 1.5 ml culture medium saturated with 75% hydrogen molecules and separated with density-gradient centrifugation. The pellet was resuspended with 6 ml medium saturated with 75% hydrogen molecules and centrifuged again (hydrogen molecule treatment). The collected sperm were used for ICSI. The control group was processed with a medium not containing hydrogen.

Main results and the role of chance: In both cases the sperm motility rates were significantly improved in the hydrogen molecule treatment groups compared to the control groups. In the first case (OAT case), the female partner's oocyte were not fertilized by ICSI in the control group. The oocytes were fertilized (100%, 5/5), cleaved (100%, 5/5) and developed to the blastocyst stage (75%, 3/4) by ICSI in the hydrogen molecule treatment group. The blastocyst obtained were cryopreserved. In the transfer cycle, the blastocyst was thawed and transferred to her. She conceived and delivered a healthy baby (male, 3184 g). In the second case (fertilization failure case), the female partner oocytes were not fertilized in the control group. The oocytes were fertilized (50%, 1/2), cleaved (100%, 1/1) and developed to the blastocyst stage (100%, 1/1) by ICSI using hydrogen molecule treated sperm. The blastocyst was cryopreserved. The egg was thawed and transferred in the transfer cycle. She conceived and delivered a healthy baby (male, 3440 g).

Limitations, reasons for caution: This study is a case report of an OAT couple and a fertilization failure couple receiving hydrogen molecule treatment as a sperm enhancer and successfully giving birth to healthy babies. More trials are needed to confirm the effectiveness and safety of hydrogen molecule treatment.

Wider implications of the findings: This is the first report of the delivery of a healthy baby for an OAT couple and a fertilization failure couple treated by hydrogen molecules as a sperm enhancer. Hydrogen molecule treatment could be an effective and safe choice for selecting good sperm for ICSI, IVF and IUI.

Trial registration number: No.

P-028 Impact of MTHFR isoform C667T on fertility through sperm DNA fragmentation index (DFI) and sperm nucleus decondensation (SDI)

A. Clement[1], D. Cornet[2], M. Cohen[3], L. Jacquesson[4], E. Amar[5], P. Clement[1], Y. Menezo[6]

[1]Laboratoire Clement, Ile de France, Paris, France
[2]Clinique de la Muette, Ile de France, Paris, France
[3]Natecia, Rhone-Alpes, Lyon, France
[4]40 boulevard de Courcelles, Ile de France, Paris, France
[5]American Hospital of Paris, Ile de France, Neuilly sur Seine, France
[6]London Fertility Associates, London, London, United Kingdom

Study question: Are MTHFR isoforms involved in the subfertility pathologic aspects through sperm nucleus structure parameters (DFI and SDI)?

Summary answer: Based on the threshold values, 40% of the patients tested had a DFI over 20% and 22% had a SDI over 20%.

What is known already: The study of sperm DNA structure is essential in the evaluation of the causes of infertility. DFI is involved in ART failures (Bungum) and afterwards in children's psychic disorders (Evenson). SDI anomalies lead to developmental arrest at early stages and to recurrent ART failures (Junca). According to a recent meta-analysis (Gong), MTHFR polymorphism increases the male infertility risks. MTHFR is a step in the 1-Carbon Cycle (1-CC): it allows the synthesis of major anti-oxidant molecules and correct DNA methylation process, part of epigenetics and imprinting.

Study design, size, duration: This is a retrospective study involving subfertile couples controlled for C677T isoforms in an IVF unit. Male partners were tested for DFI and SDI during the year 2015-2016. Eighteen patients were controlled as carrying the isoform on a heterozygote state. Nine were found to be homozygote for the C677T isoform: these patients faced 3 to 9 IVF/ICSI failures and/or miscarriages. Their DFI and SDI were compared to our control group involving more than 1400 patients.

Participants/materials, setting, methods: MTHFR isoforms detection is now part of our assessment in couples after repeated failures of IVF/ICSI failures. Determination of C677T isoform was performed with Real Time Polymerase Chain Reaction. DFI and SDF is measured using Acridine orange/Flow cytometry according to a technique recently described (Hamidi).

Main results and the role of chance: In our general sub-fertile population, 40% of the patients have a DFI > 20% and 23% have a SDI>20%; 20% being considered as the threshold value. Out of the 18 heterozygote patients, 3 have high DFI and SDF (16%). For the homozygote patients, 8/9 have pathological values: two have both high DFI and SDI (average: 41% and 31% respectively). 4 have an isolated high SDI (average: 29%), 2 have only a high DFI only (average: 28%). One patient has correct DFI and SDI values. The homozygote MTHFR C677T induces pathologies of nucleus structure measured by SDF and DFI.

Limitations, reasons for caution: The low number of homozygote patients involved in this study. We evaluated only one mutation (C677T), which is the most frequent though. The influence of potential confounding factors has to be taken into consideration: modification of life style, diet, etc…as well as environmental factors (endocrine disruptors, pollution…).

Wider implications of the findings: In case of repeated ART failures, patients with very high DFI/SDF should be tested for MTHFR. Treatments involving folic acid are useless and has to be replaced by 5 Methyl tetrahydrofolic acid, a compound of the 1-CC downstream the MTHFR.

Trial registration number: Not applicable.

P-029 Examination of the effect of seminal plasma on uterus contraction from two different donor collectives with normozoospermia

I. Hoffmann[1], L. Lotz[2], M.W. Beckman[2], R. Dittrich[2]

[1]University Erlangen, Ob/Gyn, Erlangen, Germany
[2]Erlangen University Hospital- Friedrich-Alexander University of Erlangen-Nuremberg, Obstetrics and Gynecology, Erlangen, Germany

Study question: Is there a difference in the capability to induce uterine contractions of seminal plasma of men with an infertility history and those without infertility history?

Summary answer: Application of seminal plasma into porcine uteri from voluntaries significantly increases uteri contractility more than from patients of the IVF laboratory, although both had normozoospermia.

What is known already: Adequate uterine contractility plays an important role in successful fertilization and embryo implantation. Uterine contractility is regulated by various substances such as oxytocin and prostaglandins, which cause an increase in myometrial contractility and progesterone, and that leads to a decrease in uterine contractility. The fact that these substances are ingredients of the seminal plasma stresses its relevance for the reproductive function. Examinations in animals as well as in humans showed seminal plasma's impact on conception. However seminal plasma composition and reciprocity of the substances seem to be very complex and not completely understood yet.

Study design, size, duration: In this experimental in-vitro study, the influence of human seminal plasma was evaluated on its effect on contractility by using an extracorporal perfused non-pregnant pig uteri. Ejaculate of men with normozoospermia was taken either from patients of the IVF laboratory or voluntary donors. The ejaculates were injected into the perfused uterus of 54 pigs to analyze whether a dose-dependent effect of the different seminal plasma on the uterine motility exists by repetitive intraluminal bolus application.

Participants/materials, setting, methods: After measuring the basic activity of 54 perfused uteri over 60 minutes, three 0.6 ml doses of Krebs-Ringer solution or seminal plasma from patients or voluntary donors were administered, with an interval of 45 minutes between each application. Uterine pressure as the area under the curve (AUC) was measured by a precision pressure catheter with two measure points near to the ovaries (IUP 1) and near to the cervix (IUP 2).

Main results and the role of chance: The seminal plasma application into the porcine uterus significantly increases contractility in the form of AUC, contraction frequency as well as average and maximal values of the contraction amplitude. The ovarian and the cervical measure point showed no significant difference concerning maximal and average pressure amplitude after application of 0.6 ml seminal plasma but revealed significantly higher values at IUP 2 after administration of 0.6 and 1.2 ml seminal plasma. The administration of Krebs-Ringer solution also led to a discrete rise in uterine contractility. However, the effect was clearly less pronounced than that caused by administering seminal plasma. A significant difference in the increase of myometrial activity between the two groups was identified. It was demonstrated that seminal plasma from voluntary donors led to a significantly more pronounced increase in contractility than patients' seminal plasma. This difference became especially evident after repeated administrations of the test substances. The data suggest a dose-dependent effect.

Limitations, reasons for caution: Physical disturbance variables potentially influencing the results were limited as much as possible. In avoidance of an increase in uterine contractility due to the temperature, seminal plasma was warmed up to the nutrition solution temperature. By applying a slow uniform injection, steady seminal plasma distribution and low pressure were attainable.

Wider implications of the findings: The results demonstrate the importance of physiologic seminal plasma composition and introduce new potential options in diagnostic and treatment for couples with an unfulfilled wish for a child. Further investigations about the exact composition of seminal plasma and the interaction of the ingredients are necessary.

Trial registration number: None.

P-030 How do habits and life style affect IVF-TESE outcomes?

G. Shrem[1], Y. Brudner[1], Y. Azmon[1], M. Michaeli[1], A. Ellenbogen[2], E. Shalom-Paz[1,2]

[1]Hillel - Yaffe medical center, IVF unit, Hadera, Israel
[2]Technion, Medicine, Haifa, Israel

Study question: to examine the effect of serum FSH level, BMI and smoking on TESE-ICSI and pregnancy outcomes

Summary answer: No adverse effects related to male BMI, male FSH and smoking on sperm parameters and pregnancy and delivery rates

What is known already: high serum FSH, smoking and high BMI has an adverse effect on make fertility

Study design, size, duration: Retrospective study, data were extracted from files of 52 azoospermic men who underwent TESE and IVF-ICSI in our IVF unit. Demographic information, treatment cycle follow-up and pregnancy outcomes were assessed.

Participants/materials, setting, methods: Azoospermic males requiring TESE. Retrospective cohort study

Main results and the role of chance: Fifty-two patients underwent 79 TESE due to azoospermia. There were 143 IVF cycles. Smoking was found to significantly affect sperm motility in TESE specimens before freezing (45.5% vs. 14.8%; P < 0.001). However, this did not influence the pregnancy rate. Male FSH was negatively correlated with testicular volume (r = - 0.595, p < 0.0001). Weight did not affect semen parameters after TESE or ICSI outcome.

Limitations, reasons for caution: It was retrospective and the sample size was the relatively small. All azoospermic patients who underwent TESE were

included, with no subgroup analysis according to the etiology of azoospermia. Moreover, there are some confounders that affect the patient selection, clinical and laboratory techniques to find spermatozoa.

Wider implications of the findings: Azoospermic males has poor quality and quantity sperm so smoking, high BMI and elevated srum FSH do not have additive adverse effect

Trial registration number: 0024-15-HYMC

P-031 Sperm DFI improvement only dependent on motility improvement after antioxidant therapy: A large cohort study

P. Salehi[1], A. Ajami[2], N. Tavakoli[3], M. Akhlaghi[4], M.R. Deemeh[3]

[1]Shahid Beheshti Hospital, Urology, Isfahan, Iran
[2]Nobel laboratory, Director, Isfahan, Iran
[3]Nobel laboratory, Andrology, Isfahan, Iran
[4]Isfahan Medical university, Epidemiology, Isfahan, Iran

Study question: Is sperm DFI improvement independent from semen parameters after antioxidant therapy or not?

Summary answer: Sperm DFI improvement correlated only with total and progressive motility improvement after antioxidant therapy, and independent from concentration and morphology improvement.

What is known already: Antioxidant therapy used for treatment of men with high degree of DFI and resulted in DFI improvement and semen parameters. But there is a challenge that this improvement correlated with each other or DFI and semen parameters improved separately.

Study design, size, duration: This study design as a large Prospective Cohort and lost to follow-up study. Semen sample collected during January 2016 to January 2017 in Nobel Laboratory, Isfahan, Iran. 1200 infertile men participated in this study that 505 of them finished the antioxidant therapy period.

Participants/materials, setting, methods: Semen samples from infertile individual collected and semen parameters analyzed based on WHO 2010 guideline. Sperm DFI assessed with Sperm Chromatin Structure Assay(SCSA) with flow cytometric method. Patient with high level of DFI(> 27%) under supervisor of an urologist, treated with Antioxidant supplementation including Vitamin E, Vitamin C and Q 10 during 3 month. Then patient repeated spermogram and SCSA analysis. Only improvement rate >15% accounted for analysis after Antioxidant therapy.

Main results and the role of chance: From total 1200 individuals, 468 men had normal sperm parameters. from this 468 men, 22% (103/468) had DFI > 27%. Also from 732 abnormal semen parameters, 63% (461/732) had DFI> 27 %.

DFI improvement after antioxidant thrapy was 40.7% (42/103) in men with normal sperm parameters and 45.8 % (147/321) in men with abnormal parameters. Only total motility improvement (p Value = .0017 and r = 0.331) and progressive motility improvement (p Value=0.013, r = 0.349) correlated with DFI improvement after Antioxidant therapy.

Limitations, reasons for caution: Lack of regular consuming antioxidant supplementation. Not participating individual in study after antioxidant therapy.

Wider implications of the findings: SCSA as a reliable test offer for all normal semen parameters and abnormal semen parameters individual. Antioxidant therapy is useful for men with high sperm DFI. But it must be noted that DFI improvement not correlated with concentration and morphology and only dependent with total and progressive motility improvement.

Trial registration number: Not available.

P-032 A novel solution for freezing small number of spermatozoa by a sperm vitrification device

A. Berkovitz[1], M. Belenky[2], P. Itsykson[3]

[1]Sakler School of Medicine- Tel Aviv University- Israel, CAssuta Medical Center- Tel Aviv- Israel, Tel Aviv, Israel
[2]Male Fertility Center- Rishon LeZion- Israel, Assuta Medical Center- Tel Aviv- Israel, Tel Aviv, Israel
[3]Assuta Medical Center- Tel Aviv- Israel, IVF Assuta Medical Center- Tel Aviv- Israel, Tel Aviv, Israel

Study question: Does a sperm vitrification device (VD)provide an efficient method for freezing a small number of human spermatozoa?

Summary answer: The use of a spermVD can provide an efficient method for freezing a small number of spermatozoa and can be used after testicular sperm extraction.

What is known already: Cryopreservation of a small number of human spermatozoa can provide an appropriate solution for cases of severe male infertility. Mainly after testicular biopsy an efficient method for sperm preservation is needed. Over the years, different methods for cryopreservation of small numbers of human spermatozoa were proposed (e.g. mini-straws, ICSI pipette, cryoloop, alginate beads. Each of these methods had drawbacks which prevented widespread use, mostly due to cumbersome preparation and sperm retrieval procedures. Moreover, in most of the previous methods the thawed spermatozoa were not immediately available for micromanipulion and required additional treatment which may cause harm to the thawed spermatozoa.

Study design, size, duration: A total of 15 patients with virtual azoospermia and 5 patients with frozen IMSI selected spermatozoa before oocyte donation were recruited for a prospective study between 2015-2016.

Participants/materials, setting, methods: Sperm was collected from patients diagnosed with virtual azoospermia. After centrifugation and washing the re-suspended pellet was distributed into 10 μL droplets on a Petri dish. The droplets were searched and any single spermatozoa found was transferred to 1 μL of washing medium/cryoprotectant on the spermVD. The spermVD was then plunged into LN ^{2}. At oocyte pick-up day, the spermVD was thawed and placed on the ICSI dish and spermatozoa were retrieved from the droplets and injected.

Characteristic/Outcome	Average, SD, %
Male Age	37.5 ± 8.6
Female Age	33.6 ± 8.6
No. of motile frozen sperm	17.1 ± 11.1
No. of thawed sperm	16.9 ± 10.2
Spermatozoa retrieval rate (No of thawed/No of frozen)	96.3%
% Motile sperm	29%
Fertilization rate	57%
Pregnancy rate	60%
Delivery rate (including ongoing pregnancies)	58%

Main results and the role of chance: Linear regression was used for continuous variables and logistic regression was used for categorical variables. No correlation was found between motile thawed spematozoa and fertilization rate (p = 0.661) and pregnancy rate (p = 0.083).

Limitations, reasons for caution: No limitations or reasons for caution.

Wider implications of the findings: Our efficient and simple method for freezing a small number of spermatozoa may allow the routine use of frozen spermatozoa after TESE and decrease the number of unnecessary OPU procedures.

Trial registration number: The study was approved by the ethics board No 2013042 and registration was not done because of intellectual property.

P-033 Effect of sperm DNA fragmentation in men living in desert climate on outcome of ICSI and its correlation with semen and social characteristics

B. Alomrani[1], N. Aleisa[1], M. Javed[2], M. Al Ghedan[3], H. Al Sufyan[4]

[1]King Saud University, Zoology, Riyadh, Saudi Arabia
[2]Thuriah Medical Center, Assisted Reproductive Technology Laboratories, Riyadh, Saudi Arabia

[3]Thuriah Medical Center, Genetics Laboratory, Riyadh, Saudi Arabia
[4]Thuriah Medical Center, Reproductive Endocrinology and Infertility, Riyadh, Saudi Arabia

Study question: What is the effect of sperm DNA fragmentation (SDF) in men living in desert climate on ICSI outcome?

Summary answer: No pregnancy resulted in the group when male partner's SDF was 38.54 ± 10.14 %.

What is known already: One of the important male factors affecting success after assisted reproduction is SDF. The fertility potential of men with higher than 30 % SDF is very poor, however, high SDF can be corrected by lifestyle changes and medication.

Study design, size, duration: It is a retrospective study of 94 men tested for SDF by sperm chromatin dispersion test before going to ICSI at a private infertility clinic in Riyadh, Saudi Arabia from Jan 2015 to June 2016. The study parameters were SDF, male age, body mass index, smoking, semen values and fertilization rate. The % SDF categories were; low (SDF ≤15%), moderate (SDF >15-30%) and high (SDF >30%). The Institutional review board approval was obtained.

Participants/materials, setting, methods: The 94 study couples underwent SDF test and ICSI. The SDF was tested by Halosperm G2® kit (Halotech®, Spain). The female partner's were prepared by standard ovarian stimulation protocols. The oocyte collection, ICSI and embryo culture were performed as per routine of the laboratory. The embryos were cultures at 37 °C in humidified environment of 6% CO2 in air. The pregnancy rates among groups were compared and correlations among various parameters analysed by SPSS.

Main results and the role of chance: The SDF was low (≤15%) in 53.19 % men, moderate (>15-30%) in 33 % men and high (>30%) in 14 % men. The Mean ± SD values for low, moderate and high SDF categories were; 10.46 ± 3.31%, 20.80 ± 4.68 % and 38.54 ± 10.14 %, respectively. There was no significant correlation between % SDF and semen parameters except in between the progressive motility and low SDF (r = -0.36, P = 0.008). For the social characteristics, higher body mass index, smoking and increased age were positively correlated with SDF. In high SDF category, no couple achieved pregnancy.

Limitations, reasons for caution: The study was conducted on 94 men and over a period of Jan 2015 to June 2016 at one private clinic. Larger multi center study is needed. This study suggests the need to test SDF before ICSI and to investigate any impact of SDF on congenital anomalies in the offspring.

Wider implications of the findings: Some social characteristics like high body mass index, smoking and age were significantly correlated with SDF. The patient counseling to adapt a healthy lifestyle and SDF test prior to initiation of treatment are needed.

Trial registration number: None.

P-034　evaluation of testicular tissue vitrification by ectopic transplantation and in vitro culture

N. Yamini[1], F. Amidi[2], M. Salehnia[3], G. Pourmand[4], S. Brenjian[5], N. Ataei Nejad[2], S.M.H. Noori Mougahi[6]

[1]Teran university of medical sciences/Arash hospital, Anatomy/IVF, Tehran, Iran
[2]Tehran university of medical sciences, Anatomy, Tehran, Iran
[3]TarbiatModares University of medical sciences, Anatomy, Tehran, Iran
[4]Tehran university of medical sciences, Urology, Tehran, Iran
[5]Tehran university of mdical sciences, Anatomy, Tehran, Iran
[6]Tehran university of medical sciences, Histology, Tehran, Iran

Study question: Does this simple vitrification procedure maintain testicular tissue function and structure?

Summary answer: Vitrification resulted in a success rate in maintaining testicular cell proliferation and differentiation capacity up to round spermatid and testicular tissue structure same as control.

What is known already: Fortunately survival rate of cancer in pre-pubertal males has been increasing. Infertility, as one of the adverse effects of treatments, has become an important concern for patients. Sperm freezing is the only efficient method for fertility preservation. As there are no mature spermatozoa in young patients then efficient testis tissue cryopreservation followed by transplantation or in vitro maturation is a realistic measure for preserving the fertility. Although there are a lot of findings regarding different tissue cryopreservation methods various researches are ongoing to reach simpler vitrification protocol which maintains tissue developmental function.

Study design, size, duration: In this experimental study, immature mice testicular tissue fragments were vitrified-warmed. Vitrified (n = 42) and control (fresh, n = 42) fragments were ectopically transplanted into the mature mice (n = 14) for 7 weeks in order to assess vascularization of the grafts, germ cell differentiation, proliferation and apoptosis frequency. Vitrified (n = 42) and control (n = 42) tissues were cultured for 1 and 6 days.

Participants/materials, setting, methods: 6-days postnatal BALB/c as testes donors and 10-weeks of the same strain as recipients were used. Immature mice testicular tissue fragments (0.5-1 mm^2) were vitrified-warmed by maximum cooling-warming rate and minimized vitrification media volume with a special metal grid carrier. Histological staining by H&E, immunohistochemical staining by PCNA, and TUNEL assay were used. After 1 and 6 days culturing, testicular tissue structure was evaluated by H&E staining.

Main results and the role of chance: Vascularization of the vitrified graft (59%) did not significantly differ with the control (71%). The percentage of the most advanced germ cells present in the tubules of control and vitrified grafts recovered respectively was as follow: Sertoli cell (6.5% and 6.82%), spermatocyte (56% and 62.056%), spermatogonia (8.35% and 7.56%), and round spermatids (29% and 23.434%). The frequency of intratubular cell per microscopic field (50 μm=×40) was respectively included in spermatocyte (51.52% and 54.0), spermatogonia (18.18% and 19.26%), Sertoli cell (8.13% and 11.12%) and round spermatids (22.15% and 15.59%) in control and vitrified grafts. We observed no statistically significant difference in the most advanced germ cells and frequency of intratubular cells between control and vitrified groups. Apoptosis in vitrified (8.3%) was comparable to control (6.5%) graft. Proliferation in vitrified (17.6%) and control (22.8%) tissue did not reach statistical significance. Moreover, compared to the control group, the numbers of intact (71.82% vs 64.58%), medium (17.86% vs 20.33), and degenerated tubules (10.31% vs 15.1%) were not significantly different with the vitrified group at first day. After 6 days, the numbers of intact (55% vs 49.66%), medium (21.33% vs 22.33%), and degenerated tubules (23.66% vs 28%) in control samples were similar to vitrified group.

Limitations, reasons for caution: The human testis is very different in physiology from the mice testis; further investigations are still needed to optimize the vitrification protocol and culture system for future use in humans.

Wider implications of the findings: The successful differentiation of spermatogonia using the testicular tissue transplantation might be employed in future to produce mature spermatozoa from human spermatogonia as a clinical tool for fertility preservation. Further studies would be necessary in order to demonstrate how useful is culturing testicular tissue in media before transplantation.

Trial registration number: N/A.

P-035　Gene polymorphic variants in taste receptors (TAS) genes and male fertility: a possible correlation

L. Crifasi[1], D. Campa[2], M. Gentiluomo[2], D. Locci[2], A. Luddi[1], C. Marrocco[1], R. Barale[2], P. Piomboni[1]

[1]University of Siena, Department of Molecular and Developmental Medicine, Siena, Italy
[2]University of Pisa, Department of Biology, Pisa, Italy

Study question: We analyzed possible associations between *TAS2Rs/TAS1R* and *GNAT3* (gustducin alpha-3 chain) gene variability and male fertility status, and investigated TAS genes expression in human spermatozoa.

Summary answer: Some genetic variants in taste related genes are associated with sperm parameters, and several components of taste receptor transduction cascade are expressed in mature spermatozoa.

What is known already: Male infertility is estimated to affect about 7% of men and the causes are often unknown. About 40% of infertile men have

normal reproductive hormone production and any known cause of infertility can be diagnosed. Previous studies showed the expression of taste receptors in testis and sperms, suggesting their possible role in germ cells development and sperm production. Taste sensitivity varies among individuals, being associated with functional polymorphisms in taste receptor genes. The vast genetic variability in taste genes results in a large degree of phenotypic diversity. We hypothesis that polymorphisms in taste receptors might influence sperm functionality.

Study design, size, duration: We analyzed a total of 452 individuals undergoing semen evaluation during an infertility diagnostic screening, from October 2014 to February 2016, at the Centre of Couple Sterility, Siena University Hospital.

Participants/materials, setting, methods: Enrolled subjects were characterized for main sperm parameters, according to WHO (2010) guidelines: concentration, morphology, progressive and total motility. All subjects were genotyped for 24 single nucleotide polymorphisms (SNPs) in *TAS2Rs/TAS1R* and *GNAT3* genes, using the KASPar SNP genotyping system. To assess the possible functional associations between SNPs and sperm parameters, different bioinformatic tools were used. Additionally we analyzed the expression of selected genes involved in taste receptor transduction cascade, using quantitative real time PCR.

Main results and the role of chance: Our results suggested a correlation between: TAS2R3-rs11763979 and sperm morphology; TAS2R3-r rs11763979 and sperm concentration; TAS2R14-rs3741843 and sperm motility. This last association was supported by a high statistical significance and by compelling *in silico* prediction of the SNPs effects on the gene nearby. The minor allele was associated with a decreased sperm motility and with an increased expression of the genes at the locus, suggesting that the increase in expression decreases the sperm motility. These data confirm the pleiotropic role of taste receptors, without information on the molecular mechanisms underlying these associations. Gene expression analysis of transduction cascade elicited by taste receptors was aimed to shed light on the role of these genes and their associated proteins in sperm cells. We highlighted that some these genes are not expressed in sperms (*CALHM1, USP20, GCM1, TAS1R1, TAS1R2*), whereas *PLCβ2, CAMKK1, TRPM5, TAS2R14, TAS1R3, GNAT3, SLC2A2, PDE4A,* and *MZF1* genes are expressed in sperm, although at different levels, demonstrate a high variability in mature sperm cells.

Limitations, reasons for caution: The major limitation is the sample size because some taste receptors (TAS) genes polymorphic variants have a low frequency in the population, and therefore a larger study needs to be carried out in order to validate the findings.

Wider implications of the findings: Further studies might contribute in better understanding the genetic components of male infertility; they should be crucial to clarify the cause of reproductive failure in men affected by idiopathic infertility.

Trial registration number: NONE.

P-036 Sperm DNA fragmentation test (TUNEL) and male infertility assessment. Setting a cut-off value

D. Lorenzi, M. Bilinski, M. Miguens, C. Borghi, F. Nodar, S. Papier, C. Alvarez Sedo

CEGYR Reproductive Medicine and Genetics, Reproductive Biology and Genetics, Buenos Aires, Argentina

Study question: Which is the cut-off value for TUNEL assay according to the collected data from sperm DNA fragmentation studies in fertile and infertile men?

Summary answer: The ROC curve analysis reported that the cutoff value for TUNEL assay was 15% (AUC: 0.78), with 53% of sensitivity and 100% of specificity.

What is known already: Studies have shown a negative correlation between sperm DNA fragmentation and fertility. High values of DNA fragmentation may have an adverse impact in ART outcomes, reducing the fertilization rate, poor embryo developing and recurrent miscarriages. Therefore, sperm DNA fragmentation may be important factor to be assessed for male infertility evaluation. Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling (TUNEL)

assay is one of the principal techniques for measuring sperm DNA damage. It detects single/double strand fragmentation. However, protocols are not well established. Some laboratories apply flow cytometry for fluorescence detection while others use fluorescence microscopy, been results difficult to compare.

Study design, size, duration: It is a retrospective cohort study. Forty-eight infertile men that performed a semen analysis between 20132015 were enrolled. Twenty-eight healthy male volunteers with proven fertility (< 12 months) were selected as the control group.

Participants/materials, setting, methods: From 500 initially recruited patients, just 48 were enrolled due to pure male factor infertility, it means that couples with female factor (>37, poor ovarian response, tuboperitoneal factor, polycystic ovarian syndrome, altered karyotype) were excluded. Semen analysis was performed according to the procedures established by WHO (2010). Sperm DNA fragmentation was assessed over motile sperm (selected by swim up) by TUNEL assay. Ttest and ROC curve analysis were used for statistical analysis.

Main results and the role of chance: The average age for fertile men was 32.8 ± 4.7 and 36.5 ± 5.2 for infertile men (*p*: 0.99). According to sperm concentration, the average rate was 55.1 ± 22.4 mill/mL for fertile men and 45.5 ± 40.6 mill/mL for infertile men, showing no significant differences (*p*: 0.22). Progressive motility was $57.2 \pm 6.1\%$ for control group and 47.8 ± 9.8 for infertile men (*p*: 0.01). Strict morphology was $13.2 \pm 2.5\%$ for fertile men compared to $6.5 \pm 3.8\%$ for infertile men (*p*: 0.01). Neutrophils concentration was 0.5 ± 0.01 and 1.8 ± 0.2 mill/mL respectively (*p*: 0.99). Finally, TUNEL assay value was $17.8 \pm 10.8\%$ for infertile men and 7.6 ± 3.9 for control group (*p*: 0.01).

From these seminal results, it is shown that sperm progressive motility, strict morphology and DNA fragmentation were significantly higher in patients with pure male factor compared to controls ($p < 0.05$). The cut-off value calculated from ROC curve analysis was 15% (AUC: 0.78), with 53% of sensitivity and 100% of specificity.

Limitations, reasons for caution: The cut-off value of 15% for TUNEL test was calculated from our own studies, performed by our own protocol. The application of this cut-off value in other laboratories must be done with caution.

Wider implications of the findings: A cutoff value of 15% for TUNEL assay with 100% specificity can differentiate infertile men with DNA damage from fertile men. TUNEL test for the evaluation of sperm DNA fragmentation is a useful test in the evaluation of male factor in couples with fertility problems.

Trial registration number: None.

P-037 Polymorphic chromosome variants, human inversions, and their functional consequences in male infertility

C. González-Ravina[1], M. Cruz[2], C. Rubio[3], M. Fernández-Sánchez[4], E. Oquiñena[5], R. Ferrando[6], A. Requena[7]

[1]*IVI SEVILLA, Andrology Laboratory, SEVILLA, Spain*
[2]*IVI Madrid, IVF Laboratory, Madrid, Spain*
[3]*IGenomix, Preimplantation Genetic Diagnosis, Valencia, Spain*
[4]*IVI Sevilla, Gynecologist, Sevilla, Spain*
[5]*Biokilab, Laboratory, Vitoria, Spain*
[6]*IVI Valencia, IT Consultant, Valencia, Spain*
[7]*IVI Madrid, Gynecologist, Madrid, Spain*

Study question: To assess the effect of polymorphic chromosome variants in male infertility and assisted reproduction treatment (ART).

Summary answer: The chromosome involved in the polymorphism is crucial in determining its effect on male seminal quality and the probability of success after ART.

What is known already: Polymorphic chromosome variants are still been considered "normal" as it was thought that heterochromatin has no coding potential. However, it has been described that some genes involved in fertility reside in heterochromatin, and they could have an impact on fertility potential and miscarriage rate. An increase in the frequency of polymorphic variants and inversions have been observed among infertile males, related to sperm aneuploidies, poor seminal quality and failures in ART. There is no absolute consensus on the chromosomes mainly involved in polymorphisms or their implication in seminal quality or fertility.

Study design, size, duration: Retrospective study performed in 11 private clinics belonging to IVI group from January 2012 to December 2016. We included 1193 men, of which 29.2% (n = 348) had normal karyotype and were considered as a control group; 48.7% (n = 581) were carriers of a polymorphism; and 22.1% (n = 264) showed an inversion on chromosome 9 or Y. All men underwent a fresh autologous ICSI cycle. Statistical analysis was performed by ANOVA and chi-square where applicable.

Participants/materials, setting, methods: The cytogenetic study was performed by culture of peripheral blood lymphocytes stimulated with phytohemagglutinin and subsequent staining with trypsin-Giemsa (GTG bands). 15 metaphases were evaluated for each case and the banding resolution was 400–550 bands per haploid set. Polymorphisms were included as a variant when the chromosome region was greater or smaller than the same region on the homologous chromosome; as a minimum, twice the size on the other homologue.

Main results and the role of chance: Polymorphic variants for chromosomes 1 (46,XY,1qh+), 9 (46,XY,9qh+), 13 (46,XY,13 ps+), 14 (46,XY,14 ps +), 15 (46,XY,15 ps+), 16 (46, XY,16qh+), 21 (46,XY,21 ps+), 22 (46, XY,22 ps+) and Y (46,XYqh+) were obtained, as well as inversion of chromosomes 9 or Y, being the most frequent 46,XY,inv(9)(p11q12).

When analyzing whether the chromosome involved in the polymorphism could influence clinical results, we did not found differences related to seminal quality (volume, sperm concentration, progressive motility) or clinical data like implantation, pregnancy and miscarriage rates. Male carriers of polymorphisms implying the acrocentric chromosomes showed significant lower fertilization rate compared to males with normal karyotype. Fertilization rates were as follows: 64.7% for control group; 55.2% for chromosome 13; 52.0% for chromosome 14; 64.2% for chromosome 15; 51.0% for chromosome 21; 57.8% for chromosome 22 and, 61.9% for chromosome Y (p = 0.026) meaning that somehow, polymorphism for these specific chromosomes impair the fertilization ability of their gametes. In contrast, we did not found differences related to fertilization rate but a significant increase in implantation rate for male carriers of chromosome 9 inversion (36.5%) compared to control group (29.9%), p = 0.059. Patients with chromosome 9 inversion behave similarly to the control population or even better. No significant differences were found for other analyzed parameters.

Limitations, reasons for caution: Despite the advantages that our data set confer the analysis, limitations still remain. One consequence of a retrospective study is that not all pertinent risk factors are likely to have been identified and subsequently recorded. Therefore, only association, and not causation, can be inferred from the results.

Wider implications of the findings: As "normal" polymorphic variants could play a significant and yet unknown role in clinical outcomes in infertile couples, it would be of great interest to know the individual implication of each chromosome in each analyzed parameters, to counsel carrier couples about their expected clinical outcome and the most appropriate treatment.

Trial registration number: It does not apply.

P-038 Signaling proteins as biomarkers for sperm quality evaluation

J. Vieira Silva[1], M.J. Freitas[1], B. Correia[1], A. Patrício[2], S. Pelech[3], M. Fardilha[1]

[1]University of Aveiro, Department of Medical Sciences, Aveiro, Portugal
[2]Infante D. Pedro Hospital, Urology, Aveiro, Portugal
[3]Kinexus Bioinformatics Corporation, Kinexus Bioinformatics Corporation, Vancouver, Canada

Study question: To determine the correlation between basic semen parameters and the expression and activity of signaling proteins.

Summary answer: In this study, we unraveled signaling pathways involved in regulating human sperm function and correlated the activity of signaling proteins with clinical data.

What is known already: Sperm cells are incapable of genetic expression and thus highly dependent upon post-translational modifications and signal cascades to execute their function. However, not much information is available on the biological significance of specific signaling pathways in human spermatozoa or their possible roles in male infertility.

Study design, size, duration: Thirty-seven random donors provided semen samples for *in vitro* studies with human spermatozoa carried out in an academic research institute in collaboration with a hospital.

Participants/materials, setting, methods: Thirty-seven human semen samples, obtained from a randomized group of donors, were included in this study. Basic semen parameters were analyzed according to the WHO's guidelines. Sperm DNA fragmentation (SDF) was measured using a Sperm Chromatin Dispersion (SCD) test. Antibody-based arrays were carried out to determine the expression patterns of 18 well-characterized signaling molecules when phosphorylated or cleaved. A commercial Kinetworks™ Protein Kinase Screen was used to analyze the levels of 75 protein kinases.

Main results and the role of chance: The results indicated that the phosphorylated levels of several proteins [Bad, GSK-3β, HSP27, JNK/SAPK, mTOR, p38 MAPK and p53], as well as, cleavage of PARP (at D214), and Caspase-3 (at D175)] were significantly correlated with motility parameters. Additionally, the percentage of morphologically normal spermatozoa demonstrated a significant positive correlation with the phosphorylated levels of p70 S6 kinase and, in turn, head defects and the teratozoospermia index (TZI) showed a significant negative correlation with the phosphorylated levels of Stat3. There was a significant positive correlation between SDF and the TZI, as well as, the presence of head defects. In contrast, SDF negatively correlated with the percentage of morphologically normal spermatozoa and the phosphorylation of Akt and p70 S6 kinase. Subjects with varicocele demonstrated a significant negative correlation between head morphological defects and the phosphorylated levels of Akt, GSK3β, p38 MAPK and Stat1. Additionally, 34 protein kinases were identified as expressed in their total protein levels in normozoospermic samples. From those, 8 were identified for the first time in human spermatozoa.

Limitations, reasons for caution: The major limitation of this study is the relatively small sample size. Still, *the* dataset size was considered reasonable since based on the central limit theorem it was possible to approximate the distribution of variables to a normal distribution.

Wider implications of the findings: This study contributed towards establishing a biomarker "fingerprint" to assess sperm quality based on molecular parameters.

Trial registration number: NA.

P-039 The (Pro)renin receptor is expressed in human sperm cells and is related to sperm quality and embryo development

M. Gianzo[1], Z. Larreategui[2], I. Muñoa-Hoyos[1], I. Urizar-Arenaza[1], J. Irazusta[1], N. Subiran[1]

[1]University of Basque Country UPV/EHU, Department of Physiology, Leioa, Spain
[2]IVI Bilbao, IVF Laboratory, Leioa, Spain

Study question: To investigate the presence of (pro)renin receptor (PRR) in human spermatozoa and its association with basic sperm parameters, human embryo development and reproductive success.

Summary answer: The PRR is present in human spermatozoa. Higher percentages of PRR-positive spermatozoa are associated with worst sperm quality, embryo development and embryo viability.

What is known already: There is increasing evidence that sperm molecular features, such as RNA and proteins, are involved in fertilization and embryo development; suggesting that male infertility could be caused by different deficiencies, distinct from those related with basic semen analysis. Understanding those sperm characteristics will allow to develop functionally diagnostic or tools to maximize reproductive success. Sperm fertility ability may be modulated by different molecular systems, such as the renin-angiotensin system (RAS). Several components of RAS are described in human spermatozoa. However, despite to renin is one of its most relevant peptides, the presence and role of the PRR is completely unknown.

Study design, size, duration: This prospective cohorts study (conducted February 2014 to July 2015) analyzed 120 human semen samples from the Clínica IVI Bilbao. Of these, 23 samples from normozoospermic patients were used to determine the presence and location of PRR in human spermatozoa; and a total of 97 normal and/or pathologic semen samples of couples undergoing oocyte donation cycles were used to analyze the association among the PRR

and basic sperm parameters, human embryo development and reproductive success.

Participants/materials, setting, methods: A total of 120 human semen samples and 755 embryos were examined. Sperm samples and embryo quality were examined following WHO and "Asociación Española para el Estudio de la Biología de la Reproducción" (ASEBIR) guidelines, respectively. To determine the presence of PRR and its transcript we performed expression assays by western blot, immunofluorescence and RT-PCR. The levels of PRR were measured by flow cytometry. Statistics: Spearman´s rank correlation, Kruskal-Wallis and Mann-Whitney U-test.

Main results and the role of chance: We demonstrated the existence of PRR and its transcript in human sperm by western blot and RT-PCR techniques. Immunofluorescence studies showed that PRR is mainly located in the proximal region over the acrosome and in the postacrosomal region of sperm head, and to a lesser extend along the sperm tail. On the other hand, the presence of PRR in spermatozoa is related to sperm quality. Concretely, in prepared sperm cells, the percentage of PRR-positive spermatozoa was negatively correlated with semen concentration ($p < 0.05$), and positively with the percentage of non-progressive (NP) spermatozoa ($p < 0.01$). Regarding human embryo development, semen samples with higher percentages of PRR-positive spermatozoa are associated with worst embryo development on day 6 ($p < 0.01$) and with not viable blastocysts on day 5 ($p < 0.01$).

Limitations, reasons for caution: Only high quality embryos used in fresh transferences have been considered in this study.

Wider implications of the findings: PRR is present in human spermatozoa. It may be negatively involved in sperm physiology and also it may condition human embryo quality. In-depth understanding of sperm proteins can help elucidates their role in male infertility as well as establish biomarkers for sperm selection to use in assisted reproduction techniques.

Trial registration number: CEISH/61/2011.

P-040   The efficacy and adaptation of microTESE in the day before of oocyte collection: superior motile sperm recovery and cycle planning

M. Bibancos de Rosa[1], F. Chiamba[2], V. Marchi[2], E. Semaco[3], T. Bonetti[4], E. Motta[5], A. Garolla[6], C. Foresta[6], P. Serafini[7]

[1]Huntington Reproductive Center, Urology, São Paulo- SP, Brazil
[2]Huntington Medicina Reprodutiva, Nursing, São Paulo, Brazil
[3]Huntington Medicina Reprodutiva, Andrology Laboratory, São Paulo, Brazil
[4]Huntington Medicina Reprodutiva / Universidade Federal de São Paulo, Scientific Coordinator / Gynecology endocrinology discipline- Gynecology Department, São Paulo, Brazil
[5]Huntington Medicina Reprodutiva / Universidade Federal de São Paulo, Clinical Director / Gynecology endocrinology discipline- Gynecology Department, São Paulo, Brazil
[6]University of Padova, Unit of Andrology and Reproductive Medicine- Department of Medicine, Padova, Italy
[7]Huntington Medicina Reprodutiva / Universidade de São Paulo, Clinical director / Gynecology Diiscipline- Department of Obstetrics and Gynecology, São Paulo, Brazil

Study question: What is the efficacy of performing microdissection of testicular sperm extraction (MicroTESE) for non-obstructive men in the day before oocyte collection of the female partner?

Summary answer: MicroTESE in the day before of oocyte collection allow to identify motile-sperm in about 50% of samples that showed immotile-sperm in the day of procedure.

What is known already: Non-obstructive azoospermia count for 60% of all azoospermic men, who require an invasive procedure to retrieve sperms from testicles plus ICSI. The MicroTESE has been shown to be the best approach; however, the procedure has some inconvenient as the hospital necessity is required, and the sample must be transported to IVF clinic in enough time for ICSI. Additionally, if sperm is not found in the testicle sample, the IVF procedure has to be changed without planning and oocytes cryopreserved, or fertilized by donor sperm sample to permit excellence of the results.

Study design, size, duration: Cross-sectional study included 61 non-obstructive azoospermic men who underwent microTESE between 2012 and 2016. All procedures were done by the same surgeon, in a hospital, under anesthesia. The microTESEs were handled with microsurgical material and microscopy. During the microTESE all removed tubules were analyzed by andrologist into the surgical room to preliminary identify sperm between slides under 400X microscopy, and the surgeon provide areas of testicle to be removed.

Participants/materials, setting, methods: The samples were placed into a conical tube with HEPES plus 15% SSS and transported to laboratory at 37°C. The samples were centrifuged and the pellet transferred to a petri plate with GIFV media following dissected. The material was transferred to an ICSI plate with GIFV media covered with mineral oil. After sperm identification, samples were kept under 37°C, 5% CO_2 overnight. Next day, the samples were reanalyzed and motile sperm were always preferentially injected.

Main results and the role of chance: Men were 29 to 78 years of age (40.7 ± 8.7). Among 61 microTESEs performed, 55.7% (n = 34) of samples found sperm, which is in according to literature that report 40% to 60% of sperm recuperation rate after microTESE. From those, 8.2% (n = 5) were motile sperm and 47.6% (n = 29) were immotile sperm. All samples were reanalyzed in the day after (day of oocyte collection) and the samples presenting no sperm or motile sperm in the microTESE time, kept the same result. Interestingly, from the 29 samples that presented immotile sperm in the day of microTESE, 44.8% (n = 13) presented motile sperm in the day after, which allowed superior viability for ICSI. From the 34 samples that sperm were present, oocytes were injected with microTESE sperm in 24 cases, with a mean normal fertilization rate of 47.1%. Other cases were canceled, or used donated sperm for ICSI. The normal fertilization rate was 55.1% (n = 18) when microTESE motile sperm were injected, while it was significantly lower when immotile sperm were used (33.9%, p = 0.014).

Limitations, reasons for caution: This is a retrospective study and all non-obstructive azoospermic men were included independently of azoospermia etiology, age or any other clinical characteristic, which could affect the microTESE success rate. The embryo development and pregnancy rates could not be accurately evaluated due to different female factors present in the study population.

Wider implications of the findings: MicroTESE in the day before of oocyte collection allow superior cycle planning and more detailed sperm searching. Sample incubated overnight permitted us to find motile sperm when just immotile were present in the day before. This approach can be an important tool to patients with non-obstructive azoospermia.

Trial registration number: not applied.

P-041   Outcome of intracytoplasmic sperm injection (icsi) using cryopreserved testicular sperm from azoospermic infertile men with varicocele

M. AbdelRahman[1], R. Saleh[2], R. Ezz El-Dawla[3], M. Al-Hossaini[4], M. Fawzy[5]

[1]Sohag University Hospital - Ajyal IVF/ICSI Center, OB/GYN Deprtment, Sohag, Egypt
[2]Sohag University Hospital - Ajyal IVF/ICSI Center, Dermatology- Venereology- and Andrology Departments, Sohag, Egypt
[3]Sohag University Hospital, Dermatology- Venereology- and Andrology Departments, Sohag, Egypt
[4]Sohag University Hospital - Ajyal IVF/ICSI Center Sohag, Dermatology- Venereology- and Andrology Departments, Sohag, Egypt
[5]Ajyal IVF/ICSI Center - Ibn Sina IVF/ICSI Center Sohag, Embryology, Sohag, Egypt

Study question: Does varicocele decrease the pregnancy rate in infertile men with non-obstructive azoospermia undergoing ICSI?

Summary answer: Varicocele significantly decreases the pregnancy rate in infertile men with non-obstructive azoospermia (NOA) who underwent Intracytoplasmic Sperm Injection (ICSI).

What is known already: Varicocele has been implicated as a causal factor for male infertility. The exact mechanism by which varicocele can alter spermatogenesis is debatable. Intracytoplasmic Sperm Injection using testicular sperm from men with azoospermia is the treatment of choice for this category of patients.

Study design, size, duration: This is a prospective controlled clinical study conducted at Ajyal IVF/ICSI center, Sohag, Egypt between July 2014 and June

2016. Forty infertile men with NOA who underwent ICSI with cryopreserved testicular sperm were included. Twenty two patients had clinically palpable varicocele (group 1) and 18 had no detectable abnormality in their genital examination (group2).

Participants/materials, setting, methods: Varicocele was confirmed by scrotal Doppler ultrasound. Azoospermia was confirmed by repeated absence of sperms after centrifuge. Exclusion criteria include female factor infertility, men with abnormal hormonal profiles, genetic abnormalities or genitourinary anomalies suggestive of obstructive pathology. ICSI was done using mature oocytes. The pro-nuclei was assessed at 18 hours following injection. Embryo quality was assessed on day 3 and day 5. Clinical pregnancy was diagnosed using trans-vaginal ultrasound 15 days after B-hCG.

Main results and the role of chance: Results were presented as mean $\pm$ standard deviation (SD) for continuous variables and frequency and percentage (%) for categorical variables. P-value <0.05 was significant. Men's age was 37.8 ± 5.4 years in group 1 and 34.5 ± 7.5 years in group 2 (P = 0.07). Female partner's age was 27.9 ± 5 years in group 1 as compared to 26.3 ± 3.7 years in group 2 (P = 0.35). Out of the 22 patients with varicocele, 12 (54.5%) had grade 3 and 10 (45.5%) had grade 2. Mean $\pm$ SD of number of retrieved oocytes, fertilized oocytes, good quality day 3 and day 5 embryos are shown in table 1. Clinical pregnancy was significantly reduced in group 1[7/22 cases (31.8%)] as compared to [12/18 (66.7%)] in group 2 [OR: 0.23; 95% Confidence Interval (0.06 - 0.88); P = 0.03].

Limitations, reasons for caution: One of the limitation of this study is the small sample size of the recruited patients.

Wider implications of the findings: Future research is warranted to study whether this selected category of patients would benefit from varicocele repair before recommending ICSI.

Trial registration number: NCT02306499.

P-042   Near-infrared spectroscopy assessment of testicular tissue oxygen saturation in healthy controls and male infertility

N. Kanayama[1], S. So[2], N. Murabayashi[2], H. Masuda[3], F. Tawara[4]

[1]Hamamatsu Univ. School of Medicine, Department of Obstetrics and Gynecology, Hamamatsu, Japan
[2]Hamamatsu University School of Medicine, Department of Reproductive Perinatology, Hamamatsu, Japan
[3]Tesseikai Neurosurgical Hospital, Department of Urology, Osaka, Japan
[4]Tawara IVF clinic, Medical office, Shizuoka, Japan

Study question: To determine the level of testicular oxygen saturation by Near-infrared spectroscopy which we developed currently.

Summary answer: Tissue oxygen saturation of testis is significantly low compared to that of hand and neck. That of male infertility showed different values from healthy controls.

What is known already: Near-infrared spectroscopy is a non-invasive and simple method to evaluate tissue oxygen status. There have been no reports on tissue oxygen saturation of testis in male infertility by Near-infrared spectroscopy. The objective was to asses testicular tissue oxygen saturation (StO2) by transscrotal near infrared spectrometry (NIRS) for healthy volunteers and male infertility which we currently developed as examiner's mounted tissue oximetry.

Study design, size, duration: Study design: Prospective clinical study. Size: Healthy volunteers (n =5), Male infertile patients (n = 7)

Participants/materials, setting, methods: Recently we developed examiner's mounted tissue oximetry by NIRS. We measured StO2 of hand, abdomen, testis of healthy volunteers and those of patients with male infertility by the NIRS transscrotaly.

Main results and the role of chance: We could succeed StO2 in any parts of testis rapidly just after attachment of the sensor to testis. The mean StO2 for the left testis of healthy control volunteers was 43.6+/- 2.2% and that of right was 40.5%+/-1.7%. In contrast the StO2 of hand and abdomen was $60 \pm 3.3\%$, $57 \pm 2.9\%$ respectively. The mean StO2 of left testis in varicocele patients was 45.3+/- 2.9%, and that of right was 48.7 ± 1.3. There was a significant difference of right testis between healthy volunteers and varicocele patients. The StO2 of oligospermia due to small testis of left side was 44.0 ± 2.2, that of right

side was 48.0 ± 2.8. There was a significant difference of right testis between healthy volunteers and patients with oligospermia by small testis. We discovered that StO2 of testis for healthy controls was significant lower than that of hand and abdomen.

Limitations, reasons for caution: The number of the subjects is small.

Wider implications of the findings: Our data suggest that the StO2 of male infertility could be higher than that of controls especially in right testis. Our NIRS was simple and non-invasive to detect StO2 of testis indicating that it could be useful in clinical practice.

Trial registration number: N.A.

P-043   The predictive factors for successful fertilization by in-vitro fertilization assessed by new CASA (Computer aided sperm analysis) system SMAS (sperm motility analysis system)

N. Enatsu[1], F. Takahiro[2], R. Yokota[2], K. Kishi[2], Y. Tsuji[2], O. Junko[2], M. Shiotani[2]

[1]Kobe University, Urology, Kobe city, Japan
[2]Hanabusa Women's Clinic, Gynecology, Kobe, Japan

Study question: Which parameters are important for successful fertilization in in-vitro fertilization (IVF)? Is it possible to predict the fertilization rate by using these parameters?

Summary answer: Curvilinear velocity, total motile sperm count and sperm motility index before sperm separation can be used as the predictive factors for successful fertilization by IVF.

What is known already: Sperm quality is known to affect the outcome of assisted reproductive technology (ART). However, most study is based on the quantity or morphology of sperm and the importance of the detailed sperm motility is rarely discussed. In attempt to make the assessment of sperm quality, CASA have been developed and several studies reported the CASA motility parameters may have the predictive value for fertilization. However, the definitive criteria of semen motility parameters related to fertilization is still unknown. SMAS is a newly developed system, which focuses on individual sperm movement and can analyze the detailed motility with some unique parameters.

Study design, size, duration: To identify the predictive factors of successful fertilization, IVF cycles in our clinic between June and October 2016 were analyzed. All semen was analyzed by SMAS before and after sperm separation using Percoll solution. After identification of predictive factors by statistical analysis, another IVF cycles between October and December 2016 were prospectively analyzed to verify the collectivity of predictive factors.

Participants/materials, setting, methods: By using retrospective data, clinically acceptable threshold was calculated using ROC curve in every semen parameters. All factors were then divided into two groups based on the threshold, and compared fertilization in each factor. We then conducted logistic regression analysis to identify the factors which independently related to IVF outcome. Finally, we assessed the association between fertilization rate and number of predictive factors exceeding the threshold using prospective data.

Main results and the role of chance: A total of 898 IVF cycles were evaluated to identify predictive factors. When compared the fertilization rate between threshold in semen parameters before sperm separation, statistically significant differences (p < .01) were observed in straight line velocity (VSL), curvilinear velocity (VCL), total motile sperm count (TMS), motility rate, sperm concentration, amplitude of lateral head displacement (ALH) and sperm motility index (SMI). Similarly, significant differences were observed in parameters after sperm separation with width of lateral head displacement and straightness of sperm motility in addition to VSL, VCL, TMS, ALH and SMI. Logistic regression analysis revealed VCL (>47 μm/s), TMS (>40 million) and SMI (>225) as independent predictive factors for IVF fertilization outcome. Adjustment of the model for female age, female anti-Mullerian hormone (AMH) levels did not change this finding. Prospective analysis of 332 IVF cycles revealed that IVF fertilization rate were significantly different between groups according to the number (0, 1, 2 and 3) of variables.

Limitations, reasons for caution: This study only evaluated IVF fertilization and there is no data about the pregnancy rate or live birth rate.

Wider implications of the findings: Among the above mentioned predictive factors, Curvilinear velocity and sperm motility index were only measurable

by CASA system especially SMAS. The information obtained by SMAS will be beneficial when planning strategies of ART.

Trial registration number: none.

P-044 Relationship between seasonal variations in human semen and fertilization rate after IVF

H. Tsuji[1], M. Kato[2], T. Yoshimura[1], S. Kounogi[1], E. Asano[2], N. Fukunaga[1,2,3], Y. Asada[1,2,3]

[1]Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Nagoya, Japan
[2]Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Kasugai, Japan
[3]Asada Ladies Clinic Medical Corporation, Asada Institute for Reproductive Medicine, Kasugai, Japan

Study question: Does human semen change seasonally and if so are the changes related to fertilization potential?

Summary answer: Sperm motility correlates with ambient temperature. The fertilization rate after Conventional-IVF(C-IVF) was higher in months where sperm motility rate was low.

What is known already: We have observed in our clinical setting more cases of poor sperm motility during winter period. However, reports on relationship between seasonal variations in human semen and fertilization rate after IVF are not many.

Study design, size, duration: This was a retrospective study including 4229 ART patients treated in 10083 cycles where freshly processed semen was used. The time period was 36 months (January 2013 to December 2015). Statistically significant effects were determined at the level of $p < 0.05$ using the ANOVA or chi-square test.

Participants/materials, setting, methods: Patients were seeking infertility treatment in a private IVF clinic. We calculated the semen volume, sperm concentration, total sperm count and motility sperm rate per month, and examined for seasonal variability. Similarly, the monthly fertilization rate after C-IVF and intracytoplasmic sperm injection (ICSI) were calculated and examined for any seasonal variations. Calculation of the fertilization rate was limited to the age of the wife at oocyte collection which was = >30 to <36 years old.

Main results and the role of chance: Semen volume, sperm concentration and total sperm count did not vary greatly from month to month. However, the sperm motility rate underwent a clear change with a peak at August. There was a very strong positive correlation when comparing the monthly sperm motility rate with the monthly average temperature in Nagoya city, Japan. The monthly fertilization rate after ICSI was 81.9 to 84.7% and it showed a very stable value, also there was no seasonal variation at all. On the other hand, the fertilization rate after C-IVF varied widely from month to month (60.8~71.0%). When the fertilization rate after C-IVF was divided into three monthly periods according to the sperm motility rate (High: June July August September, Middle: April May October November, Low: January February March December), the fertilization rate after C-IVF in the group with a low motility rate was significantly higher than the other 2 group ($p < 0.05$).

Limitations, reasons for caution: The study was a retrospective study.

Wider implications of the findings: Sperm motility rate has a positive correlation with ambient temperature, and we reported that seasonal variation exists. C-IVF fertilization rate was suggested to be high in winter. It might show that higher ambient temperature causes faster capacitation and higher sperm motility, which leads to exhausted sperm before processing for C-IVF.

Trial registration number: None.

P-045 Saturated fatty acids increase intracellular lipid accumulation through a PPARγ-dependent pathway

X. GE, X. Hu, L. Chen, B. Yao

Nanjing Jinling Hospital, Reproduction Medicine Center, Nanjing, China

Study question: Do saturated fatty acids disturb the lipid metabolism of Sertoli cells, and can peroxisome-proliferator-activated receptor γ (PPARγ) agonist rescue such disturbance?

Summary answer: Both palmitic acid (PA) and stearic acid (SA), which are two representative saturated acids, increased intracellular lipid accumulation, and PPARγ agonist rosiglitazone ameliorated such accumulation.

What is known already: It has been reported that obesity impairs spermatogenesis, and diminished inhibin B production, which is secreted by Sertoli cells. A disruption of blood-testis barrier was also observed in obese mice. Therefore, obesity causes Sertoli cell dysfunction. On the other hand, obesity is accompanied by an increase in the levels of saturated fatty acids, especially PA and SA. Collectively, these findings illustrate that saturated fatty acids may participate in the decline of male fertility caused by obesity. PPARγ is a transcription factor relevant to lipid metabolism. Its agonists are applied in metabolic syndrome, and can possibly ameliorate aberrant lipid accumulation.

Study design, size, duration: High-fat diet (HFD) induced obese mice were constructed, and the accumulation of fatty acids in the microenvironment around Sertoli cells was analyzed. Primary mouse Sertoli cells or cultured TM4 cells were treated with PA or SA, and lipid accumulations were observed. Expression levels of representative genes related to lipid metabolism were also analyzed. Rosiglitazone, a PPARγ agonist, was used to treat TM4 cells in combination with PA or SA, and lipid accumulations were investigated

Participants/materials, setting, methods: Mouse testes were homogenized to test fatty acid levels, and testes sections were stained with Oil Red O (ORO). Primary Sertoli cells or TM4 cells were treated with 0.2-0.4 mM PA or SA for 24 h, and ORO staining was executed. Expression levels of FASN and CPT1b were analyzed using qPCR. Rosiglitazone at 20 or 50 µM was added in TM4 cells in combination with PA or SA to investigate the involvement of PPARγ pathway.

Main results and the role of chance: Testes of HFD induced obese mice contained higher levels of fatty acids, and lipid droplets were observed around Sertoli cells in seminiferous tubule, indicating an accumulation of fatty acids in the microenvironment near Sertoli cells in obese individuals. In vitro experiments showed that both PA and SA induced intracellular lipid accumulation in Sertoli cells, demonstrating an aberrant lipid metabolism caused by saturated fatty acids. Also, both PA and SA treatment increased the expression level of CPT1b, which is involved in lipid degradation, but did not affect the expression of lipid synthetic gene FASN. These results indicate that saturated fatty acids induced lipid accumulation and promoted the lipid degradation mechanism. Rosiglitazone pretreatment ameliorated the accumulation of lipids in TM4 cells caused by PA or SA, which proved an involvement of PPARγ pathway in the influence of saturated fatty acids on Sertoli cells.

Limitations, reasons for caution: The investigation of effects of saturated fatty acids on Sertoli cells were limited on in vitro experiments in this study. An ex vivo or in vivo study should be conducted in the future.

Wider implications of the findings: These results suggest that saturated fatty acids affect lipid homeostasis in Sertoli cells, and are possibly one of the critical causes of the declined fertility in obese males. PPARγ agonists, such as rosiglitazone, can be used as candidates to recover fertility of obese men.

Trial registration number: None.

P-046 Prospective studies on semen quality of 163060 male infertility in our hospital in China

L. Weina[1], J. Miaomiao[2], L. Gang[2]

[1]Reproductive & Genetics Hospital CITIC-XIANGYA, Clinical Laboratory, Changsha-Hunan, China
[2]Institute of Reproduction and Stem Cell Engineering, Central South University, Changsha- Hunan, China

Study question: Is there decline in semen quality of infertile men? Do this semen abnormalities associated with age? If age thresholds for elements of semen quality exist?

Summary answer: Main type of infertility in male infertility is asthenospermia. 46-year is a watershed in dramatic changes in semen parameters of infertile men in our hospital.

What is known already: Infertility is a global problem to contend with and male factor infertility is on the increase. The decline in sperm quality reported over the last decades have raised concerns. However, it is unclear whether season、year、age would have differing effects on large-scale semen quality at

various parameters. Therefore, their exploration may provide useful information in cases of male idiopathic infertility.

Study design, size, duration: Population-based cross-sectional and retrospective chart review. Semen samples were collected by masturbation after abstaining for 3–5 days from 163060 male patient of age between 18 and 65 years and who were also attending infertility clinic for having children in our hospital, China from 2011 to 2015.

Participants/materials, setting, methods: The semen samples of 163060 male patient in our hospital were analyzed for sperm volume、 sperm concentration、 sperm count、 sperm progressive motility、 total motile spermatozoa and immotile spermatozoa, using Neubauer counting chamber in line with world health Organization procedures (the fifth edition). And we analyzed the dynamic changes of 163060 semen samples with the seasonal variation、 year、 age changing, and age thresholds for changes in semen parameters.

Main results and the role of chance: There is not obvious decline in semen quality of infertile men in our hospital. The main type of infertility in male infertility is asthenospermia (20.83%-46.63%), followed by oligoasthenozoospermia (8.26%-13.28%) and azoospermia (7.54%-8.79%). 55.2% sperm progressive motility and 44.53% total motile spermatozoa is lower than the standard of WHO; 62.33% of infertile men had at least one of the semen parameters (semen volume, sperm concentration, sperm count, sperm forward movement) lower than lower limit of WHO. With advancing age, the proportion of asthenospermia increased: ≤20 years (31.87%), 21-25 years (28.26%), 26-30 years (31.80%), 31-35 years (35.97%), 36-40 years (39.43%), 41-45 years (41.94%), 46-50 years (43.94%), 51-55 years (49.48%), 56-60 years (50.76%), ≥61 years (53.33%). 34 and 63 years old, 36 and 63 years old, 46 years old, 40 years old were respectively age threshold of sperm concentration, sperm count, sperm progressive motility and total motile spermatozoa, immotile spermatozoa.

Limitations, reasons for caution: We do not have actual number of infertile men in infertile couples of our hospital in China. And the effects of age on semen parameters are not for the same person, but for large numbers of infertile men.

Wider implications of the findings: There is not obvious decline in semen quality of infertile men in our hospital. Asthenospermia、 azoospermia、 oligoasthenozoospermia are associated with male infertility. Only semen parameters of 37.67% infertile men were within normal range. 46-year is a watershed in dramatic changes in semen parameters of infertile men in our hospital.

Trial registration number: Funding by national/international organization (s)-This work was supported by the National Natural Science Fund Project (81070531).

P-047 Roles of coenzyme Q10 on sperm quality in frozen-thawed samples of men with oligoasthenoteratozoospermia

J. Ngeamvijawat[1], A. Sawangchaeng[1], S. Kiatpongsan[2], P. Virutamasen[2], K. Pruksananonda[2]

[1]King Chulalongkorn Memorial Hospital, Obstetrics and Gynecology, Bangkok, Thailand
[2]Chulalongkorn University, Obstetrics and Gynecology, Bangkok, Thailand

Study question: To test if coenzyme Q10 (CoQ10) can improve sperm quality in frozen-thawed samples of men with oligoasthenoteratozoospermia.

Summary answer: CoQ10 significantly improves sperm motility and sperm kinetics in frozen-thawed samples of men with oligoasthenoteratozoospermia.

What is known already: As a dietary supplement, CoQ10 can improve sperm quality parameters but has not yet been shown to increase live birth rate or pregnancy rate. Adding CoQ10 directly to sperm culture medium (in vitro) can be beneficial but data are still quite limited.

CoQ10 has been studied primarily in fresh semen samples. There has been very limited evidence on benefits of CoQ10 in frozen-thawed samples where CoQ10 could possibly reduce negative effects of freezing and thawing processes especially in those with poor sperm parameters like oligoasthenoteratozoospermia.

Study design, size, duration: Laboratory study with a control group and an intervention group. Frozen-thawed samples (N = 10) of men with oligoasthenoteratozoospermia were used to test in vitro effects of CoQ10 on sperm

quality. In the control group, the culture medium was Ham's F10 with HSA and, in the intervention group, CoQ10 was added to culture medium (50 µg per ml). We collected data on sperm parameters at 30, 60 and 240 minutes after thawing.

Participants/materials, setting, methods: Semen samples were obtained from male infertility patients with oligoasthenoteratozoospermia at King Chulalongkorn Memorial Hospital's Fertility Clinic. Their mean age was 39.0 years (SD = 2.2). Their mean weight and height were 72.5 kilograms (SD = 9.8) and 170.3 centimeters (SD = 4.4), respectively. Semen samples were kept frozen in liquid nitrogen tank for 2 weeks before thawing and dividing to be incubated in the control medium and in the intervention medium.

Main results and the role of chance: Sperm parameters right after thawing were as followed: Concentration = 13.7 million per milliliter (SD = 1.1), motility = 10.1% (SD = 5.3), progressive motility = 1.0% (SD = 1.1), and normal morphology = 0.2% (SD = 0.4). Survival rate was 34.1% (SD = 9.6).

Sperm motility improved in the CoQ10 group at 30, 60 and 240 minutes; 12.1% versus 10.8%, 13.9% versus 9.8% and 14.6% versus 4.6%, respectively. Mean improvements were 1.3%, 4.1% and 10.0% (paired t-test; p = 0.057, 0.004 and <0.001, respectively). Progressive motility also increased in the CoQ10 group at 30, 60 and 240 minutes; 3.5% versus 0.6%, 2.8% versus 0.2% and 2.2% versus 0.0%, respectively. Mean increases in progressive motility were 2.9%, 2.6% and 2.2% (paired t-test; p = 0.001, 0.006 and 0.008, respectively).

Sperm kinetics (average path velocity, straight-line velocity and curvilinear velocity) were significantly improved at 30, 60 and 240 minutes (paired t-test; p < 0.0001 for all comparisons). TUNEL assay did not differ at 60 minutes but was better in CoQ10 group at 240 minutes (paired t-test; p = 0.001).

Sperm concentration and morphology did not differ between the CoQ10 and control groups (paired t-test; p > 0.05 for all comparisons).

Limitations, reasons for caution: Our study was conducted in a laboratory setting. We would need a larger number of samples to validate these findings before proceeding to further tests in a clinical setting.

Wider implications of the findings: While most studies report roles of CoQ10 as dietary supplement, our study shows effects of adding CoQ10 directly to culture medium. We demonstrate that CoQ10 can significantly improve sperm motility and kinetics in frozen-thawed samples of men with oligoasthenoteratozoospermia. This might be proven to be beneficial in a clinical setting.

Trial registration number: Not applicable.

P-048 Sperm DNA fragmentation and sex chromosome aneuploidy after swim-up versus density gradient centrifugation

S.W. Kim[1], B.C. Jee[2], S.K. Kim[2], J.Y. Lee[3], C.S. Suh[1], S.H. Kim[1]

[1]Seoul National University Hospital, Obstetrics and Gynecology, Seoul, Korea- South
[2]Seoul National University Bundang Hospital, Obstetrics and Gynecology, Seongnam, Korea- South
[3]Hamchoon Women's Clinic, Obstetrics and Gynecology, Seoul, Korea- South

Study question: Which one is more effective between swim-up and density gradient centrifugation (DGC) in terms of reduction of sperms with fragmented DNA, sex chromosome aneuploidy, or abnormal chromatin structure?

Summary answer: The swim-up method is superior to DGC in enriching genetically competent sperms.

What is known already: Sperm motility, the percentage of normal form, and SDF level increase significantly after swim-up. We processed semen samples with either swim-up or DGC, and evaluated sperm DNA fragmentation, sex chromosome aneuploidy, or abnormal chromatin structure.

Study design, size, duration: Prospective cohort study using semen samples obtained from 18 healthy male (single sample per person) from January to December 2015.

Participants/materials, setting, methods: Semen sample was divided into three aliquots. The first was processed by the swim-up method. The second was processed by the DGC method. The third was not processed and served as the control. The percentage of sperms with fragmented DNA is measured using the sperm chromatin dispersion test. The percentage of normal X or Y chromosome is measured using fluorescence in situ hybridization. The percentage of abnormal chromatin structure is measured using toluidine blue staining.

Main results and the role of chance: The percentage of sperms with fragmented DNA was significantly lower in the swim-up fraction (9.7%, P <.05), but not in the DGC fraction (27.8%, P >.05) compared with that in the unprocessed fraction (27%). The percentage of normal X or Y sperms was similar in the three fractions. The percentage of sperms with abnormal chromatin structure significantly decreased after DGC (from 15.7% to 10.3%, P <.05). The swim-up method also tended to reduce the percentage of sperms with abnormal chromatin structure, but the difference was not significant (from 15.7% to 11.6%, P >.05).

Limitations, reasons for caution: Because the results of this study obtained from semen samples of healthy male partners who attended infertility clinics, these cannot be extrapolated to patients with severe male factor. There are diverse methods to assess sperm DNA fragmentation. However only sperm chromatin dispersion test was used in the present study.

Wider implications of the findings: Even if the percentage is decreased substantially, sperms with genetic abnormality still remain after swim-up. It is expected that adding novel methods for sperm preparation to conventional swim-up will be able to select functionally and genetically competent sperms one by one just like natural selection.

Trial registration number: This study is not a clinical trial.

P-049 Heterozygous mutation of CFTR gene leads to activation of autophagy in Sertoli cells

C. Ravel[1,2], N. Bourmeyster[3], F. Becq[3], A. Burel[4], M.T. Lavault[4], C. Pimentel[5], G. Jouve[5], S. Veau[5], S. Sarandi[5], B. Jegou[6], M. Yefimova[7]

[1]Hôpital Sud Anne de Bretagne, Laboratoire de Biologie de la Reproduction - CECOS, Rennes Cedex 2, France
[2]INSERM UMR1085- 9 av du Pr Léon Bernard- 35000 Rennes, IRSET, Rennes, France
[3]Equipe CMCS- ERL CNRS 7368., Laboratoire STIM-, Poitiers, France
[4]BIOSIT, Plateforme de MRIC TEM cellulaire, Rennes, France
[5]CHU de Rennes, Département de Gynécologie Obstétrique et Reproduction Humaine, Rennes, France
[6]INSERM, IRSET-UMR1085, Rennes, France
[7]Institut Sechenov, Academie des Sciences, Saint-Pétersbourg, Russia C.I.S.

Study question: Sertoli cells have a strong autophagy activity to eliminate different substrates during the seminiferous epithelium cycle. There has never been a study of autophagy in testis of patients CFTR mutated.

Summary answer: CFTR mutated patients show evidence of activation of testicular autophagy.

What is known already: Autophagy is necessary for the resorption of apoptotic germ cells at all stages of their differentiation but also is essential for the regression of the tubulo-bulbar complexes and the residual bodies present during the elongated spermatid stage. Autophagy defect is known to be associated with cystic fibrosis (CF), an incurable lung disease caused by a mutation in the gene coding for cystic fibrosis transmembrane conductance regulator (CFTR). The most common mutation of CFTR gene is a deletion of three nucleotides coding for phenylalanine at the 508th position on the protein (F508delCFTR).

Study design, size, duration: Electron microscopy study of testis specimens from control and F508del CFTR+/- patients. Study of autophagy in cultured Sertoli cells (TM4) transfected with normal (wt) CFTR or mutated F508delCFTR (GFP coupled).

Participants/materials, setting, methods: Search for autophagic markers in several morphological observations of Sertoli cells by electron microscopy obtained from testicular biopsies of patients carrying a mutation of the CFTR gene.

Main results and the role of chance: We have identified by electron microscopy in F508delCFTR +/- patients the presence of compartments such as mitochondria or lipid droplets delimited by a double membrane, characteristic structures of autophagy. These structures are found in Sertoli cells but, surprisingly, also in germ cells. Confocal microscopy observation of murine TM4 Sertoli cell line expressing human F508del CFTR and wt CFTR demonstrates the presence of multiple autophagosomes stained with antibodies against autophagy membrane marker LC3 protein, in F508delCFTR cells, while in cells expressing CFTR WT they are rather rare.

Limitations, reasons for caution: The CFTR protein, besides its function of regulation of the ion channels, is involved in the modulation of the phenomena of exocytosis and endocytosis.

Wider implications of the findings: It could be a mechanism triggered in order to counteract the deleterious effect of the presence of the mutated protein.

Trial registration number: GMR 2017-01

P-050 "In vitro" outcome of different follicle-stimulating hormone preparations on pre-pubertal porcine Sertoli cells: preliminary results

G. Luca[1,2], I. Arato[1], F. Mancuso[1], M. Calvitti[1], M.C. Aglietti[3], G. Carpinelli[2], C. Lilli[1], C. Bellucci[1], T. Baroni[1], M. Bodo[1], R. Calafiore[2,3]

[1]University of Perugia, Department of Experimental Medicine, Perugia, Italy
[2]Saint Mary Hospital, Division of Medical Andrology and Endocrinology of Reproduction, Terni, Italy
[3]University of Perugia, Department of Medicine, Perugia, Italy

Study question: At present, there are no 'in vitro" studies on the effects of different preparations of follicle-stimulating hormone (FSH) on pre-pubertal Sertoli cells, which could provide important information in reproductive medicine.

Summary answer: We aimed to assess the effects of different FSH preparations on porcine pre-pubertal Sertoli cells (pSC) by evaluating modulation of their specific markers.

What is known already: It is known that FSH is the main regulator of spermatogenesis. The different preparations of FSH available in the market, are obtained by either recombinant technology (α and β follitropin) or post-menopausal urine (urofollitropin). The reason for the structural and functional heterogeneity of FSH lies on their different content in sialic acid C-terminus residue of the oligosaccharide chain. In the male testis, FSH-receptor (FSH-r) is exclusively localized on Sertoli cells that represent the unique testis target of this hormone. The use of FSH in oligo-zoospermic males, while representing a useful therapy in selected patients, is adversely affected by conflictual findings.

Study design, size, duration: Set-up an "in vitro" comparative study of different FSH preparations on ultrapure, viable and functional pSC to evaluate, at 48 hours of FSH stimulation, the modulation of SC specific markers by:

(1) Real Time PCR analysis of anti- Müllerian hormone (AMH), inhibin B, FSH-r;
(2) Western blotting analysis (WB) of FSH-r;
(3) ELISA assay, both in cell extract and culture medium, for AMH and inhibin B.

Participants/materials, setting, methods: pSC, obtained from 15-20 days old neonatal porcine testes, were evaluated in terms of purity by AMH (unique pre-pubertal pSC marker), INSL3 (specific Leydig cells marker), ASMI (unique peritubular cells marker) and PGP9.5 (gonocytes and spermatogonial cells marker) immunostaining under immunofluorescence and cytofluorimetric analysis. Thereafter pSC culture were treated with:

- α-follitropin, β-follitropin or urofollitropin at the same molar concentration (100 nM) for 48 hours;
- Testosteron (T): 0.2 mg/ml;
- Combinations of different FSH preparations with T.

Main results and the role of chance: In our model we observed, in the tested experimental conditions, that:

- All three preparations of α-follitropin, β-follitropin and urofollitropin induced, as expected, a reduction of AMH in terms of mRNA, cell extract and secreted protein;
- All three preparations induced an increase of inhibin B in terms of mRNA and cell extract protein and, while interestingly, only α-follitropin induced an increase of inhibin B secreted in the culture medium;

- All three preparations induced, as expected, a reduction of FSH-r mRNA but only α-follitropin was associated with downregulation of FSH-r (WB).

These results preliminarily showed, that the three FSH preparations were associated with different effects in terms of inhibin B secretion, posing the question if, in the treatment of the infertile male, use of FSH preparations that increase inhibin B secretion (with a potential down-regulation of endogenous FSH) or those that do not induce this increase should be preferred.

Limitations, reasons for caution: Dose and time-dependent relationship.

Wider implications of the findings: The present original study, based on the use of an 'in vitro" model of pre-pubertal pSC, could help better understanding of the effects of different FSH preparations, thus providing important information on both, the conflictual findings with regard to use of FSH in oligozoospermic males and, in general, reproductive medicine.

P-051 Exogenous oral combination antioxidants in idiopathic infertile males, having higher DNA fragmentation index, before ICSI cycle may improve live birth rate

S. Kanta Goswami[1], R. Chattopadhyay[2], S. Ghosh[2], B. Ghosh[2], S. Yasmin[2], M. Goswami[2], B. Chakravarty[2]

[1]Institute of Reproductive Medicine, ART, Calcutta, India
[2]Institute of Reproductive Medicine, ART, Kolkata, India

Study question: Does oral combination antioxidant supplementation correct DNA abnormality in idiopathic infertile males and thereby improve live birth rate in ICSI cycles?

Summary answer: Study confirms the efficacy of oral combination antioxidants in treating DNA abnormality in idiopathic male infertility (IMI) and improvement in live birth rate following ICSI.

What is known already: IMI associated with oxidative stress (OS) may have higher DNA Fragmentation Index (DFI) which may be responsible for failed fertilization or abnormal fertilization leading to implantation failure or pregnancy loss. Antioxidants like Vitamin C, Lycopene, Zinc and Selenium protect sperm DNA by scavenging off excess free radicals and reducing DNA oxidation rate, whereas folic acid and methyl cobalamine synthesize healthy DNA and thus help in normal fertilization and conception.

Study design, size, duration: A prospective study involving 162 men with IMI was done from August 2012 to August 2016 at Institute of Reproductive Medicine, Kolkata, India.

A combination of antioxidants containing vitamin C, Lycopene, Zinc, Selenium, Folic Acid and methyl cobalamine etc. was administered for six months before ICSI cycle in a universally recommended dosage. There was a history of at least two failed cycles or pregnancy loss. Female partners (age ≤ 38 yrs) were apparently normal.Participants/materials, setting, methods:

Group A (n = 104) males were used as controls, Group B (n = 58) had infertile males having OS and high DFI (≥ 25%)

OS was confirmed by the high level of Reactive Oxygen Species (ROS) and reduced Total Antioxidant Capacity (TAC) by Chemiluminescence Assay. Sperm count, motility, morphology and leucocyte count were evaluated. ICSI was done in 148 cycles. Embryo transfer was performed in 110 index cycles. In 38 cycles frozen embryo transfer (FET) was done.

Main results and the role of chance: In Group A there was improvement in sperm count (29.5 ± 7.96 vs 54.65 ± 11.05, NS) and motility (15.8 ± 3.13 vs 28.60 ± 4.37, p = 0.0179) after six months' therapy. Sperm count in Group B was 18.40 ± 3.15 vs 46.70 ± 5.65, p = 0.0001, Motility in Group B was 19.20 ± 2.80 vs 35.50 ± 4.35, p = 0.0019.

ROS level in Group A was 32107.15 ± 9623.52 vs 31257.0 ± 9240.0, NS. TAC level in Group A was 1164.20 ± 99.76 vs 2010.65 ± 116.30, p = 0.0001.

ROS level was reduced, (72330.50 ± 9124.45 vs 41230.65 ± 6245.10, p = 0.005) and TAC level was enhanced (1144.50 ± 134.45 vs 1640.75 ± 175.60) significantly after therapy in Group B.

DFI decreased in Group A (24.40 ± 2.82 vs 21.75 ± 2.39, NS) In Group B there was significant decrease in DFI (29.45 ± 2.55 vs 20.30 ± 2.24, p = 0.0078) after therapy.

Improvement in sperm morphology and leucocyte count was not significant after therapy in Group B.

Pregnancy rate was 48.27% (Group B) and 30.76% (Group A),p = 0.04. Live birth rate was 32.14% in Group B and 9.37% in Group A, p = 0.04.

Other factors for implantation and pregnancy loss need to be excluded to minimize the role of chance.

Limitations, reasons for caution: Only antioxidant therapy may not be sufficient in IMI if some other causative factors for development of OS are present. Therefore, it is essential to remove the causative factors before initiation of antioxidant therapy. Moreover, ideal combination and optimum duration of treatment is still unclear.

A prospective study is needed.

Wider implications of the findings: A very simple and safe therapy by combination of antioxidants may reduce implantation failure and pregnancy loss and increase live birth rates by correcting DNA abnormality in certain percentage of IMI induced by OS.

Trial registration number: Not applicable.

P-052 Sperm DNA Fragmentation Testing and significance, where do we stand?

E. Hassanen[1], K. Elqusi[1], H. Zaki[2]

[1]Ganin Fertility Center, Clinical Embryology, Cairo, Egypt
[2]Ganin Fertility Center, Gynecology and Obstrics, Cairo, Egypt

Study question: Assessment of the most prevalent sperm DNA fragmentation and sperm selection techniques. Also looking into the most prevalent technique that has yielded better outcomes.

Summary answer: Among all available sperm DNA Fragmentation testing techniques, TUNNEL Assay and SCD were the most commonly used with significant difference from the others.

What is known already: Sperm DNA integrity assessment is getting more important nowadays in the evaluation of semen fertility. There are different available techniques, and each of them has its own merit. Also, sperm selection techniques are currently more widely used according to the result of the sperm DNA fragmentation test.

Study design, size, duration: This web based cross-sectional survey included 23 questions categorized into 4 categories (DNA fragmentation techniques, interpretation of results, lab procedures to deal with abnormal DFI, and related embryological factors & clinical outcome). Data was collected during January 2016 and 120 responses were received.

Participants/materials, setting, methods: Of the 120 collected responses, 100 were completed correctly, and 82 of the participants were clinical embryologists and andrologists. Data was collected and analyzed using an online survey software and questionnaire tool.

Main results and the role of chance: Fifty three percent of the responders were using sperm DNA fragmentation testing. The most prevalent Technique was TUNEL Assay. TUNNEL Assay (34.62%), and SCD (32.69%) were significantly more commonly used than the COMIT, SCSA, and other techniques combined (P = 0.0006). The indications were (multiple answers were allowed): 73% Repeated miscarriage, 71% previous ICSI failure, 55% unexplained infertility, and 51% poor semen parameters. Threshold values parameter, 44.23% said it's dependent on technique used, 30.77% center's guidelines. 25% general threshold. The preferred ART modality in cases of abnormal DFI was 84.62% ICSI (P < 0.0001) Compared To IVF, IUI, and OI. The survey revealed that there's no significant difference between IMSI, PICSI, TESE, and MACS as a preferred sperm selection technique for abnormal DFI patients. General improvement was observed in prognostic lab indices after using a sperm selection technique it included fertilization rate, cleavage parameters, and blastulation rate and quality. Recipients were asked to specify the improvement in their clinical outcome after using sperm selection technique, a higher pregnancy rate by 5% and lower miscarriage in the 1st trimester got the highest percentages. Retrospective analysis of responses whose having positive clinical outcome showed that 40% of them were using TUNEL Assay.

Limitations, reasons for caution: The number of responses is relatively low to reach a level of significance in the results and it doesn't represent a worldwide view since it's only 29 countries responded to the survey. However we've received responses from the most eminent centers worldwide and covers over 100 thousand cycles per year.

Wider implications of the findings: Out from the received responses, Sperm DNA fragmentation testing has been used by more than 50% of the participants. Urgent studies are needed to set up a universal threshold value for each technique. The most clinically relevant technique for assessment of sperm DNA fragmentation need to be looked at.

Trial registration number: NA.

P-053　The effects of HPV infection on semen: first results from a new approach

L. Bosco[1], M.A. Ragusa[1], G. Capra[2], R. Schillaci[2], M.C. Roccheri[1], A. Perino[2]

[1]University of Palermo, Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies, Palermo, Italy
[2]University of Palermo, Department of Sciences for Health Promotion and Mother-Child Care "G. D'Alessandro", Palermo, Italy

Study question: The effect of Human Papilloma Virus (HPV) infection on semen characteristics was investigated using a new method that allow to evaluate virus localization in the different semen components.

Summary answer: Our data indicate a correlation between HPV infection of exfoliated epithelial cells (from spermatic ducts and accessory glands) and reduction of sperm cell motility.

What is known already: HPVs are agents of the most common sexually transmitted diseases. Both in men and in women, HPVs cause a variety of clinical symptoms ranging from warts to cancer. It has been shown (IARC, 2009) that infection with 12 oncogenic HPVs is the major cause of development of cervical cancer in women and it is also related to penile cancers in men. HPV infects epithelial cells and can bind other cell types. Its presence in semen is widely known, but the effects on fertility and reproductive function are still controversial.

Study design, size, duration: From January 2015 to December 2015, twenty men were enrolled. From each subject seminal parameters were evaluated according to WHO guidelines. HPV was detected and genotyped both in total semen and in swim up-fraction. HPV detection was performed also in separated semen fractions: sperm cells from total semen and from swim-up and epithelial cells. Semen parameters of positive samples were compared with parameters of negative samples. Moreover, HPV genome wholeness in sperm cells was evaluated.

Participants/materials, setting, methods: Partners of women with high-grade squamous intraepithelial lesions. DNA was purified after differential lysis. HPV genotyping was performed by a conventional reverse hybridization and HPV detection in the different semen components was performed by nested PCR with the use of universal primers (MY09 / 11, GP5+ / 6+). HPV genome wholeness was evaluated by Real Time-PCR using six different target genes.

Main results and the role of chance: Samples were distributed into HPV positive and negative based on the conventional genotyping (total DNA extraction and reverse hybridization method) or on the new method (differential lysis, DNA extraction from separate fractions and nested PCR method) for every different fraction. In any case, we did not find any statistically significant difference on semen volume, sperm concentration, morphology. On the contrary, only when we compared HPV-positive epithelial cell samples to negative samples in the same fraction, we found a difference in sperm motility. The average percentage of sperm linear progressive motility amounted to $10\% \pm 11.5$ in the positive samples and $54.4\% \pm 23.3$ in the negative samples (two-tailed P value = 0.0003). Moreover the HPV genome wholeness was tested by RT-PCR. Results performed on DNA extracted from sperm cells of a sample showed that the copy number of E1 and E2 genes was lower than LCR (Long Control Region) and E6 copy numbers (copy number ratio: 0.4 ± 0.05). These data indicate that in this sample more than half viral genomes are defective, suggesting that a recombination event could be occurred into the sperm heads.

Limitations, reasons for caution: Low number of samples because of the sporadic frequency of infection with a single high-risk HPV genotype.

Wider implications of the findings: The data support the proposed role of HPV in decreased male and couple fertility. The presence of defective viral genomes rises the idea that these defective forms could be integrated in the sperm genome. In turn, this risk prompts new possible consequences of the viral infection in semen.

Trial registration number: Not required.

P-054　Does protein supplements taken in relation to workout impact sperm quality?

H.O. Elbaek[1], K. Shathmigha[1], R. Laursen[1], B. Alsbjerg[1], B.B. Povlsen[1], T. Haahr[1], P. Humaidan[2]

[1]The Fertility Clinic Skive- Skive regional Hospital, Department of clinical medicine-Aarhus University, Skive, Denmark
[2]The Fertility Clinic Skive- Skive regional Hospital, Department of Clinical Medicine-Aarhus University Hospital, Skive, Denmark

Study question: Does termination of intake of workout related dietary supplements affect sperm concentration in oligospermic men?

Summary answer: A two months abstinence time elevated the sperm concentration and had an important impact in the clinical decision-making.

What is known already: The market for dietary supplements is growing and especially young men who enter fitness gyms for workout seem to have a large intake with an average of 5 times/week. Recently, it was shown that 23/24 selected dietary supplements from fitness shops contained anabolic steroids. However, these so called pro-androgenic supplements are presumably not in the same category as the more commonly used whey and soy protein supplements. Importantly, protein supplies are not medical drugs, but dietary supplements. Hence protein supplements are not tested like medical drugs and consequently, they might contain known and unknown active mediators that impact reproductive health.

Study design, size, duration: Case-series.

Participants/materials, setting, methods: A total of 11 men who used dietary supplements as part of their workout, and who were submitted to a tertiary fertility clinic were prospectively enrolled. The sperm concentration had to be below 15million/mL at time of enrollment. After 2 months abstinence from dietary supplements a new semen analysis was measured according to WHO criteria and patients underwent a clinical examination and completed a questionnaire to assess potential confounders.

Main results and the role of chance: The median difference in sperm concentration was 1.6 million/mL (Interquartile range: 0-5.1) higher at the follow-up 2 months later compared to baseline. A total of four patients did not need donor back up following the dietary abstinence which was otherwise indicated from their baseline sample. Furthermore, one couple changed from IVF to IUI treatment. Another case showed a percentage-wise large increase in sperm concentration from only 1 spermatozoa seen to 0.6 mio/mL, interestingly the size of the testes was 12 and 10 ml, respectively. One patient had azoospermia in the initial sample and no difference was observed after termination of the dietary supplement intake. Only one patient had a slightly lower sperm concentration following protein abstinence.

Limitations, reasons for caution: Although patients where prospectively enrolled, this is a case-series, emphasizing the need for future corroboration. Moreover, the study might have unknown confounders even though no patient used anabolic steroids or smoked. Furthermore, the type of dietary supplemental product, the active components, and the dose might vary for each case.

Wider implications of the findings: As there is no health benefit from protein supplies for young and otherwise healthy men, we suggest fertility doctors to advice for caution in the use of protein supplies while undergoing fertility treatment. Further research is urgently needed.

Trial registration number: N/A.

P-055　Induction of DNA damage during sperm selection for ARTs: DNA fragmentation (sDF) in the viable sperm fraction following density gradient centrifugation (DGC) and swim-up

M. Muratori[1], M. Cambi[2], S. Danti[3], N. Tarozzi[4], M. Nadalini[4], A. Casini[5], C. Azzari[6], A. Borini[4], E. Baldi[7]

[1]University of Florence, Experimental- Clinical and Biomedical Sciences, Firenze, Italy
[2]University of Florence, Experimental and clinical Biomedical Sciences, Florence, Italy
[3]University of Florence, Experimental and clinical biomediacla sciences, Florence, Italy
[4]Tecnobios Bologna, Tecnobios Bologna, Bologna, Italy
[5]Anna Meyer Children's Hospital, Anna Meyer Children's Hospital-, Florence, Italy
[6]Anna Meyer Children's Hospital-, Anna Meyer Children's Hospital-, Florence, Italy
[7]University of Florence, Dpt Experimental and clinical biomedical sciences, Florence, Italy

Study question: Is DGC-induced sperm DNA damage more sensitively detected by evaluating DNA fragmentation in the viable sperm fraction and prevented by swim-up procedure?

Summary answer: DGC induced DNA damage is detected with higher sensitivity when measured in viable spermatozoa and is partially prevented by swim-up procedure

What is known already: Although many studies reported that sperm selection improves sperm DNA integrity, some recent papers showed that sperm selection with DGC can increase sperm DNA fragmentation levels. In particular, a recent study from our group has shown that DGC induced an additional sperm DNA damage in about 50% of male partners of infertile couples who subsequently experienced a 50% lower probability to achieve pregnancy after Assisted reproduction Techniques (ARTs). These results rise concerns about the safeness of DGC and suggest that identification of the subjects undergoing sperm DNA damage during selection may allow a better management during ARTs.

Study design, size, duration: We measured sDF both in total (total sDF) and in viable (viable sDF) sperm populations before and after selection in 20 semen samples processed with DGC and in 20 processed with swim-up, collected from January 2016 to December 2016. We compared the number of subjects showing an increase of sDF during selection with both procedures and the average percentage increase of sDF, in total and viable sperm populations.

Participants/materials, setting, methods: Semen samples were from male partners of infertile couples undergoing routine semen analysis. Selection was conducted by layering semen upon a 40:80% PureSperm density gradient for DGC or on Human Tubal Fluid/Human Serum Albumin for swim-up. Total and viable sDF were simultaneously detected by a flow cytometric technique using DAPI to define the sperm population, Tunel to detect sDF and L10120 to discriminate between viable and not viable sperm.

Main results and the role of chance: In the 20 semen samples selected by DGC, an increased level of DNA damage was found in 10 subjects when total sDF was considered and in 12 when sDF was evaluated in viable sperm. In the 20 semen samples selected by swim-up, the number of subjects showing an increase of DNA damage was 3 when total sDF was considered and 8 when sDF was measured in viable sperm. Interestingly, the average percentage increase of DNA damage was much greater in the viable than in total sperm population (respectively $388.7 \pm 435.5\%$ vs $150.4 \pm 231.3\%$ in samples processed by DGC and $61.5 \pm 42.3\%$ vs $21.4 \pm 27.3\%$ in samples processed by swim up). These results suggest that the measure of sDF in the viable sperm fraction is more sensitive in detecting the eventual induction of the damage by selection. In addition, swim up resulted less invasive than DGC because it provoked an increase of sDF in a lower number of subjects and a lower average percentage increase of DNA damage in their samples.

Limitations, reasons for caution: The comparison between DGC and swim-up was conducted in different semen samples not allowing to compare directly the effect of the two procedures. However, using the same samples would have caused a selection bias (samples with low sperm number could not be included).

Wider implications of the findings: Viable sDF is a more sensitive tool to identify those patients increasing sDF level during selection and, possibly, expecting a lower pregnancy rate after ART. In these patients, swim-up could be recommended for sperm selection in ART lab as it results a less invasive procedure than DGC.

Trial registration number: NA.

P-056   High magnification-sperm morphology and hyaluronic acid-binding assay: is there a correlation?

M. Palmieri, C. Crescenzo, R. Russo, G. Russo, G. Quaranta, S. Russo

Centro Hera, IVF, Giugliano in Campania, Italy

Study question: Is there a significant correlation between sperm cells morphology at high magnification (6600 X) and their capacity to bind hyaluronic acid (HA)?

Summary answer: The correlation is significant only for spermatozoa belonging to the first (+) and fifth (-) class of Bartoov-Berkovitz classification.

What is known already: Several studies have shown that sperm selection at high magnification (MSOME) may increase the blastocyst formation rate and implantation rate. HA, the main constituent of the biochemical matrix layer that covers the oocyte, can play an important role in the selection of sperm during fertilization in vivo. Only mature sperms have receptors for HA on their plasmatic membrane. In vitro, it was observed that, by contacting the sperm with HA, if these are mature have a characteristic movement only of the tail while the head remains blocked by the receptors that bind HA molecules.

Study design, size, duration: We evaluated 102 fresh ejaculated samples derived from patients aged 22-60 years, enrolled in the department of PMA of the Clinic Center Hera (NA) in the year 2016.

Were excluded from the study cases of:

- Cryptozoospermia
- Azoospermia
- Teratozoospermia (% of typical forms <4)
- Oncological patients

Participants/materials, setting, methods: We capacitated 102 semen samples by conventional "swim-up" or "density gradient" methods, depending on the sample properties. Following the Bartoov-Berkovitz criteria, we classified the capacitated sperm cells with high magnification microscopy (in five groups) and then we carried out an HA-binding assay (putting sperms in contact with a medium containing HA). So we performed the classification of the same samples only for the portion of sperm cells blocked in the interface with HA.

Main results and the role of chance: By morphological comparisons at high magnification among capacitated sperm samples (A) and their HA-binder fraction (B), we highlighted in group B a decrease (57.51% vs 46.03%) in the percentage of spermatozoa belonging to the fifth group of morphological classification according to the criteria of Bartoov-Berkovitz (head with abnormal chromatin, with large vacuole> 4% of the head); the two-tailed P value is <0.0001. For conventional criteria, this difference is considered as highly statistically significant. Similarly we showed an increase (28.27% vs 38.95%) in the percentage of sperms of the first group of classification (normal head size, shape and chromatin, with 0 or 1 vacuole <4% of the head) with P value < 0.0001. The statistical analysis was performed using paired *t*-test. Some studies suggested that vacuoles occur during the sperm maturation process even from the early stage. Their size decrease during spermatogenesis and epididymal transit, sometimes correlating with male subfertility, lower mitochondrial membrane potential, increased incidence of chromosomal abnormalities and packaging of sperm chromatin. On the other hand HA allows us to select a mature sperm. So, on the basis of our studies we suggest to select a sperm for injection according to the high-magnification morphology in the HA-binder fraction.

Limitations, reasons for caution: The study should be extended to a larger number of samples for more thorough statistical analysis.

Wider implications of the findings: Our results agree with several studies in which the presence of vacuoles correlate with a lower sperm maturity, evaluated indirectly by means of HA-binding capacity. These data suggest a combined selection method, more rapid than classical IMSI, possibly to improve the outcome of injection procedure mostly in male subfertility cases.

Trial registration number: Not applicable.

P-057   Preliminary results of the FertiSCI protocol: evolution and risk factors of alteration of sperm parameters in spinal cord injured adult males. A prospective study

C. Chalas[1], M. Laanani[2], N. Le Foll[1], V. Drouineaud[1], J. Wolf[4], F. Guiliano[3]

[1]Hôpital Cochin-Port Royal, CECOS-Biology of Reproduction unit, Paris Cedex 14, France
[2]Hopital Hotel Dieu, Epidemiology and Biostatistic unit, Paris, France
[3]Hopital Raymond Poincaré, Neuro-uro-andrology unit, Garches, France

Study question:

(1) Is there one or several factors responsive of a degradation of sperm parameters in spinal cord injured (SCI) men

Summary answer:

(1) Retrospective studies showed no sperm degradation in SCI men and concluded that there is no risk for fertility and no preventive sperm cryopreservation to propose.

What is known already:

(1) Fertility is a main concern of men with SCI. Because of the spinal lesion, they have erection and ejaculatory dysfunction that can be solved for 60% of them by penile vibratory stimulation (PVS). Sperm parameters present normal to diminished sperm volume, normal sperm concentration but a marked decrease in sperm mobility and viability and a rise of round cells principally polynuclear. Several studies reported the presence of ROS and high sperm DNA fragmentation in this population and SCI men are frequently subjected to urinary tract infections. These factors could contribute to sperm degradation over time.

Study design, size, duration:

(1) 35 SCI men were recruited for a prospective study consisting in four sperm retrievals every 6 month for a total study duration of 18 month. Inclusion criteria were age limitation from 18 to 60 years and antegrade ejaculation by masturbation or PVS. Inclusion was realized in a specialized center for SCI reeducation. The duration, level and completeness of the lesion were noticed as well as medical intercurrent events, treatments, bladder management and way of life.

Participants/materials, setting, methods:

(1) On each retrieval, semen parameters and sperm morphology were studied according to WHO recommendations. Inflammation parameters were considered by counting round cells, polynuclear cells evaluated by leucoscreen test and elastase dosage by ELISA. A systematic bacteriological analysis of sperm and urine were realized. Oxidative stress was evaluated by flow cytometer by measuring DNA fragmentation using tunnel assay on total and alive spermatozoa and spermatozoa 8 hydroxy DNA guanosine by oxy DNA Kit.

Main results and the role of chance:

(1) Results presented here are preliminary as they concern uniquely the first sperm retrieval after inclusion. The 35 patients were included in two years, demonstrating the feasibility of the project and the interest of SCI men about their fertility. Mean age was 29.8 ± 6.4 years, mean age at injury was 21.5 ± 8.2 years and time postinjury 8.2 ± 8.7 years. 32 patients had a spinal lesion at T10 or upper. On 35 patients included, 31 came for their first sperm retrieval, 3 had a no ejaculation and 1 presented an azoospermia. 27 semen were analyzed with a mean sperm volume $= 1.3 \pm 1.2$ ml, sperm numeration $= 155.8 \pm 226.9$ million, round cells concentration $= 37 \pm 37.3$ M/ml, a+b motility$= 14 \pm 12\%$ and viability$=23.8 \pm 18.8\%$. Mean polynuclear cells were evaluated to 11.6 ± 15.3 M/ml and elastase (n $= 12$) to 162.1 ± 212.1 ng/ml. Oxidative stress could be evaluated in 14 sperm. Total DNA fragmentation $= 47.4 \pm 24.9$ % and fragmentation on alive spermatozoa$=28.7 \pm 27.8\%$, 8OHdG was measured at $20.2 \pm 10.6\%$. More than half patients had a positive urinary analysis (53.6%) and 1/3 a positive spermoculture. The population was then divided in two groups considering the delay postinjury superior (n $= 15$) or inferior (n $= 13$) to 5 years. No significant differences were observed concerning sperm numeration, motility, viability but also DNA fragmentation (total and alive spermatozoa).

Limitations, reasons for caution:

(1) This study is limited by the number of patients included. It constitutes a pilot study demonstrating its feasibility to propose next a multicentric study. Technically, the diminished sperm volume was limitative to realize all planned analyses and the high number of round cells could interfere with flow cytometer analyses.

Wider implications of the findings:

(1) Considering oxidative stress, we confirm increased total DNA fragmentation but a limited fragmentation on alive spermatozoa corroborated by low elastase level in sperm. We also demonstrate that in this population there is no risk of sperm degradation over the time.

Trial registration number:

(1) NCT02144558

P-058   Effects of seminal plasma and semen application during in vitro fertilization treatment - systematic review and meta-analysis

M. Spinelli[1], G. Saccone[2], A. Di Spiezio Sardo[3], A. Ciardulli[4], C. Caissutti[5], D. Surbek[6], M. Von Wolff[7]

[6]University of Bern, Obstetrics and Gynecology, Bern, Switzerland
[7]University of Bern, Division of Gynecological Endocrinology and Reproductive Medicine, Bern, Switzerland

Study question: Does the intracervical and intravaginal application of seminal plasma (SP) or semen has an effect on clinical pregnancy rate (CPR) in IVF treatment?

Summary answer: The application of SP or semen around the time of oocyte aspiration or embryo transfer is associated with higher CPR.

What is known already: Several studies have demonstrated the potential role of seminal plasma (SP) in non-human and human implantation by modulating endometrial function and the maternal immune system. The effect appears to be due to highly active cytokines and growth factors and is independent from sperm quality. Two pilot studies had suggested but not proven that semen and/or SP might improve CPR by improving endometrial function which seem to be negatively affected in conventional gonadotropin stimulated IVF. Several trials, based on this concept, has been performed since then but a meta-analysis has never been performed so far.

Study design, size, duration: A systematic review and meta-analysis was performed, including all studies identified by searching electronic databases from their inception until October 2016. Trials were considered if women were exposed to any kind of SP or semen (either SP/semen injection or sexual intercourse) around the time of oocyte aspiration and embryo transfer and analysis regarding outcome was performed.

Participants/materials, setting, methods: Eight prospective randomized trials (RCTs) of women undergoing IVF were identified.

Main results and the role of chance: The eight identified RCTs included 2,128 women. The intervention included four studies which analyzed the effect of prepared undiluted and one study of thawed diluted SP after oocyte aspiration, one study which used untreated diluted semen and two studies, which analyzed the effect of sexual intercourse around the time of oocyte aspiration and/or embryo transfer. Women randomized in the intervention group had a significantly higher rate of CPR compared to controls (30.0% vs 25.1%; RR 1.20, 95% CI 1.04 to 1.39). No significant differences were found in the secondary outcomes, including livebirth rate, biochemical pregnancy rate, miscarriage rate, multiple pregnancies and birth weight. The subgroup analysis (4 RCTs, 780 participants) including only those RCTs in which prepared undiluted SP was injected just after oocyte aspiration concurred with the overall analysis for the primary outcome (46.3% vs 37.2%; RR 1.23, 95% CI 1.05 to 1.45).

Limitations, reasons for caution: In the overall meta-analysis only four of the eight studies used placebo as control and were double blind. In the subanalysis three of the four studies included used placebo as control and were double blind. Some of the intervention protocols and the definitions of CPR were different.

Wider implications of the findings: The findings support the hypothesis that first SP does play a role in the regulation of implantation which involves a coordinated modulation of the maternal immune system and second that SP could be used as an implantation supporting therapy in fresh transfer following high dosage gonadotropin stimulation.

Trial registration number: PROSPERO International Prospective Register of Systematic Reviews, CRD42016054354.

P-059 Differential external morphological changes between laser-assisted immobilized and mechanical immobilized human sperm: by SEM comparison

D.Y. Chan

The Chinese University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Is the external structure of laser-assisted immobilized sperm different from mechanical immobilized one?

Summary answer: Laser-assisted immobilized sperm showed no external physical damage but distinct morphological changes were observed while mechanical immobilized sperm showed clear external damages.

What is known already: Sperm immobilization can be achieved by both mechanical and laser-assisted methods and showed equivalent fertilization and embryo cleavage rate. However, there is so far no study comparing physical damages between the two methods.

Study design, size, duration: At least 600 human sperm were immobilized by mechanical and laser-assisted methods and then were examined external structure using scanning electronic microscope.

Participants/materials, setting, methods: Ten normospermic samples were collected in our andrology unit for the immobilization-SEM study. ICSI injection needles were used for mechanical immobilization while non-contact infra-red diode laser was used for laser-assisted immobilization. Immobilized sperm were then under SEM for examination. Modified viability test on the two immobilization methods was used to examine differential membrane integrities.

Main results and the role of chance: We found external damages on mechanical kinked sperm, surprisingly, external damage was not found on laser-assisted immobilized sperm. Although no external damage was found on the membrane of laser-assist immobilized sperm, there were three types of morphologic changes were observed. When laser applied on end piece area resulted in 100% immobilization and 94% with immediate coil tail formation was noted; while laser applied on sperm principal piece area resulted in 100% immobilization but only 8% sharp bend of sperm tails were observed. Our modified membrane integrity assay also revealed that majority (91%) of laser-assisted immobilized sperm retained membrane intactness significantly (<0.001) compared to mechanical method that coherent with our SEM observation.

Limitations, reasons for caution: Our study is limited on human sperm with normal WHO semen parameters.

Wider implications of the findings: The intactness of the membrane and external structure on laser-assisted immobilization showed that complete membrane rupture is not necessary for sperm immobilization. This finding is opposite to general concept that both of the immobilization methods can cause physical damages immediately on sperm and losing theirs membrane integrities.

Trial registration number: NA.

P-060 two types of pathologic feature in Klinefelter syndrome result in different sperm retrieval rates during micro-TESE

J. Zhang, G.H. Liu, L.G. Zhao, X.Y. Liang, Z.Y. Wang

The Sixth Affiliated Hospital of Sun Yat-Sen University, Reproductive Center, GuangZhou- GuangDong, China

Study question: Are there different testis pathologic features between patients with Klinefelter syndrome(KS) who can obtain sperm through micro-TESE and those who can't find the sperm?

Summary answer: Patients with KS can be classified into two types according to the pathologic features, sperm retrieval rate(SRR) and microscopic findings would be different between them.

What is known already: Azoospermic patients with KS could have the chance to find sperm through micro-TESE. The reported SRR of KS ranged from 16% to 78%. Testicular volumes and serum level of FSH, LH, inhibin B and testosterone can't predict the SRR, patient's age is the only prognosis factor found as significant in some studies. The mechanisms of severe spermatogenic failure and focal spermatogenesis are unclear. There are two popular hypotheses on how spermatogenesis occurs in Klinefelter patients: spermatozoa arise from patches of 46,XY spermatogonial stem cells in the testes or 47,XXY germ cells are able to undergo meiosis occasionally.

Study design, size, duration: This is a retrospective study. From Dec.2014 to Dec.2016, 35 NOA patients with KS underwent micro-TESE and were categorized into two groups according to the pathologic features: Leydig cells hyperplasia and most of the seminiferous tubules present severe hyalinization (group A,n = 27), and seminiferous tubules with hyalinization interlace with tubules of maturation arrest (group B,n = 8).

Participants/materials, setting, methods: Micro-TESE was performed at x20 magnification under the operating microscope. Seminiferous tubules were removed and immediately placed within a sperm buffer. Then the tubules were dissected and examined immediately by an embryologist under a phase microscope at x200 magnification. The two groups were compared in age, testicular volumes, FSH, LH, testosterone, SRR and microscopic findings during the operation.

Main results and the role of chance: Leydig cells hyperplasia and most of the seminiferous tubules present severe hyalinization are the frequent pathologic appearances of KS testis(27/35). Within these cases(group A),12 patients (44.4%) showed heterogeneous thickness of seminiferous tubules and 9 of them(75%) found sperms from the focal spermatogenesis area during micro-TESE. The SRR of group A was 33.3%. Meanwhile, in the cases of seminiferous tubules with hyalinization interlacing with tubules of maturation arrest(group B), heterogeneous tubules were easy to find in all of the testes during micro-TESE, nevertheless, none of them had sperm(0/8). Testicular volume in group A was lower than group B (1.8 ± 0.7 ml vs. 2.6 ± 0.9 ml, p < 0.05). However, no significant difference was observed in age (29.5 ± 4.2 vs. 29.8 ± 6.4 years), FSH (41.1 ± 12.9 vs. 37.4 ± 7.7 mIU/ml), LH(25.7 ± 8.7 vs. 23.2 ± 7.8 mIU/ml), and testosterone levels (2.1 ± 1.6 vs. 1.4 ± 0.7 ng/ml) between the two groups (All p > 0.05).

Limitations, reasons for caution: More cases should be included in the following study to confirm our conclusion that KS testis would have great opportunity to show heterogeneous seminiferous tubules during micro-TESE but the SRR would be depressed if the pathologic appearance is that seminiferous tubules of maturation arrest interlace with tubules presenting severe hyalinization.

Wider implications of the findings: Aneuploidy is the homogeneous etiology of all the KS cases, however, testis pathologic features are extremely different between the patients. Multiple seminiferous tubules present maturation arrest in some cases implies that the major cause of spermatogenic failure might be abnormal testicular environment instead of meiotic failure in 47,XXY germ cells.

Trial registration number: not applicable.

P-061 Omega-3 free fatty acids inhibit sertoli cell apoptosis Induced by palmitic acid

X. Hu, X. Ge, B. Yao

Nanjing Jinling Hospital, Reproduction Medicine Center, Nanjing, China

Study question: What is the effect of elevated free fatty acids(FFA) on the survival of sertoli cells?

Summary answer: The saturated FFA palmitic acid(PA) promoted apoptosis of sertoli cells while omega 3 polyunsaturated FFAs could partly protect sertoi cells from the damage.

What is known already: Nowadays, obesity had become an important risk factor related with male infertility. It had been reported obese men often showed decreased serum Inhibin B and semen parameters but increased serum FFAs. Elevated FFAs including PA had been demonstrated to inhibit the survival of leydig cells in the testis in vitro.

Study design, size, duration: Testis sertoli cells and TM4 sertoli cell line were used to investigate effect of the saturated PA and omega 3 polyunsaturated FFAs on the survival of sertoli cells in vitro. Different treatment time and doses of FFAS were taken into consideration. Viability of sertoli cells was the main outcome measures. Furtherly, we investigated the possible mechanisms by which PA induced apoptosis of sertoli cells.

Participants/materials, setting, methods: MTT assay was used to evaluate the viability of sertoli cells. Apoptosis was detected by flow cytometry

stained with annexin-V and PI dye solution. The expression of apoptosis-relevabt genes were analysed by qPCR. Western Blot was performed to validate the key pathway. 2', 7' dichlorofluorescin diacetate (DCFH-DA) was used to measure the reactive oxygen species(ROS) generation. The ultrastructure of TM4 sertoli cells after free fatty acids exposure was examined by transmission electron microscopy.

Main results and the role of chance: PA induced the decreased survival of sertoli cells in a time- and dose-dependent manner. However, omega 3 polyunsaturated fatty acid had the potential to protect sertoli cells from the damage from PA while itself had no influence on the viability of sertoli cells in the Physiological concentration range. Flow cytometry demonstrated that the apoptosis of sertoli cells was increased by PA treatment. QPCR and Western blot analysis proved that bcl2/bax might involve in the apoptotic pathway and ROS level was also increased inthe PA treatment group which means mitochondria played an important role in the process. Furtherly, TEM showed the accumulation of lipid in the cytoplasm and the swelled mitochondria. These results indicated that PA caused the accumulation of lipid in the TM4 sertoli cells which furtherly damaged the function of mitochondria leading to the release of ROS. Finally, sertoli cells was attacked by the oxidative stress and apoptosis was induced. Omega 3 polyunsaturated fatty acids decreased the apoptotic rates by increasing nrf2 expression which improve the anti-oxidative stress ability of TM4 sertoli cells.

Limitations, reasons for caution: Obesity was associated with complicated dysregulation oflipid metabolism and changes of reproductive function. In the present study, only PA andomega 3 polyunsaturated fatty acids were chosen to investigate the effects of lipid on survival of sertoli cells.

Wider implications of the findings: Saturated fatty acids damage male reproductive function by inducing the sertoli cells apoptosis, while omega 3 polyunsaturated FFAs protects sertoli cells from the attack of PA, indicating that taking food rich in omega 3 polyunsaturated fatty acids and lower content of saturated fatty acids may be beneficial for male reproduction.

Trial registration number: None.

P-062 Reciprocal translocations – a retrospective study in infertile couples

R. Arantes[1], M. Souto[2], P. Botelho[2], Z. Gomes[3], M. Brito[3], O. Moutinho[3], M. Martins[4], R. Pinto Leite[1]

[1]Hospital Center of Trás-os-Montes and Alto Douro, Cytogenetic Laboratory-Andrology Laboratory, Vila Real, Portugal
[2]Hospital Center of Trás-os-Montes and Alto Douro, Cytogenetic Laboratory, Vila Real, Portugal
[3]Hospital Center of Trás-os-Montes and Alto Douro, Gynecology/Obstetric Service, Vila Real, Portugal
[4]Hospital Center of Trás-os-Montes and Alto Douro, Genetic Service, Vila Real, Portugal

Study question: Incidence of reciprocal translocations in infertile couples. Should it be considered?

Summary answer: Although the low incidence of reciprocal translocations detected (1.18%), this analysis permitted a more accurate diagnosis, allowing an adequate genetic counselling for infertile couples.

What is known already: Infertility prevalence is increasing in the developed world affecting 10-15% of couples in reproductive age. It is a complex multifactorial condition with male and female factors involved. The cytogenetic analysis is considered an important approach in this area since numerical and structural alterations can be responsible for infertility. Individuals with reciprocal translocations are fenotipically normal, but due alterations at the meiotic segregation, have an increased risk of producing gametes with chromosomal imbalances leading to infertility, increased risk of pregnancy loss and birth of handicapped children.

Study design, size, duration: Couples who participated in the infertility consultation between November 2009 and December 2016 at the Hospital Center of Trás-os-Montes and Alto Douro conducted a cytogenetic study and analysis of semen in the man. When a cytogenetic anomaly was detected the couple was referred to a genetic consultation. The relationship between the reciprocal translocations found with the semen parameters was evaluated, as well as a bibliographic review of the cytogenetic alterations described in this study.

Participants/materials, setting, methods: This work presents the reciprocal translocations found in 680 cytogenetic studies of 340 couples. Chromosome analysis was performed according to standard techniques and, at least, 20 metaphases were analyzed. In all the men, semen analysis (ejaculate volume, motility, vitality, hypo-osmotic swelling test, sperm concentration and morphology) was performed according to World Health Organization (WHO, 2010) guidelines.

Main results and the role of chance: Eight cases of balanced reciprocal translocations (1.18%) were detected in different couples, 4 in men and 4 in women:

- 46,XY,t(11;22)(q14.2;q13.1) is the most reported translocation, with different break points described, our included.
- 46,XX,t(12;15)(q13.3;q24.3) was also detected in a woman with Family Stickler Syndrome not being associated with infertility.
- 46,XY,t(4;22)(p16.1;q11), 46,XY,t(6;8)(p23;q21.3), 46,XY,t(4;10)(q31.3;p15), 46,XX,t(5;9)(p13;q34), 46,XX,t(10;15)(q11.23;q13) had already been described although with different break points.
- 46,XX,t(2;3;15)(p22;p12.1;q26.2) karyotype patient with a three-break rearrangement, is described for the first time.

Family studies are still ongoing to confirm if these cytogenetic anomalies are *de novo* or inherited.

The semen analysis in the case with a 46,XY,t(6;8)(p23;q21.3) karyotype reveal normal values, in the 46,XY,t(4;22)(p16.1;q11) case an oligoastenozoospermia was detected and in cases 46,XY,t(11;22)(q14.2;q13.1) and 46,XY,t (4;10)(q31.3;p15) an oligoteratozoospermia was found.

Limitations, reasons for caution: Despite the small number of cases, the results of this study strongly point out the importance of peripheral blood karyotype analysis of infertile couples.

Wider implications of the findings: Cytogenetic analysis in infertile couples may allow an accurate diagnosis: a balanced translocation in one of the couple's members may be responsible for early miscarriages before the woman realizes she is pregnant. On the other hand, reciprocal translocations in men may explain the worst semen parameters, namely, motility and morphology.

Trial registration number: not applicable.

P-063 The natural antioxidant Cinnamtannin B-1 could prevent DNA sperm fragmentation

A.M. Fabregat Reolid[1], M.D.R. Fernández Santos[2], E. García Hernández[1], J.J. Garde López Brea[2], B. Lledó Bosch[1], A. Turienzo Díez[1], A.J. Soler Valls[2], J.A. Ortiz Salcedo[1], R. Bernabeu Pérez[3]

[1]Instituto Bernabeu, Biotech, Alicante, Spain
[2]Universidad de Castilla la Mancha, SaBio IREC CSIC – UCLM – JCCM / Faculty of Pharmacy UCLM, Albacete, Spain
[3]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Could Cinnamtannin-B1 prevent DNA sperm fragmentation?

Summary answer: Cinnamtannin B-1 is able to prevent sperm DNA fragmentation after exposure to oxidant factors like time and temperature.

What is known already: Oxidative stress is known to interfere with the fertilization capacity of spermatozoa damaging sperm nuclear DNA and affecting the epigenetic profile of these cells. Antioxidants could improve sperm media, protecting spermatozoa from DNA damage. Cinnamtannin B-1 is a naturally occurring A-type proanthocyanidin found in a limited number of plants including *Linderae umbellateae* and *L. nobilis*, which exhibit a large number of cellular actions mostly derived from their antioxidant properties. The objective of this study is to evaluate if Cinnamtannin B-1 could protect the sperm DNA fragmentation after the oxidative stress produced by incubation at 37°C.

Study design, size, duration: Ninety samples were evaluated from fifteen sperm donors. Sperm samples were collected with an abstinence between 48-72 h and were incubated at 37°C for 4 h with 0, 10 and 100 μM of Cinnamtannin B-1. DNA integrity was checked by measuring the index of sperm DNA fragmentation (DFI), for which TUNEL assay (Terminal dUTP Nick-End Labeling) was used. Since Cinnamtannin B-1 was prepared in ethanol, the control tube received an equivalent volume of ethanol.

Participants/materials, setting, methods: A prospective study was carried out to achieve our objective. Sperm donors were selected according to Instituto Bernabeu sperm donation program requirements and ASRM and ESHRE guidelines

for gamete donation. After liquefaction, we washed the sperm samples with PBS and performed TUNEL assay in different aliquots. This assay consists in measuring the existing breaks in DNA chain incorporating molecules marked with a fluorochrome. For the statistical analysis we used the SPSSv20.0, using the t-Student test.

Main results and the role of chance: We did not observe significant differences in DFI by adding a small volume of ethanol to the fresh sample required for Cinnamtannin-B1 resuspension. After 4 h incubation, we obtained a significant increase of DFI in the sperm sample without antioxidant (10.27 vs 16.47; $p < 0.05$) suggesting that sperm DNA is damaged after incubation at 37°C. However, when we add Cinnamtannin-B1 to the semen sample at different concentrations, we observed a significant decrease in the DFI when we compared the samples incubated with $10\,\mu M$ (9.47 ± 1.39) and $100\,\mu M$ Cinnamtannin-B1 (9.73 ± 1.36) versus control (16.47 ± 2.82) ($p < 0.05$). This results suggest that CinnamtanninB-1 supplementation prevents the increase of DNA damage. In addition, this results also showed that antioxidant concentrations higher that $10\,\mu M$ do not confer a greater protective effect.

Limitations, reasons for caution: We believe that sample size may be a limitation in this study as well as the use of normozoospermic samples. Further studies should be carried out to verify Cinnamtannin B-1 protective effect in samples with low seminal quality or high fresh sperm DNA fragmentation.

Wider implications of the findings: An interesting topic could be evaluating if addition of Cinnamtannin-B1 in sperm crioprotectors could be useful in sperm cryopreservation where spermatozoa are submitted to oxidative stress. Given the beneficial effect of Cinnamtannin B-1 *in vitro*, its use could also be considered as a feeding supplement especially in infertile men.

Trial registration number: not applicable.

P-064 Reduced ejaculatory abstinence period may improve embryo quality for those with high sperm DNA fragmentation

E.G. Pabuccu[1], E. Kocbulut[2], G.S. Cağlar[1], S. Sertyel[2], A.H. Haliloğlu[3], R. Pabuçcu[1]

[1]Ufuk University School of Medicine, Obstetrics and Gynecology, Ankara, Turkey
[2]Centrum Clinic ART Center, Reproductive Endocrinology, Ankara, Turkey
[3]Ufuk University School of Medicine, Urology, Ankara, Turkey

Study question: Does reduced ejaculatory abstinence period improve embryo quality in ICSI cycles for those with high sperm DNA fragmentation (SDF) and repeated ART failures?

Summary answer: it seems that reduced ejaculatory abstinence period enhance overall embryo quality without compromising other semen parameters when compared to standard abstinence period

What is known already: Accumulating evidence suggests examination of the SDF particularly for those with repeated miscarriages or ART failures through ART. Despite controversies regarding the optimal cut-off point and methodology, several approaches have been suggested to overcome SDF related drawbacks such as oral intake of antioxidants, use of testicular spermatozoa obtained with either testicular sperm aspiration (TESA) or testicular sperm extraction (TESE) or sperm selection techniques.Yet, none of these interventions, alone or combined, have been unequivocally proven to be of clinical value to overcome the potential detrimental effect of high SDF on ART outcomes.

Study design, size, duration: This is an observational study conducted between 2015 and 2016 in a single center including 24 couples with >2 previous ART cycles, All couples were offered to undergo a new ICSI cycle using spermatozoa obtained by reduced abstinence period (1 hour following the first ejaculation on the day of oocyte retrieval) due to high SDF (>20%). Total of 23 cycles (SHORT) were compared with previous 49 standard cycles of couples (STAND), being their own controls.

Participants/materials, setting, methods: The average frequency of intercourse for the men before producing their first semen specimen for study was between once and twice weekly. Exclusion criteria for men were; azoospermia cases, failure to follow the ejaculatory abstinence protocol, current smoking, presence of varicocele, consumption of anti-oxidants or genital infection within 6 months. All female subjects had normal uterine cavity, hormone levels and karyotype. Poor responders, advanced age (>40 years) and cases with other medical disorders were excluded.

Main results and the role of chance: Total of 73 cycles were evaluated. Only 2 cycles were cancelled due to poor ovarian response and were not included. Blastocysts with ICM, A or B and trophectoderm grade A (i.e. AA or BA) were considered to be top quality. Significantly lower spem count was detected in SHORT group, while significantly higher numbers of top quality blastocyst were detected. Accordingly, 25% implantation and 24% live birth rate was detected in SHORT group despite previous unsuccessful cycles.

Table 1 Demographics.

woman age (yrs)	33.5
infertility duration (yrs)	8.4
No of prev. cycles (N)	2.9
mean AMH (ng/ml)	2.5
mean AFC (N)	12

Table 2 Semen parameters.

	STAND (49)	SHORT (24)	
volume (ml)	2.8	1.3	**0.00**
total count	70.2	27.1	**0.00**
concent. (/ml)	29.8	21.9	NS
mean normal morphology %	4.7	5	NS
motility A+B %	48	53	NS
SDF %	33	–	NA

Table 3 Embryology outcomes.

	STAND (49)	SHORT (24)	
No of MII	8	8.5	NS
fertilization%	67	75	0.07
total No of embryos on day 3	4.7	6.3	**0.03**
No of good quality cleavage embryos	1.3	4	**0.00**
No of top quality blastocyts	0.6	3	**0.00**
No of transferred embryos	1.8	1.9	NS

Limitations, reasons for caution: This study is not a randomized controlled one and the main limitation is the lack of SDF data of SHORT group. Moreover, total antioxidant capacity and reactive oxygen species (ROS) levels are also not available.

Wider implications of the findings: Sperms obtained by reduced ejaculatory abstinence has been shown to reveal low SDF, ROS levels and higher antioxidant capacity. This has been validated even for normozoospermic cases. Therefore, performing ICSI with those spermatozoa seems to be effective in terms of top quality embryos particularly for those with repeated ART failure.

Trial registration number: NA.

P-065 Lower oxytocin mRNA expression levels are present in samples with abnormal sperm parameters

E. Neofytou[1], S. Lymperi[2], E. Kolibianakis[1], M.G. Bazioti[2], T. Tarlatzi[3], A. Lambropoulos[4], B. Tarlatzis[1]

[1]Medical School- Aristotle University, Unit for Human Reproduction- 1st Dept of Obstetrics and Gynecology, Thessaloniki, Greece
[2]Andrology Laboratory, Private Diagnostic Laboratory Agias Sofias, Thessaloniki, Greece
[3]Erasme Hospital- Université Libre de Bruxelles, Fertility Clinic- Department of Obstetrics and Gynecology, Brussels, Belgium
[4]Medical School- Aristotle University, Laboratory of Molecular Biology- 1st Dept of Obstetrics and Gynecology, Thessaloniki, Greece

Study question: Is oxytocin mRNA expression different between normal samples and samples with at least one abnormal sperm parameter?

Summary answer: Compared to samples with normal sperm parameters, mRNA oxytocin expression is significantly lower in samples with at least one abnormal sperm parameter.

What is known already: Oxytocin is synthesized in the penis, testis, epididymis and prostate, whereas its receptor has been detected throughout the male reproductive tract. Furthermore, oxytocin regulates androgen levels by stimulating the conversion of testosterone to DHT by 5-a reductase. During orgasm, a burst of oxytocin is released into the systematic circulation to stimulate contractions of the reproductive tract. Various studies have shown that exogenous administration of oxytocin increases the spermatozoa concentration of ejaculated sperm. Although oxytocin seminal plasma levels have been shown to be lower in fertile men compared to men with oligoasthnoteratozoospermia, mRNA expression levels have never been assessed until now.

Study design, size, duration: A prospective study was performed in 2016, including a total of 41 samples from equal number of men. All samples had $>1*10^6$ spermatozoa/ml and $<1*10^6$ leukocytes/ml. Semen analysis was performed according to WHO 2010 criteria and mRNA was extracted to assess the mRNA expression levels of oxytocin. mRNA expression levels were compared between different categories of sperm samples, classified according to their concentration, motility and morphology (oligozoospermia, asthenozoospermia, oligoasthenozoospermia, teratozoospermia and oligoasthenoteratozoospermia).

Participants/materials, setting, methods: All semen samples were subjected to mRNA extraction, cDNA synthesis and quantitative Real-Time PCR (RT-PCR) for the expression of the oxytocin gene. The relative standard curve method was selected as the most appropriate due to the nature of human spermatozoa. Each sample was run in duplicate and normalized to β2-microtubulin. Differences in oxytocin mRNA expression levels were analyzed between different sperm categories using the generalized linear model. Values are expressed as mean±bootstrap standard error.

Main results and the role of chance: Compared to normal samples, samples with at least one abnormal sperm parameter had significantly lower mRNA oxytocin expression levels (14.73 ± 3.61 vs. 4.32 ± 1.63, p = 0.017). Samples with >60% immotile spermatozoa had significantly lower mRNA oxytocin expression levels compared to samples with normal motility, defined as <60% immotile spermatozoa (0.84 ± 0.39 vs. 10.26 ± 2.86, p = 0.000). Furthermore, asthenozoospermic samples with progressive motility <32% had significantly lower mRNA oxytocin expression levels compared to samples with normal progressive motility, defined as >32% (0.85 ± 0.43 vs. 9.96 ± 2.60, p = 0.000). Oligozoospermic samples with concentration $<15*10^6$ spermatozoa/ml had significantly lower mRNA oxytocin expression levels when compared to samples with normal concentration of spermatozoa, defined as $>15*10^6$/ml (2.18 ± 1.0 vs. 11.30 ± 3.0, p = 0.004). Samples with >10% rapid progressive spermatozoa (spermatozoa with a speed >25μm/sec at 37° C), compared to samples with <10% rapid progressive spermatozoa, had significantly lower mRNA oxytocin expression levels (11.26 ± 2.92 vs. 2.27 ± 1.22, p = 0.006). mRNA oxytocin expression levels was negatively associated both with the proportion of midpiece defects present in spermatozoa (p < 0.011) and the teratozoospermia index, (TZI >1.8) (p < 0.036).

Limitations, reasons for caution: Given that the current study was not conducted in a large sample group, the results should be interpreted with caution.

Wider implications of the findings: We have shown for the first time that mRNA expression levels of oxytocin are lower in semen samples with at least one abnormal sperm parameter. If the results of the current study are confirmed, oxytocin mRNA expression could be used as a novel diagnostic tool of male infertility.

Trial registration number: Not required.

P-066 Male contribution to repeated ICSI failure

H. Elattar[1], E. Hassanen[2], K. Elqusi[2], H. El Khedr[3], H. Zaki[4]

[1]Ganin Fertility Center, Infertility specialist, cairo, Egypt
[2]Ganin Fertility Center, Clinical embryology, Cairo, Egypt
[3]Ganin Fertility Center, Embryology, Cairo, Egypt
[4]Ganin Fertility Center, Director, Cairo, Egypt

Study question: Is sperm DNA fragmentation index (DFI) more prevalent in cases of repeated ICSI failures and which risk factors are more associated with abnormal DFI.

Summary answer: DFI was found to be high in cases those have done ICSI before or not. Age and forward sperm motility were found to be significant.

What is known already: A substantial number of studies has focused on the effect of female factor in cases of repeated ICSI failures, however much less number of studies has correlated male factor with repeated ICSI failure. Moreover, routine seminal fluid analysis (SFA) is less reliable in distinguishing between infertile and fertile men. Male chromatin damage has been associated with conception problems and repeated pregnancy loss. Sperm DFI has been found to be more correlated than (SFA) concerning fertilization rates, cleavage rates, blastocyst formation, embryo fragmentation and implantation rates.

Study design, size, duration: We have performed a prospective observational study on DFI for those attending infertility clinic from the beginning of May to the end of December 2016. DFI was observed in 1012 male partners.

Participants/materials, setting, methods: New comers to the infertility unit during the study period have been divided into two groups. Group A those who have done ICSI before. Group B those who have not done ICSI before. Risk assessment profile consistent of age, smoking, varicocele, previous and current SFA parameters, previous miscarriages, IUI, and type of infertility. DFI was evaluated in semen by TUNEL assay. Threshold value was considered to be abnormal if equal or above 19.25.

Main results and the role of chance: DFI was prevalent in both groups being 54.7% in group A and 52% in group B with no significant difference in between groups. No correlation between DFI and smoking, varicocele, previous SFA parameters, previous miscarriages, IUI, number of ICSI failures and type of infertility. There was high correlation between age of the male and DFI abnormality. DFI was significantly elevated for men > 35 years old. Relative to men <30 years old, those >45 years were TWO fold more likely to have abnormal DFI. Relative to men <30 years old, those >45 years were FIVE fold more likely to have repeated ICSI failure because of abnormal DFI. Forward sperm motility at the sample where DFI was performed was correlated to the DFI result.

Limitations, reasons for caution: This is a tertiary referral center with a special program for repeated ART failure cases. Also, Cairo is one of the most air polluted capitals, that might explain the high prevalence of abnormal DFI in both study groups. The study results cannot be extrapolated to different communities with different characteristics.

Wider implications of the findings: DFI was abnormal in those who have done ICSI before or not which indicates that the DFI problem is there from the beginning and ignoring it would continuously fail the subsequent ICSIs.

Trial registration number: N/A.

P-067 A new approach to detected copy number variation in Y-chromosome that affects the spermatogenesis

E.M. Garcia Hernández[1], B. Lledó Bosch[1], J.A. Ortiz Salcedo[1], R. Morales Sabater[1], A. Fabregat Reolid[1], J. Llácer Aparicio[2], R. Bernabeu Pérez[2]

[1]Instituto Bernabeu, Molecular Biology, Alicante, Spain
[2]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Do CNVs in Y-chromosome variations detected by MLPA affect the spermatogenesis?

Summary answer: MLPA showed a higher sensibility to detect CNVs, suggesting that the presence of duplications in AZF do not have any significant effect on spermatogenesis

What is known already: CNVs in AZF region of Y-chromosome have been associated with the risk of spermatogenic failure. Detect CNVs using multiplex ligation-dependent probe amplification assay (MLPA) has many advantages over multiplex-PCR technique. MLPA allows the detection of microduplications and deletions in a single assay.

Several research groups have investigated the effect of specific gene copies in AZF region, suggesting that duplications present in this region do not have a significant effect on spermatogenesis, whereas the presence of some types of deletions is a risk factor for male infertility. However, the clinical significance of partial duplications on the spermatogenesis are also in controversy.

Study design, size, duration: A retrospective study was performed. A total of 197 patients with abnormal seminogram (azoospermic, criptozoospermic and oligozoospermic) were included in the study. These patients had been previously Y-chromosome microdeletions tested by multiplex PCR method and any alteration in the CNVs were observed.

In control group, we included 41 normozoospermic healthy donors included in the Semen Donation Program of Instituto Berbabeu, selected on the basis of normal semen parameters according to the WHO criteria (2010).

Participants/materials, setting, methods: MLPA was carried out according to the manufacturer's instructions with the P360-B1 Y-Chromosome Microdeletions Probemix, on the infertility patient and control group. MLPA PCR products were analyzed in a AB310 sequencer. The results were analyzed using the Coffalyser v 1.4 software.

Statistical analysis was performed by SPSS 20.0 using a chi-square. P-values <0.05 were considered significant.

Main results and the role of chance: We observed a 4.6% of microdeletions in the patients group, but no deletions were seen in the control group ($p = 0.179$). However, duplications were seen in both groups (control 14.6% vs patients 7.6%). On the other hand, the percentage of duplications in AZF region was higher in control group than in patients ($p = 0.181$).

Five types of CNVs were identified by MLPA. These 5 CNVs consisted in 2 deletions (gr/gr, b1/b3) and 3 duplications (gr/gr, b1/b3 and b2/b4). Regarding to deletions, only gr/gr (3.6%) and b1/b3 (1%) were detected in patients group. However, due to the samples size no significant differences were found. According to duplications, no significant differences were showed for gr/gr duplications (control 4.9% vs patients 6.1%; $p = 0.805$). However, we obtained significant differences in the frequency of b1/b3 (7.3%-1.5%; $p = 0.036$) and b2/b4 (2.4%-0%; $p = 0.028$) duplication among control and patient samples,

To verify how affect the presence or absence of CNVs the spermatogeneis, we analyzed the frequency of duplications and deletions versus control group and azoospermic, criptozoospermic and oligozoospermic patients. Results showed that the highest deletion frequency (7.7%) was found in azoospermic samples ($p < 0.05$). Nevertheless, the frequency between two other patient group were similar ($p>0.05$) when compared with control samples.

Limitations, reasons for caution: The number of control and patient's samples studied should be higher. Moreover, homogeneous groups to perform the study could show a clear effect of CNVs on the spermatogenesis.

Wider implications of the findings: MLPA is a higher sensitive technique that allows to detect the CNVs in the Y-chromosome, than Multiplex PCR. A more accurate diagnosis could be offer to male factor patients. In addition, our results suggest that duplications could be exert a protective role in the spermatogenic process.

Trial registration number: not applicable.

P-068　Oxidation-reduction potential can help distinguish semen samples under oxidative stress

S. Roychoudhury[1], C. Dorsey[2], B.P. Choudhury[1], K.K. Kushal[3]

[1]Assam University, Department of Life Science and Bioinformatics, Silchar, India
[2]Aytu Bioscience, Englewood, U.S.A.
[3]Mediland Fertility Clinic, Mediland Hospital and Research Centre, Silchar, India

Study question: Identify if the sORP marker can be used to identify semen that meet the normal reference range of WHO parameters from those that do not.

Summary answer: Over 90% of semen samples with a sORP 1.23 mV/10^6 sperm/mL[S1] were correctly identified as meeting all the WHO parameters.

What is known already: Discrete measures of free radicals, antioxidant activity, and oxidative damage suggest an ambiguous relationship between the redox system and male fertility. Static oxidation-reduction potential (sORP) measures the balance between all oxidants and antioxidants providing a comprehensive status of the redox system. In previous studies, sORP has been tested in semen samples using the MiOXSYS System as an alternative method for measuring oxidative stress and distinguishing normal controls from male factor infertility patients; thus sORP levels may be used to clarify the relationship between the redox system and semen parameters associated with male infertility.

Study design, size, duration: This prospective study was carried out jointly by the Mediland Hospital,Research Center, and Department of Life Science and Bioinformatics of Assam University on 48 subjects. The study was approved by the institutional ethics committee and subjects were consented prior to participation. Subjects were grouped into those that had all normal semen parameters (concentration, total motility, and morphology) according to WHO 2010 guidelines and those who failed to meet one or more criteria.

Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of STD or chronic disease, use of prescription, OTC medications or antioxidants. Samples were collected and semen parameters assessed using the WHO 2010 guidelines. sORP was measured(mV) using the MiOXSYS system and normalized to concentration (mV/10^6 sperm/mL). For group comparisons, only those samples with a concentration >0.999x10^6 sperm/mL were included.

Main results and the role of chance: The measure of sORP reflects the oxidative relationship between the sperm cell and its environment - the expulsion of oxidants, a by-product of cellular metabolism, into the seminal environment and the deactivation of them by extracellular antioxidants. Thirty one samples failed to meet one or more criteria for semen quality; 17 met all WHO criteria. ORP results were significantly negatively correlated with sperm concentration ($p < 0.01$) and morphology ($p < 0.01$). The area under the curve (AUC) was 0.863. The sORP cut-off value 1.23 mV/10^6 sperm/mL), while excellent at differentiating samples with normal concentration and morphology, was less useful in identifying those according to motility.

Limitations, reasons for caution: The current study was performed at a single fertility clinic. Study enrollment was limited and more cases are needed in order to assess the relationship with other semen parameters.

Wider implications of the findings: Measuring sORP can help a clinician understand if comparatively one semen sample is under higher state of oxidative stress than another.

Trial registration number: not applicable.

P-069　Influence of chromosomal structural rearrangement on sperm parameters: study on 305 male carriers

L. Hesters[1], A. Le Bras[2], L. Tosca[3], S. Brisset[3], V. Gallot[4], G. Tachdjian[3], N. Achour-Frydman[2]

[1]Hospital A. Béclère, Unit of reproductive biology, Clamart Cedex, France
[2]Antoine Béclère Hospital, Unit of reproductive biology, Clamart, France
[3]Antoine Béclère Hospital, Unit of cytogenetic, Clamart, France
[4]Antoine Béclère Hospital, Unit of reproductive medicine, Clamart, France

Study question: Robertsonian translocations have a deleterious effect on spermatogenesis. For reciprocal translocations, this effect is observed when acrocentric, small metacentric or submetacentric chromosomes are involved.

Summary answer: Robertsonian translocations have a deleterious effect on spermatogenesis. For reciprocal translocations, this effect is observed when acrocentric, small metacentric or submetacentric chromosomes are involved.

What is known already: Chromosomal rearrangements are thought to account for 2-8% of male factor infertility. They stop germ cells maturation or lead to the production of defective spermatozoa. Several studies have analyzed the cytogenetic pattern in infertile male population. But only two studies have compared sperm parameters between the most frequent chromosomal structure rearrangements ie Robertsonian (RT) and Reciprocal (RCT) translocations. They reported an impact on spermatogenesis especially for RT but not for

RCT. The present study aimed to analyze sperm parameters according to the chromosome involved in the structural rearrangement.

Study design, size, duration: This study was conducted retrospectively. We included an overall of 305 couples that benefited from a preimplantation genetic diagnosis (PGD) for a male chromosomal translocation (171 for RCT and 134 for RT) between 2006 and 2015. Sperm parameters on initial macroscopic examination (concentration, motility) and after sperm preparation (number of progressive spermatozoa) were analyzed according to the type of translocation and the chromosomes involved in the rearrangement.

Participants/materials, setting, methods: Our study group was compared to a control group of 120 couples with normal karyotype and proven fertility enrolled in PGD for monogenic disease during the same period. Sperm parameters were assessed according to the WHO 2010 references. For each RCT the number of progressive spermatozoa (NPS) obtained after preparation was plotted on a karyogram. The NPS was considered of poor quality when it was $\leq 1 \times 10^6$. Statistical analyses were performed using GraphPad Prism (ver. 5.02).

Main results and the role of chance: Compared to the control group, the mean sperm concentration and mean progressive sperm motility were significantly reduced in RCT and RT male carriers ($P < 0.0001$). Of note, lower sperm characteristics were observed for RT compared to RCT male carriers ($P < 0.0001$). Compared to the WHO references, 32.7% of RCT and 73.2% of RT male carriers had a sperm concentration below 15×10^6 per ml. 48.8% of RCT and 78.9% of RT had a progressive sperm motility that was below 32%. The mean NPS obtained after preparation was lower in RT compared to RCT male carriers ($1.6 \times 10^6 \pm 0.3$ vs $12.4 \times 10^6 \pm 1.5$ respectively, $P < 0.0001$). For each RCT male carrier, the NPS obtained after sperm preparation was plotted on an original karyogram. This representation permits us to show that acrocentric, small submetacentric and metacentric chromosomes were more often associated with a NPS $\leq 1 \times 10^6$ ($P = 0.02$).

Limitations, reasons for caution: Data about environmental gonad toxicity are missing in the present study. This may constitute a bias in our analysis.

Wider implications of the findings: Structural chromosomal rearrangement involving acrocentric, small submetacentric and metacentric chromosomes, are more prone to alter spermatogenesis. The practice of aCGH systematically for these patients would be of interest to specify the break point and identify gene candidate involved in spermatogenesis.

Trial registration number: NA.

P-070   High levels of seminal oxidation reduction potential (ORP) in infertile men with clinical varicocele

R. Saleh[1], A. Agarwal[2]

[1]Faculty of Medicine- Sohag University, Dermatology- Venereology and Andrology, Sohag, Egypt
[2]The Cleveland Clinic, American Center for Reproductive Medicine, Cleveland, U.S.A.

Study question: Does seminal oxidation reduction potential (ORP) increases in infertile men clinical varicocele?

Summary answer: Seminal ORP is significantly higher in infertile men with clinical varicocele as compared to those with no detectable abnormality in their genital examination (idiopathic infertility).

What is known already: Varicocele is found in approximately 40% of men presenting with primary infertility and up to 80% of secondary infertility. Seminal oxidative stress (OS) plays an important role in the pathogenesis of varicocele-mediated male infertility through different mechanisms. Oxidation reduction potential (ORP) is a measure of the balance between oxidants and antioxidants that provides a comprehensive analysis of the redox system. Measurement of ORP, directly in the neat semen, has been recently shown as a simple, rapid and reliable test seminal OS.

Study design, size, duration: A prospective controlled pilot study was conducted on 36 men seeking medical advice for an infertility problem between October, 2016 and January, 2017. Following clinical examination, and scrotal color Doppler ultrasound, infertile men were divided into two groups. Group1: infertile men with clinical varicocele; and group 2: infertile men with idiopathic infertility (no detectable abnormality in their genital examination).

Participants/materials, setting, methods: Patients were examined in an infertility center by the same Andrologist. Semen analysis was performed

according to the WHO manual (2010). Seminal ORP was measured using the MiOXSYS system (Aytu BioScience, Inc., Englewood, CO, USA). Absolute values of ORP, in millivolts (mV), were normalized for sperm concentrations and results were expressed as $mV/10^6$ sperm/mL. Quantitative measures were presented as median and inter-quartile range (25th and 75th centiles). P value less than 0.05 was considered significant.

Main results and the role of chance: The study included 17 patients in group 1 and 19 in group 2. Patient's age and duration of infertility in group 1 [32 (30, 34) years] & [4 (1.5, 5) years] were not significantly different from group2 [33 (30, 36.5) years] & [2 (1.25, 3.5) years] (P values = 0.64 & 0.27; respectively). Patients in group 1 had significantly lower sperm concentrations [20 (5, 30) $\times 10^6$ /mL], and normal forms [3 (2, 4) %] as compared to those in group 2 [30 (20, 72.5 $\times 10^6$ /mL]; and [4 (3, 5) %] (P values = 0.03 & 0.005; respectively). Levels of seminal ORP were significantly higher in group 1 [3.04 (1.94, 7.75) $mV/10^6$ sperm/mL] as compared to group 2 [1.12 (0.42, 2.25) $mV/10^6$ sperm/mL]. A significant inverse correlation was found between ORP and sperm concentration ($r = -0.531$, $p = 0.001$), total sperm count ($r = -0.453$, $p = 0.008$), progressive motility ($r = -0.460$, $p = 0.007$), total motility ($r = -0.526$, $p = 0.002$) and normal forms ($r = -0.597$, $p < 0.001$). A significant positive correlation was found between ORP and seminal leukocytes ($r = 0.476$, $p = 0.003$).

Limitations, reasons for caution: The sample size was relatively small and semen samples from fertile men, with and without varicocele, were not included.

Wider implications of the findings: These findings may have important diagnostic and therapeutic implications. Further studies are warranted to explore the mechanism of increased ORP in a subset of infertile men with clinical varicocele. In addition, future studies may help determine those patients who would benefit from antioxidant therapy and/or surgical repair of varicocele.

Trial registration number: not applicable.

P-071   New phenotype of total Globozoospermia: nuclear sperm quality and molecular investigation

H. Ghédir[1], A. Braham[1], A. Saad[1], S. Viville[2], S. Ibala-Romdhane[1]

[1]Farhat Hached University Teaching Hospital, Laboratory of Human Cytogenetic-Molecular Genetics and Reproductive Biology, Sousse, Tunisia
[2]Laboratoire de Diagnostic Génétique, UF3472-génétique de l'infertilité, Hôpitaux Universitaires de Strasbourg

Study question: SPATA16 defects could influence the meiosis process besides its crucial role in acrosome formation and lead to a new phenotype of total globozoospermia?

Summary answer: Particular defects of round-headed spermatozoa (double/multiple round-headed and multi-tailed) due to an abnormal meiosis were detected in total globozoospermic patients showing SPATA16 mutation.

What is known already: Total globozoospermia is a rare but severe form of teratozoospermia. Lack of acrosome and round-headed spermatozoa are its main characteristics. Three genes (DPY19L2, SPATA16 and PICK1) are known to be associated to total globozoospermia. Recently a new SPATA16 mutation was identified in Tunisian patients. It was reported in the literature that alterations in SPATA16 gene influence the acrosome formation during spermiogenesis, whereas the meiosis was not disturbed. On the other hand, chromatin abnormalities were associated to round-headed spermatozoa, while the studies of sperm aneuploidy and DNA fragmentation were controversial.

Study design, size, duration: This is a case control study carried out on three unrelated Tunisian globozoospermic patients and 20 fertile men with normal semen profiles included as a control group. Patients were recruited between April 2015 and January 2017.

Participants/materials, setting, methods: Chromatin condensation was assessed by aniline-blue Staining. Fluorescence in situ hybridization for chromosomes X, Y and 18 was performed to study the chromosomal meiotic segregation. Sperm DNA fragmentation was evaluated by terminal desoxynucleotidyl transferase mediated deoxyuridine triphosphate biotin nick-end labelling (TUNEL) assay. We performed PCRs and Sanger sequencing for mutations screening of DPY19L2, SPATA16 and PICK1 associated to globozoospermia.

Main results and the role of chance: Sperm analysis for the three globozoospermic patients showed a total sperm immobility (akinetozoospermia) and a severe oligozoospermia. Besides the presence of 100% round-headed acrosomeless spermatozoa, a predominance of double or multiple round-headed (between 17% and 42.5%) and multi-tailed (between 14.5% and 53.5%) spermatozoa were observed. To the best of our knowledge, this is the first description of this particular morphological sperm defects frequently observed for these three total globozoospermic Tunisian patients. The mean DNA fragmentation index was significantly higher in patients compared to the control group (P < 0.001; 46.67 ± 11.93% VS 10.25 ± 3.83%). The total aneuploidy rate was considerably higher in patients compared to controls (P < 0.01) with a significant increase in the frequency of disomy for chromosomes X, Y and XY (P < 0.05). The rate of spermatozoa with abnormal nuclear chromatin condensation was significantly higher in patients compared to the control group (43.66 ± 10.67% VS 12.7 ± 6%, p < 0.05). For the molecular analysis, two patients were found to be homozygous for the new SPATA16 exon 2 deletion. Whereas, no mutation was identified for the third one.

Limitations, reasons for caution: A limitation of this study is the low number of patients considering the rarity of this syndrome and the novelty of the phenotype observed.

Wider implications of the findings: We confirm that defects in SPATA16 could be associated to an abnormal meiosis leading to a new particular morphological sperm defects in total globozoospermia. Phenotype examination, cytogenetic and molecular characterization can orientate the selection of the best treatment options and management of these infertile couples.

Trial registration number: not applicable.

P-072 Possible involvement of interleukin-34 in the development of spermatogenesis

M. Huleihel[1], N. Geller[2], A. Sawaid[3], M. Abofoul-Azab[3], A. Troib[3], E. Lunenfeld[4]

[1]Ben-Gurion University of the Negev, The Shraga Segal Dept. of Microbiology & Immunology, Beer - Sheva, Israel
[2]Ben-Gurion University of the Negev, The Shraga Segal Dept. Microbiology-Immunology and Genetics, Beer-Sheva, Israel
[3]Ben-Gurion University of the Negev., The Shraga Segal Dept. Microbiology-Immunology and Genetics, Beer-Sheva, Israel
[4]Soroka Medical Center and Faculty of Health Sciences- Ben-Gurion University of the Negev, Fertility and IVF Unit- Dep. OB/GYN, Beer-Sheva, Israel

Study question: Dose testicular cells produce interleukin-34 under normal conditions? Is its affected by age?

Summary answer: Sertoli, Leydig, peritubular cells, macrophages, premeiotic and meiotic cells produced it. Its levels were age-dependent in testicular homogenates (the highest levels in the younger age).

What is known already: Interleukin-34 (IL-34) is a protein produced mainly by neurons and keratinocytes. It is the ligand for colony stimulating factor-1 receptor (CSF-1 R).

IL-34 and CSF-1 are secreted proteins and have great structural resemblance. They compete on binding to the same site on CSF-1 R, but IL-34 binds stronger.

In mice with a mutated CSF-1 R receptor, CSF-1 has been found as the primary factor in development of the male and female reproductive system. In addition, CSF-1 R is expressed on spermatogonial stem cells, and CSF-1 was demonstrated to induce spermatogonial cell proliferation.

Study design, size, duration: Sexually immature ICR mice (1, 2 weeks old) and mature mice (3, 4, 8, 12 weeks old) were sacrificed, and the testes were collected and homogenized to quantify IL-34.

Participants/materials, setting, methods: The expression levels of IL-34 and CSF-1 R were evaluated by qPCR analysis using specific primers. Four micron thick sections from Bouin's fixed, paraffin-embedded testicular tissue and isolated cells of immature and mature mice were used for localization of IL-34 by immunofluorescence staining (IF) using specific antibodies.

Main results and the role of chance: Our results show the localization of IL-34 in different testicular cells such as tubular cells [germ cells (GC), meiotic/postmeiotic cells (MC/PM)], peritubular cells (PC) and interstitial cells (ISC) in all examined ages. IL-34 was also appeared in the branches (Bra) of Sertoli cells in testis of 4-weeks-old mice.

High expression of IL-34 was examined in testicular homogenates of 1-2 – weeks-old mice. This expression was significantly decreased with age starting from 2 weeks-old compared to 1-2 week-old mice (p< 0.05). The expression of CSF-1 R (IL-34 binding receptor) was basal in testicular homogenates of 1 and 2 week-old mice but significantly increased in testicular homogenates of 4 week-old mice (p< 0.05) and significantly decreased in testicular homogenates of 8 and 12 week-old mice compared to 4 week-old mice (p< 0.05) to reach the levels of 1 and 2 week-old mice. Using double IF staining we could show that Leydig cells, VASA (spermatogonial cells) and CREM-1 cells (meiotic cells) and macrophages also produce IL-34. Our results also showed the localization of IL-34 in the cytoplasm of Sertoli cell cultures, and over 2 weeks of age IL-34 began appearing in the nucleus as well. Over 4 weeks of age IL-34 appeared in Sertoli cell branches.

Limitations, reasons for caution: The study was performed in mouse model and the correlation with human should be considered. The specific function of IL-34 in the testis needs to be elucidate.

Wider implications of the findings: This is the first study that shows the expression of IL-34 in testicular tissue and cells, and the possibility to be under hormonal regulation.

Thus, it is possible to suggest that IL-34 could be involved in the regulation of spermatogenesis development, since its receptor was demonstrated in spermatogonial cells.

Trial registration number: NA.

P-073 Intervention to reduce sperm DNA damage prior to fertility treatment

P. Christensen[1], J. Cloherty[2], H. Ryan[3], R. Downer[3], U. Conway[2], E. Lowe[2], D. Egan[2], J. Michielsen[3], D. Keane[3], E. Parner[4]

[1]SPZ Lab A/S, Copenhagen, Denmark
[2]Galway Fertility Clinic, Western Distributor Road, Galway, Ireland
[3]ReproMed, Rockfield Medical Campus, Dublin, Ireland
[4]Aarhus University, Department of Public Health- Section for Biostatistics, Aarhus, Denmark

Study question: Can changing various factors such as diet, exercise, smoking, or intake of antioxidants help to reduce the level of sperm DNA damage?

Summary answer: The average index for sperm DNA damage (DFI) was reduced significantly from 34.1 to 25.7 (P < 0.0001) for the 96 men included in this study.

What is known already: Sperm DNA damage negatively affects the outcome of ART, including IVF and ICSI treatments. Factors such as tobacco smoking or metabolic syndrome are among the more common causes of sperm DNA damage. Furthermore, it has been shown that oral intake of antioxidants may reduce sperm DNA damage. However, DNA damage is multifactorial and many factors currently remain unknown. The overall aim of the study was to determine if sperm DNA damage could be reduced and identify the factors leading to such improvement.

Study design, size, duration: Sperm DNA damage was tested in 2287 male patients. The DFI was above 15 for 1178 patients (51.5%), who were then invited to participate. In total, 96 patients were enrolled in the study with interventions individually designed during consultations between physician and patient. The DFI was re-tested after a recommended period of 3 to 9 months. All changes implemented by the patient were recorded using an online self-assessment questionnaire.

Participants/materials, setting, methods: Patients were enrolled at 2 fertility clinics. DFI was determined by a diagnostic laboratory using the sperm DNA integrity test (SDI-test), modified from Evenson & Jost (Current Protocols In Flow Cytometry 2000;7,13:1–27). Data from all 96 men before and after intervention was analysed using a paired t-test as well as the bootstrap method. Changes made by individuals were highlighted using the intra-individual variation of the SDI-test (estimated from control-group data of a previous RCT).

Main results and the role of chance: The overall DFI was reduced significantly from 34.1 to 25.7 (8.4 percentage units, P < 0.0001). This reduction in

DFI was determined by the paired t-test and was confirmed by the bootstrap method. Intra-individual variation (SD_W) of the SDI-test was determined using double-blinded control-group data from a previous RCT. Using the SD_W (=6.36%), 27 men were determined to have improved their DFI significantly (on average from 40.7 to 19.8). One man, however, had increased his DFI significantly from 59.4 to 87.6. The factors implemented by the 27 men were related to dietary changes to reduce possible insulin resistance: Reductions in meat intake (13/27), white bread (13/27), soft drinks (13/27) and alcohol (24/27). In addition, an increased fruit and vegetable intake was reported (15/27), together with increased exercise levels (14/27). Out of the 27 men, 15 reported losing weight. Three men (3/27) reported stopping smoking. Twenty men (20/27) reported starting to take antioxidants. Nine men (9/27) reported taking medication, and one man, who had stopped taking a SSRI medication, achieved the highest reduction in DFI (from 92.0 to 34.1). The man who increased his DFI significantly had taken a high dosage of various antioxidants and was confirmed to have iron intoxication.

Limitations, reasons for caution: This prospective study is based on 96 men with an initial DFI of above 15. For most men, several factors were implemented. It should be noted that some factors, i.e. smoking, may not result in a high DFI unless other factors, i.e. lack of antioxidants, are also involved.

Wider implications of the findings: Reduction of sperm DNA damage before ART is desirable as it may increase treatment success rates. Furthermore, such intervention may also have a positive effect on general male health as DNA damage in sperm is often linked to increased DNA damage in somatic cells.

Trial registration number: None.

P-074 Expression of pigment epithelium derived factor PEDF in mouse testicular tissue; possible involvement in testicular functions

E. Lunenfeld[1], E. Abaev[2], N. Bgdadi[3], M. Azab-Abofoul[3], M. Huleihel[3]

[1]Soroka University Medical Center, Department of Obstetrics and Gynecology-Faculty of Health Sciences and The Center of Advanced Research and Education in Reproduction CARER, Beer - Sheva, Israel
[2]Ben-Gurion University of the Negev, The Shraga Segal Dep. of Microbiology-Immunology and Genetics, Beer-Sheva, Israel
[3]Ben-Gurion University of the Negev, The Shraga Segal Dep. of Microbiology-Immunology and Genetics- The Center of Advanced Research and Education in Reproduction CARER, Beer-Sheva, Israel

Study question: Dos PEDF express in testicular cells under physiological conditions? and is it under hormonal regulation?

Summary answer: PEDF expressed by Sertoli, peritubular, Leydig cells and macrophages. The levels of PEDF in testicular homogenates were significantly decreased with age, suggesting hormonal regulation.

What is known already: Pigment epithelium derived factor (PEDF) is released as a soluble, monomeric glycoprotein, encoded by SERPINE-1 gene. The PEDF is known as an anti-angiogenic factor. In endothelial cells, PEDF promotes apoptosis in new vessels and exerts anti-tumor properties. Spermatogenesis occurs in the seminiferous tubules of the testis, which are avascular. However, there are blood vessels in the interstitial tissue close to the seminiferous tubules wall. Recently, it has been shown that cultures of human testicular peritubular cells constitutively secrete PEDF, and suggested that PEDF may prevent vascularization of human seminiferous tubules.

Study design, size, duration: Sexually immature (1, 2 weeks old) and mature (4, 8, 12 weeks old) ICR mice were sacrificed, and their testis were collected for histological examination and/or homogenized to quantify PEDF by qPCR. Some testes were also used to establish Sertoli and peritubular cell cultures and for Leydig cell isolation.

Participants/materials, setting, methods: Testes of mice from different ages were used for RNA extraction, histological evaluation and immunostaining and for establishment of primary cultures for Sertoli and peritubular cells. The expression levels of PEDF was examined by qPCR analysis, and its cellular localization in the testis and Sertoli and peritubulae cultures and in isolated Leydig cells and macrophages was examined by double immunofluorescence staining using specific antibodies for PEDF and specific marker for each examined testicular cell type.

Main results and the role of chance: In testicular sections, PEDF was stained in germ cells, peritubular cells, Sertoli cells, and interstitial cells in both mature and immature mice. In addition, meiotic/postmeiotic cells were also stained in seminiferous tubules of mature mice. High expression levels of PEDF were detected in testicular homogenates of 1-2 weeks-old mice. This expression was significantly decreased with age starting from 4 weeks-old compared to 1 week-old mice. Double immunoflurescence staing showed specific PEDF staining in isolated Leydig cells and macrophages. In addition double immuno-flurescence staing showed specific PEDF staining in the cytoplasm of established Sertoli and peritubular primary cell cultures(isolated from mice of different ages).

Limitations, reasons for caution: The study was performed in mouse model and the correlation with human should be considered. The specific role of PEDF in the different cell type of the testis need to be clarified.

Wider implications of the findings: This is the first study to show that mouse peritubular cells, Sertoli cells, Leydig cells and macrophages constitutively produce PEDF; and the possibility to be under hormonal regulation. We suggest that PEDF could be involved in testicular physiological function (spermatogenesis, seminiferous tubule avascularization, testicular immune privilege site)

Trial registration number: NA.

P-075 Biological properties of mouse spermatozoa prepared with the microfluidic sperm sorter

K. Ohata, M. Kobayashi, A. Yoshida

Kiba Park Clinic, Research center, Tokyo, Japan

Study question: The purpose of this study was to investigate the biological properties and the developmental ability of spermatozoa prepared by the microfluidic sperm sorter (MFSS).

Summary answer: In this study, we demonstrated that spermatozoa with high sperm motility and developmental ability were able to separate by using the MFSS.

What is known already: The microfluidic sperm sorter (MFSS) is a novel device that is able to separate spermatozoa with high motility and low DNA fragmentation from raw semen without washing and centrifugation process. However, some biological properties and effect on embryonic development of spermatozoa separated by the MFSS are as yet unexplained.

Study design, size, duration: Spermatozoa obtained from cauda epidetimis of C57Bl/6J mice were divided into two aliquots. One aliquot was processed by the MFSS and separated into high-motility (HM) and low-motility (LM) spermatozoa; the second aliquot was processed by the swim-up procedure (SU). Motility parameters and mitochondrial membrane potential (MMP) were studied. Fertilization and blastocyst rate were compared between embryos with spermatozoa separated by MFSS and those with spermatozoa processed by SU.

Participants/materials, setting, methods: Sperm motility parameters were analyzed with the sperm motility analyzing system (SMAS). MMP was evaluated with the flow cytometer after JC-1 staining. In addition, spermatozoa of each group were injected into ovulated oocytes derived from BDF1 female mice. After 3.5 hours from ICSI, a part of fertilized oocytes derived from each group was stained immunohistochemically with gamma H2AX antibody to detect DNA damage, and the others were cultured until to the blastocyst stage.

Main results and the role of chance: By the SMAS analysis, the motile sperm rate was 90.5%, 47.8%, and 89.5% for HM, LM, and SU, respectively. The average speed of HM was significantly higher than that of LM and SU (HM: 116.8 ± 8.6 μm/sec, LM: 68.2 ± 8.2, SU: 83.1 ± 4.1, $p < 0.05$). MMP of spermatozoa in HM and SU were significantly higher than that of LM. After ICSI, there was no significant difference in the rate of pronuclear formation between each group. By immunohistochemical staining, high positive rate of gamma H2AX was observed in male pronucleus of embryos with LM spermatozoa. In addition, the blastocyst rate of embryos with HM was significantly higher than that of LM and was comparable to that of SU (HM: 84.3%, LM: 56.1%, SU: 79.7%, $p < 0.05$).

Limitations, reasons for caution: This study was conducted using a mouse model, and this finding does not directly represent human infertility.

Wider implications of the findings: This study shows clearly that the MFSS could separate more functional spermatozoa for fertilization and development

compared with swim-up procedure. In addition, by optimizing the MFSS system, the most appropriate spermatozoa for IVF/ICSI would be provided efficiently.

Trial registration number: Not applicable.

P-076 Effect of ejaculatory abstinence period on sperm DNA fragmentation and fertilization

K.H. Lee, I.H. Park, H.G. Sun, J.W. Kim, H.J. Chi, S.G. Kim, Y.Y. Kim, J.Y. Park, C.S. Yoo

Mamapapa & baby Hospital, OBGY, Ulsan, Korea- South

Study question: Does ejaculatory abstinence period (EAP) have effect on sperm DNA fragmentation and fertilization?

Summary answer: Longer EAP is correlated with serial increase of sperm DNA fragmentation. EAP above 7 days has negative effect on fertilization rate in conventional IVF cycles.

What is known already: In many clinics, male partners undergoing IVF cycles were advised to sexually abstain for 2 to 7 days prior to semen collection for ART. However, there is currently little evidence to support such advice. This advice may be based on World Health Organization guideline recommending abstinence for 2-7 days before semen collection for evaluation of infertility. Prolonged ejaculation abstinence period maximizes sperm concentration in the ejaculate. However, with long abstinence, sperm could be damaged by oxidative stress. In some study, increased EAP has positive correlation with sperm DNA fragmentation.

Study design, size, duration: This retrospective cohort study included 836 couples undergoing IVF cycles between January 2015 and December 2016.

Participants/materials, setting, methods: On the day of oocyte aspiration, semen collection was done. Sperm DNA fragmentation was examined by sperm chromatin dispersion test (SCD). We divided the couples into three groups by abstinence interval.

  GI: interval $\leq$ 4 days
  GII: 5 days $\leq$ interval $\leq$ 7 days
  GIII: interval $\geq$ 8 days

  Fertilization rates and pregnancy rates of each group were compared in conventional IVF cycles and ICSI cycles.

Main results and the role of chance: In each group, the age of male and female partner and the number of oocytes did not show significant differences. Sperm DNA fragmentation index(DFI) of GI, GII, GIII were 16.6%, 19.3%, 22.1%. If abstinence interval was increased, sperm DNA fragmentation index (DFI) was also significantly increased[GIvs. GII, P = 0.002; GIvs. GIII, P = 0.001; GIIvs. GIII, P = 0.018]. Fertilization rates of GI, GII, GIII in conventional IVF cycles were 53.7%, 58.8%, 47.8%. Fertilization rate of group C was significantly lower than that of group B[P = 0.004]. There were no significant differences among pregnancy rates of three groups in conventional IVF cycles[47.8%(65/136) vs. 51.3%(41/80) vs. 50.0%(20/40), P=NS]. Fertilization rates of GI, GII, GIII in ICSI cycles were 60.2%, 57.2%, 67.3%. They did not show significant differences. Pregnancy rates in ICSI cycles were similar among three groups[45.7% (134/293) vs. 42.6%(69/162) vs. 46.4%(58/125), P=NS].

Limitations, reasons for caution: This is retrospective study. EAP was recorded by memory of male partner. It could cause some recall bias.

Wider implications of the findings: Increased EAP is correlated with high sperm DNA fragmentation. Prolonged EAP above 7 days has negative effect on fertilization rate in conventional IVF cycle. However, in ICSI cycle, fertilization was not affected. Shorter EAP is advisable and if abstinence period is increased, fertilization by ICSI could minimize harmful effect.

Trial registration number: None.

P-077 Does weight loss improve fertility with respect to semen parameters and reproductive hormones? results from a large cohort study

J. Mir[1], K. Rao[2]

[1]*Milann The Fertility Center, Embryology, Bangalore, India*
[2]*Milann The Fertility Center, Reproductive Medicine, Bangalore, India*

Study question: Does weight loss improve fertility potential of over weight and obese men?

Summary answer: weight loss has positive impact on major fertility parameters suggestive of improved fertility potential. Weight loss must be considered part of infertility management.

What is known already: while much is known about obesity and its impact on fertility among females, there is little evidence about male obesity and its impact on fertility. Previous studies have shown that normal weight men have better fertility potential compared to obese men. However, there is no data on weight loss by natural means except one. There is a need to understand a better management of fertility issues among obese men.

Study design, size, duration: This study used a prospective interventional design. A total of 105 participants were recruited after initial screening according to our inclusion criteria for the study. Data was prospectively collected between April 2012 and May 2015

Participants/materials, setting, methods: Obese men aged 25 to 40 years (Mean age = 32.5 $\pm$ 7.5) with body mass index (BMI) more than 25 kg/m^2 were recruited for the study. The subjects underwent a weight loss intervention and were followed up for one year post intervention. Participants were recruited from infertility center as well as fitness centers around the clinic set up. Participants were advised for weight loss through diet counseling and exercise.

Main results and the role of chance: The subjects underwent a weight loss intervention and were followed up for one year post intervention. We performed blood tests, including the serum sex hormone levels, and conventional and computer-assisted semen analyses. The sperm DNA fragmentation (SDF) was evaluated using the sperm chromatin dispersion test (SCDt) to determine the SDF index (SDFI). The fertility parameters were compared before and after weight loss. The weight loss increased the testosterone to 35.40 $\pm$ 20.51 ng/ml compared with 27.16 $\pm$ 20.71 ng/ml, and sex hormone binding globulin (SHBG) to 23.72 $\pm$ 9.01 µg/dl compared with 19.18 $\pm$ 10.44 µg/dl, while as follicle stimulating hormone (FSH) and luteinizing hormone (LH) were non-significant. Weight loss also showed significant changes in progressive motile sperm from 29.35 $\pm$ 21.91% to 41.06 $\pm$ 24.40%, static sperm from 53.70 $\pm$ 24.27% to 39.97 $\pm$ 22.50% and no significant change in other semen parameters. Weight loss also decreased the SDFI to 17.49 $\pm$ 8.28% compared with 20.21 $\pm$ 9.31%.

Limitations, reasons for caution: Only a single measure of semen analysis and hormone assay was performed. Variations in the semen parameters may provide inadequate information. Despite the weight loss many participants still remained obese.

Wider implications of the findings: Considering the well established association between male obesity and altered reproductive hormonal profile, especially testosterone which is required in large concentrations to maintain spermatogenesis, it is reasonable to consider obesity to also affect semen quality. Weight loss should be considered in the management of infertility especially in obese male partner.

Trial registration number: Not applicable.

P-078 Does sperm origin affect embryo morphokinetics parameters?

F. Scarselli[1], V. Casciani[1], M.G. Minasi[1], E. Iovine[1], S. Muzzì[1], A. Pristerà[1], V. Zazzaro[1], G. Franco[2], M.C. Greco[1], C. Arrivi[1], A. Caragia[1], A. Greco[1], E. Greco[1]

[1]*European Hospital, Center for Reproductive Medicine, Rome, Italy*
[2]*Sapienza University, Gynaecological-Obstetrical and Urological Sciences, Rome, Italy*

Study question: Does sperm origin, testicular or ejaculated, interfere with embryo morphokinetic development?

Summary answer: Embryos derived from testicular spermatozoa showed earlier second polar body (II-PB) extrusion and 4-cells stage while later 9-cells stage, compared to ejaculated normal sperm.

What is known already: It is well known that ejaculated and testicular sperm differ in the degree of nuclear maturation. During spermiogenesis, the transit of spermatozoa in the epididymal tract favors DNA packaging by stabilizing the chromatin structure through protamine dephosphorilation and the formation of molecular bridges. Additional difference in sperm maturity may involve the centrioles, structures implicated in embryo cleavage. Based on these observations,

sperm maturity can affect the timing of fertilization and later cellular divisions during embryo development.

Study design, size, duration: In this retrospective observational study (October 2014-July 2016), we analyzed the developmental kinetics of embryos obtained either with testicular sperm (N = 70 embryos; 21 cycles; TS-group) or with thawed donated sperm (N = 109 embryos; 22 cycles; DS-group). Only correctly fertilized (2PN) oocytes were studied. As expected, the fertilization rate was higher in DS (137/215=63,5%) than TS (239/457=52,3%) groups (p = 0.0060). The developmental markers observed were: II-PB extrusion, pronuclei (2PN) appearance, 2PN fading, divisions at 2 to 9- cells.

Participants/materials, setting, methods: Embryo development was analyzed with time lapse technology. Development timings were recorded for all embryos (TS-group: female mean age=34.47 $\pm$ 4.66; DS-group: female mean age=34 $\pm$ 4.5). Anova Test was used for statistical analyses. Average hour$\pm$SD from ICSI insemination are reported. Donor's age ranged between 18 and 40 years old; sperm parameters for donors recruitment were, on fresh sperm, > 80 million/ml with >50% progressive motility and >4% morphology and, after density gradient, concentration>8 million/ml, progressive motility>50% and morphology>4% (WHO2010).

Main results and the role of chance: In TS versus DS groups respectively, II-PB was extruded at 3.63 $\pm$ 1.53 h (N = 239) and 4.04 $\pm$ 1.65 h (N = 137) (p = 0.0147); 2PN appeared at 10.17 $\pm$ 3 h (N = 239) and 10.29 $\pm$ 3.16 h (N = 137) (NS); 2PN disappeared at 25.53 $\pm$ 5.75 h (N = 239) and 26.26 $\pm$ 4.67 h (N = 137) (NS); cleavage at 2-cells was at 28.85 $\pm$ 5.82 h (N = 204) and 29.85 $\pm$ 5.68 h (N = 110) (NS); 3-cells at 38.69 $\pm$ 8.56 h (N = 139) and 40.3 $\pm$ 8.07 h (N = 86) (NS); 4-cells at 41.69 $\pm$ 8.81 h (N = 201) and 43.98 $\pm$ 10.46 h (N = 106) (p = 0.049); 5-cells at 49.99 $\pm$ 10.70 h (N = 160) and 52.19 $\pm$ 11.27 h (N = 83) (NS); 6-cells at 54.72 $\pm$ 10.85 h (N = 148) and 54.56 $\pm$ 8.03 h (N = 71) (NS); 7-cells 57.41 $\pm$ 10.61 h (N = 128) and 56.35 $\pm$ 7.06 h (N = 64) (NS); 8-cells 62.44 $\pm$ 13.12 h (N = 137) and 60.80 $\pm$ 6.16 h (N = 55) (NS); 9+-cells at 70.85 $\pm$ 14.86 (N = 94) and 65.04 $\pm$ 5.55 (N = 28) (p = 0.0005). In brackets numbers of embryos at each specific developmental stage are reported. Data on embryos are relative to cultures until day-3. We observed a significant anticipation in the time of II-PB extrusion in TS-group compared to DS-group. Also the time at which embryos reached the 4-cells stage was anticipated in the TS-group as compared to the DS-group. Conversely a highly significant delay in the timing of the 9 cells-stage was observed in the TS-group.

Limitations, reasons for caution: A limitation of our study is the use of cryopreserved sperm as control, whereas our study group included both cryopreserved or fresh sperm. An additional limitation is the small population size due to the fact that we have started using donor-sperm only after the Constitutional Court Sentence 162/2014 restoring gamete-donation.

Wider implications of the findings: An early paternal effect could be visible after ICSI (II-PB extrusion) and in early cellular divisions (4-cells). A later paternal effect could lead to the retardation seen at 9-cells in the TS-gorup. Morphokinetic parameters might give predictive information for embryo development in relation to the type of sperm used.

Trial registration number: Not applicable.

P-079 Which sperm source and transferred embryo has the best artifical reproductive techniques (ART) outcomes in Klinefelter syndrome (KS)

M.M. Basar[1], E. Turgut[2], C. Pirkevi-Cetinkaya[2], S. Unal[2], Y. Kumtepe-Colakoglu[2], S. Kahraman[2]

[1]Memorial Sisli Hospital, Urology and Andrology, istanbul, Turkey
[2]MEMORIAL SISLI HOSPITAL, IVF and Reproductive-Genetics&Embriology Laboratory, Istanbul, Turkey

Study question: Are there any differences between fresh and thawed testicular spermatozoa, fresh and frozen embryo transfers (FET) over the ART outcomes in KS.

Summary answer: Although fresh testicular sperm usage had high ART success rate than thawed spermatozoa for KS patients, no difference had been observed between fresh and FET.

What is known already: Klinefelter syndrome is the most common sex chromosomal disorder among infertile males. It is now well accepted that new developments in ART have made paternity possible in these cases. Although most of the KS men have azospermia, Mic-TeSe provides high sperm recovery with 35 and 45% success rate. In the literature, while it was reported that fertilization rate was lower in KS cases than other azoospermic male, pregnancy and live birth rates were not different in KS groups than others. However, there was limited knowledge about ART results with cryopreserved–thawed spermatozoa in KS cases.

Study design, size, duration: A total of 133 fresh ET and 24 FET cycles in 206 KS patients were evaluated between 2002- 2016. Fresh or thawed testicular and ejaculated spermatozoa were used for ART. The demographics data, embryological parameters such as total number of retrieved oocytes (COC) and metaphase II oocytes (MII), fertilization (PN), implantation, clinical pregnancy and live birth rates were compared according to the source of spermatozoa. Moreover, fresh and FET cycles were evaluated.

Participants/materials, setting, methods: KS cases were divided into three groups according to sperm source as fresh testicular, ejaculated and cryopreserved-thawed spermatozoa, and all parameters compared among these groups. Additionally, patients' age, clinical pregnancy rate and live birth rates were compared in fresh and frozen-thawed ET cases. Kruskall-Wallis test, Mann-Whitney U test and Pearson Chi-square test were used to determine the independent parameters.

Main results and the role of chance: While 26 (9.4%) of 206 patients had mosaic KS, the rest of them were pure KS cases. 203 out of 206 KS patients underwent to micro-TeSe. Spermatozoa were found in 88 patients (43.3%). Testicular sperm aspiration was performed only in 2 patients. Ejaculated spermatozoa were used in 16 cases, and 13 (81.3%) had mosaic karyotype. Thawed testicular sperms were used in 29 cycles.

Mean age of men displayed statistical difference between groups (p= 0.015). Moreover, mean age of women, duration of infertility, COC, MII and PN rates were similar between groups (p= 0.530, 0.031, 0.03, 0.018, 0.052, respectively). Implantation, clinical pregnancy and live birth rates were significantly different between groups (p= 0.001) and all were at the highest value in favor to ejaculated spermatozoa. This statistical difference is arising from mosaic cases in which ejaculated spermatozoa were used cycles and all were mosaic KS. Clinical pregnancy and live birth rates are significantly higher in fresh testicular spermatozoa compared to thaw testicular spermatozoa cycles among pure KS patients (p= 0.012).

Pregnancy outcomes were evaluated between fresh ET and FET cycles. Demographic data and ART outcomes did not display statistically difference between groups (p>0.05).

Limitations, reasons for caution: The distributions of the participants are not equal in groups. Furthermore, predictive parameters for spermatozoa retrieval rate were not considered in the study.

Wider implications of the findings: We plan using fresh micro-TeSe at the same day with oocyte pick-up and if we are able to retrieve mature spermatozoa for fertilization and generate suitable embryos for transfer, then we can adjust the type of transfer according to the patients situation in KS patients.

Trial registration number: None.

P-080 Effect of Paternal Ethnicity on Live Birth Rates after IVF/ ICSI Treatment: Analysis of a National Database

H. Abbassi[1], B. Campbell[2], W. Maalouf[2], K. Jayaprakasan[2]

[1]Birmingham, United Kingdom,
[2]University of Nottingham, Division of Child Health- Obstetrics and Gynaecology, Nottinghamshire, United Kingdom

Study question: What are the potential effects of paternal ethnicity on IVF/ ICSI clinical outcome?

Summary answer: Biochemical pregnancy and live birth rates following a single IVF cycle were significantly higher amongst couples with Chinese and white European male partners.

What is known already: In the literature, a limited number of powered studies were published on the relationship between ethnic background and IVF/ ICSI treatment outcome, and they are generally focused on the ethnicity of the

female patient only. Very limited information is known about the paternal patient's ethnicity and its effects on clinical success rates.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of IVF and ICSI treatment in the UK. Data from 2000 to 2010 involving 47,500 treatment cycles of White British female patients, of which 28,488 patients were analysed during their first cycle. The data has been analysed retrospectively to determine the differences in IVF outcome amongst patients whose male partner is of different ethnicity.

Participants/materials, setting, methods: Data on all men whose partners is White British and undergoing their first stimulated fresh IVF treatment cycle during the period from 2000 to 2010 were analysed primarily for live birth rate per cycle and cumulative live birth rate. Data analysed after adjusting for age, cause and type of infertility and treatment type (IVF or ICSI) to express results as odds ratio and 95% confidence intervals.

Main results and the role of chance: Partners of White British female patients who are White European (2.06; 0.90 – 4.72) or Chinese (3.56; 0.94 – 13.50) had a significantly higher odds of live birth rate per fresh IVF/ICSI cycle than White British partners, while partner of mixed background (0.55; 0.35 - 0.85) had a significantly lower odds, all other ethnicities had equivalent live birth rates; White Irish (1.24; 0.81 - 1.88), Mediterranean (0.98; 0.48 – 2.01), SA Indian (0.60; 0.26 – 1.41), SA Pakistani (0.71; 0.20 – 2.58), Black African (0.87; 0.36 – 2.1), Black Caribbean (0.59; 0.22 – 1.60), and Black British (0.84; 0.40 – 1.75). The cumulative live birth rates also showed similar pattern across different ethnic groups.

Limitations, reasons for caution: Controlling for confounders like women's BMI, smoking status, treatment protocol and gonadotrophin dose could not be done because these data were not available.

Wider implications of the findings: Ethnicity should be considered while counselling couples about their realistic chances of IVF/ ICSI success. Further research is needed to understand the reasons behind the variation in treatment outcome between ethnic groups which can potentially lead to a more tailored treatment protocols so IVF/ ICSI success rate is maximised.

Trial registration number: Not applicable.

P-081   Combined treatment with inositol and alpha-lipoic acid of dispermic patients significantly improves semen parameters

P. Scaruffi[1], A. Dal Lago[2], C. De Leo[3], M. Gallo[2], C. Rizzo[1], E. Licata[2], P. Anserini[1], R. Rago[2], P. Canepa[1]

[1]IRCCS AOU San Martino - IST, UOS Fisiopatologia della Riproduzione Umana, Genoa, Italy
[2]Ospedale Sandro Pertini – ASL Roma 2, UOSD Fisiopatologia della Riproduzione e Andrologia, Rome, Italy
[3]Università degli Studi di Genova, Laboratorio di Andrologia, Genoa, Italy

Study question: Does combined treatment with inositol and alpha-lipoic acid of dispermic patients improve semen parameters?

Summary answer: For the first time, we show that the combined treatment with inositol and alpha-lipoic acid is effective in treatment of infertile dispermic patients.

What is known already: Reduction in motility and number of spermatozoa and change in their morphology are some of the most relevant causes of infertility in men. One of the factors which may influence male infertility is the production of reactive oxygen species (ROS), since these chemical compounds can affect motility, morphology and DNA stability of spermatozoa. Research over the past decade has demonstrated that the pro-inflammatory state seen in metabolic dysfunction and the subsequent development of oxidative stress may provide a pathophysiologic explanation for the direct effects on normal spermatogenesis and sperm function.

Study design, size, duration: This study included 78 infertile men, 18-55 years aged, no-smokers, with a diagnosis of dispermia due to one or more altered semen parameters, without any testicular pathologies, with a normal endocrinological/metabolic profile (HOMA Index <2.5; testosterone, prolactin, FSH, LH normal serum values), and no concomitant consumption of drugs. Patients signed an informed consent to the enrollment in the study. Semen

analysis was performed before (T0) and after 90 days (T90) of treatment and results were compared.

Participants/materials, setting, methods: Diet of patients was supplemented with alpha lipoic acid, myo-inositol, folic acid, vitamin B2, B6, B12, and betaine (2 tablets/day of Sinopol®, Laborest, Italy). At T0 and T90 we evaluated liquefaction, semen viscosity, volume, pH; sperm motility, vitality and numbers; concentration of round cells; sperm morphology. Mann-Whitney test was performed using MedCalc® software (Mariakerke, Belgium), in order to investigate differences between semen parameters before and after the treatment. Results were considered statistically significant at P < 0.05.

Main results and the role of chance: Analyses of data showed an improvement of semen quality after 90 days of treatments, in terms of a statistically significant increase of sperm concentration (percentage increase = 50%, P = 0.0105), of number of spermatozoa (percentage increase=54%, P = 0.0054), of number of motile spermatozoa (percentage increase=56%, P = 0.0008), of progressive motility (percentage increase=41%, P = 0.0006), and of normal sperm morphology (percentage increase=60%, P < 0.0001).

Limitations, reasons for caution: Enrollment is ongoing to validate results in a larger cohort of patients, evaluating also their BMI and metabolic profile at T0 and T90. Moreover, we are collecting data on IVF cycles before and after the treatment, in order to compare fertilization and cleavage rates, quality of embryos, and pregnancy outcome.

Wider implications of the findings: For the first time, we report that the combined treatment with inositol and alpha-lipoic acid is effective in treatment of male infertility. Therefore, our pilot study suggests an important role of such a dietary supplement in clinical management of dispermia by a 'nutraceutical" able to act on the metabolic function.

Trial registration number: Not applicable.

P-082   Do chronic viral infections influence the seminal parameters?

W.A. Pereira de Carvalho, B.B. Parra, I.H. Yoshida, C.H. Suganuma, B. Bianco, C.P. Barbosa[1]

Instituto Ideia Fértil de Saúde Reprodutiva, IVF, Santo André, Brazil

Study question: To ascertain if viral load therapy and the immunological conditions of patients with chronic viral infections may interfere with sperm function.

Summary answer: Patients with chronic viral infections did not present alteration results in sperm function.

What is known already: The seminal analysis evaluated the fertile potential of man, being divided into the following groups: macroscopic, microscopic and morphological evaluation of the spermatozoa according to the parameters of the World Health Organization (WHO, 2010).Studies have shown that patients infected with hepatitis B and C virus present changes in seminal parameters, as well as decreased testosterone levels, leading to a decrease in total sperm concentration. In HIV-positive patients, sperm production was deficient. One possible reason for this fact would be the influence of viral load therapy and the patients' immunological conditions on sperm function.

Study design, size, duration: A retrospective case-control study using spermogram data from 388 patients from 2010 to 2015.

Participants/materials, setting, methods: The patients were divided to: control (299 seronegative patients), Hepatitis B (22 patients), Hepatitis C (25 patients) And HIV (42 patients) groups. Those who had some other disease besides chronic viral infections, smokers, alcoholics, who made continuous use of any drugs that might cause interference were excluded from the study. The following seminal parameters were evaluated: volume, pH, initial concentration, motility (progressive and non-progressive) and morphology.

Main results and the role of chance: All seminal parameters evaluated in this study did not present significant differences between the studied groups. Only in the Hepatitis B group, 9% of the patients had a pH lower than 7. In control group, 1% of the patients had acid pH and the other groups had normal values. Since frequency is very low, caution is required to establish any causal relationship to such a non-specific event. The results found in this study corroborate with Lorusso et al. (2009) who also verified that the viral infections did not alter the seminal quality of the analyzed patients.

Limitations, reasons for caution: Some cases, the altered result that was found in the patient's seminal analysis may not have been influenced by the chronic viral disease. This information could not be verified since there was no seminal analysis prior to virus contamination.

Wider implications of the findings: No relation between chronic viral infection and seminal quality was found, making not possible to establish a causal relation between infection and the infertility only by seminal quality.

Trial registration number: None.

P-083 Nutritional factors and sperm motility and progressive motility in oligoasthenoteratozoospermia (OAT) men

A. Kouhkan[1,2], S. Abbasihormozi[3], A. Matinibehzad[4], Z. Zolfaghar[5], A. Shahverdi[3], A. Alizadeh[3]

[1]Cell Science Research Center- Royan Institute for Stem Cell Biology and Technology- ACECR, Department of Regenerative Biomedicine, Tehran, Iran
[2]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Embryology-, Tehran, Iran
[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology-, Tehran, Iran
[4]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Embryology, Tehran, Iran
[5]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology, Tehran, Iran

Study question: To evaluate which nutritional factors have impact on sperm motility and progressive motility in Iranian OAT men.

Summary answer: Macro- and micronutrients have structural or protective role in sperm function. Clinicians should be aware about the impact of nutrients on sperm motility and motility progressive.

What is known already: Healthy nutrition is necessary to produce motile and progressive sperm cells. Studies suggest that food dietary intake may play an important role in male reproduction system and pathogenesis of infertility. Dietary intake consisted of macro- and micronutrients have effect on sperm parameters especially motility. Sperm motility has a principal role in male fertility. Little information exists on the optimal fertility diet. Also, the effect of nutritional factors on sperm motility and progression is unclear. The aim of this study was to determine which dietary factors are related to sperm motility and progression in Iranian OAT men.

Study design, size, duration: This cross sectional study was conducted on 300 subfertile men, aged 20-50 years, referring to Royan infertility clinic (Tehran, Iran) from March to September 2014. Participants were categorized into two groups; of 62 normospermic and 238 OAT patients according to World Health Organization 2010 criteria.

Participants/materials, setting, methods: After enrollment and receiving informed consent, all men underwent face-to-face private interviews. Participants completed two questionnaires including FFQ and general data. Dietary data was collected monthly by means of twelve 24 h dietary recalls (24hDR). Subjects completed 168-item semi-quantitative FFQ. Semen analysis was examined after 2–5 days of sexual abstinence based on WHO-recommended methods by CASA system (computer-assisted sperm analysis). Data adjusted for age and BMI. Statistical analysis was conducted by T-test and regression.

Main results and the role of chance: The mean age and BMI were $(34.63 \pm 5.3$ vs $33.71 \pm 5.2)$ and $(26.73 \pm 4.1$ vs 27.05 ± 10.1, P>0.05) in normospermic and OAT men, respectively. Sperm motility was associated to omega-2 PUFA ($\beta = 2.01$, P < 0.05), vitamin C ($\beta = 2.02$, P < 0.05) and also progressive motility was associated to omega-6 PUFA ($\beta = 1.27$, P < 0.05), MUFA ($\beta = 7.05$, P < 0.05) in total population. After dividing population into two groups, the reults indicated that some dietary intakes were positively associated with **sperm motility** including Na (β: 0.863, P < 0.001), Vitmin A(β: 0.64, P < 0.01) and Vitamin C (β: 1.10, P < 0.0001) and also other nutrients are relaed to **progressive** motility consisted of protein (β:10.035, P < 0.0001), cholestrol (β: 3.92, P < 0.001), MUFA (β:4.29, P < 0.0001), omega-2 PUFA ($\beta = 7.57$, P<.0001), omega-6 PUFA ($\beta = 6.682$,P<.0001), Na (β: 2.56, P < 0.001), K ($\beta = 6.87$,P < 0.001), vitamin A ($\beta = 5.54$,P < 0.001) and vitamin B6 ($\beta = 10.53$,P < 0.001) in Iranian subfertile men.

Limitations, reasons for caution: It was better to evaluate serum concentration of these factors.

Wider implications of the findings: Our results support of this concept that healthy diet is necessary to improve sperm motility, progressive and function in OAT subjects.

Trial registration number: no.

P-084 Vitrified-thawed mouse oocytes can be efficiently used to determine the oocyte activation potential of human sperm

D. Bonte[1], M. Ferrer-Buitrago[1], V. Thys[1], D. Deforce[2], L. Leybaert[3], P. De Sutter[1], B. Heindryckx[1]

[1]Ghent University Hospital, Ghent-Fertility And Stem cell Team G-FAST - Department for Reproductive Medicine, Gent, Belgium
[2]Ghent University, Laboratory for Pharmaceutical Biotechnology - Faculty of Pharmaceutical Sciences, Gent, Belgium
[3]Ghent University, Physiology Group - Department of Basic Medical Sciences, Gent, Belgium

Study question: Can vitrified mouse oocytes substitute fresh oocytes to diagnose the activation potential of human sperm in cases of failed or low fertilization after ICSI?

Summary answer: Vitrified mouse oocytes can be reliably used to determine the activation potential of human sperm.

What is known already: The mouse oocyte activation test (MOAT) is a diagnostic test offered to patients experiencing failed or low fertilization following standard ICSI. In this test, mouse oocytes are injected with human sperm to reveal oocyte activation deficiencies in the sperm, whereafter assisted oocyte activation can be applied. Still, the MOAT is only applied by very few IVF laboratories, mainly due to the lack of mouse housing facilities. Vitrified mouse oocytes could provide a solution for this, but oocyte vitrification can affect parameters important in oocyte activation.

Study design, size, duration: Both fresh and vitrified-thawed mouse oocytes were micro-injected on the same day with human spermatozoa from a control with normal fertilization rates after routine ICSI. A total of 3 controls were used. Experiments were repeated 2 times per control sample. Two-cell formation (activation rate) was evaluated 24 hours after injections and compared to a negative (sham injection and medium control) and a positive (strontium chloride, $SrCl_2$) control group.

Participants/materials, setting, methods: MII mouse oocytes (B6D2F1, 7-12 weeks old) were vitrified within 3 hours after collection. Frozen-thawed human sperm from fertility proved donors was used for injections. After micro-injections, both fresh and vitrified-thawed mouse oocytes were cultured in KSOM-4%BSA medium until next day to evaluate activation rate. Control oocytes (fresh and vitrified) were either not injected, sham-injected (injection with media without sperm) or exposed to $SrCl_2$ (10 mM, 4 hours).

Main results and the role of chance: A total of 86 fresh and 62 vitrified-thawed mouse oocytes were injected with human sperm from 3 fertility proved controls. Survival rate after ICSI between fresh and vitrified-thawed oocytes was not significantly different, 80.2% (69/86) and 83.9% (52/62) respectively (p>0.5).

All fresh $SrCl_2$-exposed mouse oocytes underwent parthenogenetic activation successfully (23/23), whereas a similar amount vitrified-thawed counterparts were activated (13/15) (p>0.5). No activation was observed in both fresh (0/27) and vitrified-thawed (0/23) sham-injected control groups. None of the fresh medium control oocytes were activated (0/48), whereas only 3.4% of the vitrified-thawed medium control oocytes showed activation (1/29) (p>0.5). The same mean activation rate of 94.2% was observed between fresh (65/69) and vitrified-thawed (49/52) mouse oocytes micro-injected with control spermatozoa (p>0.5).

Limitations, reasons for caution: Until now, only the activation potential of control human sperm was tested after heterologous ICSI using vitrified mouse oocytes. However, vitrification can also affect the calcium pattern during oocyte activation, which requires additional calcium imaging and is currently ongoing.

Wider implications of the findings: Vitrified-thawed mouse oocytes can be efficiently used to perform a MOAT, as an alternative to fresh mouse oocytes. Most importantly, using commercially available vitrified mouse

oocytes, MOAT can be performed without the requirement of mouse housing facilities.

Trial registration number: not applicable.

P-085   Sperm separation by microfluidic sperm sorter (MFSS): Comparison of DNA fragmentation index and embryo quality with density gradient centrifugation

S. Ramakrishnan, S. Balasubramanyam, S. Amita, P. Kumar

Cloudnine Hospitals, Fertility Department, Chennai, India

Study question: Does Sperm separated using microfluidic sperm sorter (MFSS) have lesser DNA fragmentation index assessed by Sperm chromatin dispersion assay and result in better ICSI outcome in terms of embryo quality?

Summary answer: Sperm separation by MFSS is found to be equally efficient to density gradient centrifugation (DGC) in terms of DNA fragmentation index and embryo quality

What is known already: Conventional sperm separation techniques such as swim up and DGC involves one or more centrifugation steps. There is evidence in the literature on increased DNA damage in samples processed using percoll / density gradient methods, which is attributed to reactive oxygen species generation due to centrifugation process. High DNA fragmentation is implicated in poor outcome in ICSI cycles. MFSS is a polycarbonate device with two chambers into which unprocessed sperm sample is loaded and actively motile sperm are separated by laminar effect after thirty minutes of incubation. Some earlier studies have reported high sperm sorting efficiency using this device.

Study design, size, duration: This prospective sibling oocyte study involved nineteen patients, who were undergoing IVF/ICSI cycles between September 2016 to December 2016 and were also found to have high sperm DNA fragmentation index (DFI) on initial semen analysis

Participants/materials, setting, methods: On the day of ovum pick up, oocytes collected for each patient, involved in the study were equally divided and injected with sperm separated by DGC and MFSS. Total number of oocytes injected in DGC and MFSS groups were 110 and 121 respectively. Sperm DNA fragmentation was assessed in pre-wash and post processed samples using sperm chromatin dispersion test. Fertilization rate and embryo quality on Day 3 were recorded

Main results and the role of chance: DFI on initial semen analysis in these 19 patients was 36 +/- 12.19. On the day of ovum pickup (OPU), the DFI was found to be 37.63+/-12.41. Patients had variable days of antioxidant therapy and repeated ejaculation between the initial semen analysis and the day of ICSI. DFI in density gradient separated sperm on the day of OPU was 15.61+/-11.66 and in MFSS was 9.73 +/- 8.21. Fertilization rates (76% vs 79%) were similar in density gradient (84/110) and MFSS (94/121). Embryo quality on day 3 was also found to be similar (66/84 grade 1 embryos in density gradient group vs 75/94 in MFSS group). Statistical analysis of difference in DFI between two separation techniques by Mann Whitney U test was found to be non significant.

Limitations, reasons for caution: Poor responders and elderly women in whom benefits of using sperm with good DNA integrity might have been more evident were not included in the study. Another potential limitation was, patients with severe oligo astheno teratozoospermia were also not included as MFSS did not yield enough sperm for injection.

Wider implications of the findings: Results obtained provides evidence towards a positive trend in separation of sperm with better DNA quality post MFSS clinically, though not statistically significant. Extrapolation to pregnancy rates, miscarriage rates, live birth rates and involvement of larger number of patients might yield conclusive information on the advantage of this technique.

Trial registration number: not applicable.

P-086   microRNA-155-5p levels in serum and seminal plasma as a biomarker of male reproductive function

G. Malm[1], C. Tsatsanis[1,2], A. Giwercman[1], D. Trzybulska[1]

[1]*Molecular Reproductive Research, Department of Translational Medicine, Lund University*
[2]*Department of Clinical Chemistry, School of Medicine, University of Crete*

Study question: Do levels of microRNA-155-5p (miR-155-5p) differ between serum and seminal plasma and are they associated with reproductive hormone levels and semen parameters?

Summary answer: miR-155-5p expression was higher in seminal plasma compared to serum. Seminal concentration of miR-155-5p correlated to sperm concentration, FSH, inhibin B and free testosterone.

What is known already: miRNAs are a class of small non-coding RNAs which regulate, mainly at the post-transcriptional level, expression of two-thirds of human genes implicated in a multitude of biological processes. Since different miRNAs are regulated by reproductive hormones and interact with genes controlling spermatogenesis, their potential as functional biomarkers is of great interest. miRNAs are found intracellularly, in the serum and in other biological fluids where they function as paracrine or endocrine messengers. Detection of miRNAs in serum and seminal plasma may serve as biomarkers of male fertility. Earlier studies from our group have associated serum levels of miR-155-5p with male subfertility.

Study design, size, duration: As a part of a study on seasonal variation in male reproductive parameters, 221 Norwegian men from the general population, aged 19-40 years, were enrolled in 2001-2002.

Participants/materials, setting, methods: Semen parameters (total sperm number, concentration, motility, volume, morphology and DNA fragmentation index (DFI)) and reproductive hormones were analyzed. miR-155-5p was determined in seminal plasma (n = 153) and serum samples (n = 199) by quantitative real-time PCR (qPCR) and analyzed for correlation with reproductive parameters.

Main results and the role of chance: qPCR analysis revealed that miR-155-5p had significantly higher expression in seminal plasma in comparison with serum (n = 150 pairs, p < 0.001). We observed weak but significant correlations between miR-155-5p levels and sperm concentration (rS=0.165, p = 0.043), DFI (rS=0.172, p = 0.038), FSH (rS=-0.167, p = 0.042), inhibin B (rS=0.191, p = 0.019), and free testosterone (rS=-0.159, p = 0.051). No statistically significant correlation was observed between miR-155-5p levels in serum and seminal plasma which might suggest that other biological processes underlying medical conditions affect expression of this miRNA in serum and disrupt correlations found for hormones at semen level.

Limitations, reasons for caution: The results cannot be generalized to other miRNAs. Lack of information about miR-155-5p levels at tissue/cell level in this group.

Wider implications of the findings: Correlations found between miR-155-5p and selected semen parameters as well as reproductive hormones suggest that its levels in seminal plasma might reflect spermatogenesis related processes with higher probability than miR-155-5p measured in serum.

Trial registration number: Not applicable.

P-087   Improving pregnancy rate in IVF cycles by preparing sperm via microfluidic sperm chips

O. Alagoz, G. Ozkara, M.G. Kocer Yazıcı, C. Ficicioglu

Yeditepe University Hospital, IVF, Istanbul, Turkey

Study question: Do microfluidic sperm chips increase pregnancy, implantation, fertilization rates in IVF cycles comparing to conventional gradient centrifugation (Percoll) method?

Summary answer: As one of the novel sperm preparation technologies, microfluidic sperm chips increase pregnancy rate in IVF cycles comparing to conventional gradient centrifugation method.

What is known already: Effect of microfluidic sperm chips to sperm motility and DNA integrity improvement is already known by some studies. Although, microfluidic technologies were introduced in ART field at the beginning of 21st century and are being advanced from day to day by several days, there is still no prevailing utilization in laboratories and theare are few studies presenting their effect on ART outcomes.

Study design, size, duration: This is a retrospective, randomized study evaluating the data of 185 patients between December 2014 and January 2017. Patients were grouped according to sperm preparation technique (Chip or Percoll), each group incluided 88 and 97 patients respectively. Patients were further grouped by the number of their previous cycles. Previous cycles were

divieded to 3 groups: 0-1, 2-3, 4 and more. Chip effect was compared in each group in terms of fertilization, pregnancy and implantation rates.

Participants/materials, setting, methods: Sperm was applied into chips according to manufacturers' instructions. %90 density gradient was used in percoll method. Fertilization rate was defined as percentage of 2PN oocytes per total injected MII oocytes. Implantation rate was defined as percentage of 2PN oocytes per total injected MII oocytes. Chi-square test was performed for method/ pregnancy comparitions. Statistically significant results were further analyzed by regression analysis. Mann-Whitney U test was performed to assess fertilization and implantation rates in groups.

Main results and the role of chance: Retrived oocyte number, sperm motility %, previous cycle number were similar between chip and percoll group (p>0,05 with Kolmogorov-Smirnov test) (retrived oocyte number 7,8 ± 3,8-7,6 ± 3,6, sperm motility % 50,1 ± 16,4-51,0 ± 17,2, pervious cycle number 2,1 ± 2,3-1,4 ± 1,9)

Statistically significant result was obtained between chip and percoll group in terms of pregnancy rate (p: 0,03). 1,97 fold increase was found to improve pregnancy rate with chip utilization as sperm preparation method in all patient group. Fertilization and implantation rates were not found statistically significant between two groups (p: 0,06 and p: 0,65) (fertization rate 85,6 ± 15,6 and 84,1 ± 15,8; implantation rate 31,7 ± 42,1 and 21,5 ± 38,3 respectively).

If previous cycle number is 0-1 chip utilization has no effect on pregnancy, fertilization and implantation rates (p: 0,25 p: 0,49, p:0,40). Similar results were obtained for the patient group if previous cycle number is 4 or more (pregnancy p:0,65, fertilization p: 0,81, implantation p: 0,51).

If previous cycle number is 2-3 chip utilization improve pregnancy and implantation rate (p: 0,01, p: 0,02), however has no effect on fertilization rate (p: 0,48). 4,8 fold increase was found to improve pregnancy rate with chip utilization as sperm preparation method in patient group if previous cycle number is 2-3).

Limitations, reasons for caution: Statistically significant difference (p:0,029) at female patients'ages was observed between chip and percoll groups(34,2 ± 4,3 and 32,1 ± 4,7 respectively).Sperm count and morphology was also found statistically different (p:0,019) between groups (39,9 ± 33,1 and 53,1 ± 42,4; 1,4 ± 1,1 and 1,7 ± 1,1 respectively).Statistic tests might be repeated with more patients grouped by similar ages and sperm count.

Wider implications of the findings: Embryo quality was not evaluated in this study. Results might be extended by incluiding embryo quality results.

Trial registration number: not applicable.

P-088 Factors influencing the variability in the morphological assessment of human sperm during external quality control (EQC)

S. Daoud[1], Z. Rebei[1], N. Chakroun-Feki[1], A. Sellami[1], S. Jellad[2], K. Chaabene[3], L. Ammar-Keskes[1], T. Rebai[1]

[1]Medical School of Sfax, Histology-Embryology Laboratory and Research Unit, Sfax, Tunisia
[2]Military Hospital, Laboratory of reproductive biology- Department of sterility exploration and PMA, Tunis, Tunisia
[3]Hedi Chaker academic Hospital, Gynaecology and Obstetrics Department, Sfax, Tunisia

Study question: What are the sources of variability between laboratories in the assessment of sperm morphology?

Summary answer: Our results confirm the wide variability in the assessment of sperm morphology. The level of experience has an impact on the extent of the variability.

What is known already: Sperm morphology has been shown to have a high predictive value for the outcome of assisted reproductive technologies. However, it is known that the highest variability during external quality control programs is found for sperm morphology assessment.

Study design, size, duration: An external quality control for sperm morphology assessment was conducted in 7 laboratories performing semen analysis in Sfax region (Tunisia). A survey requesting information about experience and methods used to undertake semen analysis was concomitantly distributed.

Participants/materials, setting, methods: Each laboratory received two stained slides (Shorr staining) prepared from two semen samples and was asked to assess sperm morphological abnormalities in the same way *as routine* examination is done.

Main results and the role of chance: All laboratories assessed sperm morphology according to David's criteria. The average inter-laboratory coefficient of variation (CV) was 33 % for normal forms (NF) and 15.5 % for Multiple Abnormalities Index (MAI). The variability was lower in experienced laboratories for NF compared with unexperienced laboratories. The lowest CV were observed for the percentage of post acrosomal abnormalities and bent midpieces (38 % each), of coiled tails (44 %) and of post acrosomal abnormalities (46 %). The highest CV were found for head size abnormalities: thin (176 %) and tapered (160 %).

Limitations, reasons for caution: Other sources of variability in the assessment of sperm morphology, such as different systems of classification and various staining methods, should be considered in future EQC programmes.

Wider implications of the findings: The need for adequate initial and continuing training of the laboratory staff is crutial. The compliance with the guidelines and the use of micrometer eyepiece could be of a great help to minimize the *variation* within and *between laboratories*.

Trial registration number: No trial registration number.

P-089 DMC1 is an encouraging biomarker for non-obstructive azoospermia patients

S. Aktuna[1], E. Unsal[1], L. Ozer[2], G. Kolsal[1], S. Polat[3], A. Baltaci[4], T. Duman[5], C. Hurdag[6], K. Aydos[7], V. Baltaci[2]

[1]Mİkrogen Genetic Diagnosis Laboratory, Molecular Genetic, ankara, Turkey
[2]Mikrogen Genetic Diagnosis Laboratory, Genetic, ankara, Turkey
[3]Genart IVF Center, Andrology, ankara, Turkey
[4]Genart IVF Center, Gynecology, ankara, Turkey
[5]Ankara University, Biology, ankara, Turkey
[6]Istanbul Bilim University, Histology and Embryology, Istanbul, Turkey
[7]Ankara University, Medicine, ankara, Turkey

Study question: To establish a meiotic biomarker for non-obstructive azoospermia patients enabling us to interprete spermatogenesis status of patient.

Summary answer: DMC1 expression, a protein with a key role in meiotic recombination, shows significant correlation with positive testicular sperm extraction (TESE) outcome.

What is known already: Male-related factors are involved in more than half of infertility cases. Among these patient group 10 % of cases are diagnosed as non-obstructive azoospermia (NOA). Diagnostics tests available for these patient group is limited and standard semen analysis frequently used for male fertility would not provide much infromation for patients. Proteins involed in meiotic recombination may be good candidates for this patient group. PCNA was used for this purpose in a previous study. Another study suggested that interaction between Lim15/Dmc1 and PCNA mediates the recombination-associated DNA synthesis during meiosis which makes Dmc1 a good candidate as a biomarker.

Study design, size, duration: The study took place in Genart IVF center between the years of 2013-2017. 300 NOA patients and 10 sperm positive controls were included in the study. Following testicular sperm extraction patients with negative sperm outcome were involved in patients group and patients with positive sperm outcome were enrolled in control group.

Participants/materials, setting, methods: Testicular sperm extraction tissue of NOA patients was used in the study. RNA was extracted using Zymo-Spin RNA extraction kit. Following RNA extraciton cDNA was prepared using New England Biolabs ProtoScript II First Strand cDNA Synthesis Kit. Real Time PCR was performed using Roche Light Cycler 480 with target probes (PCNA, DMC1) and reference probe (Actin) provided by Roche. Immunohistochemical staining was also performed to compare expression of Pcna and Dmc1 in TESE samples.

Main results and the role of chance: Relative expression of DMC1 and PCNA was calculated relative to reference gene(Actin).Relative expression

DMC1 gene was significantly higher in control group of 10 samples where positive testicular sperm extraction was observed compared to patients. PCNA (expressed in spermatogonial cells) was used as an additional control. Following reevaluation of control group with seperate real time PCR, similar expression results were achieved.

DMC1 and PCNA expression was also evaluated using immunohistochemical staining with testicular sperm extraction tissue. Results also supported presence of DMC1 and PCNA in both sperm positive and sperm negative patients. Higher Dmc1 expression was observed in sperm positive samples. Expression results can be misleading in samples If Testicular sperm extraction tissue is contaminated with fibrotic tissues which would elevate PCNA expression.

Limitations, reasons for caution: Obtaining good quality RNA from TESE material is crucial to avoid failure in evaluating expression since additional TESE material from patients is not available in most cases.

Wider implications of the findings: These results suggested existence of meiosis and potential of spermatogenesis in NOA patients with negative sperm outcome. Instead of repeated TESE trials elective TESE will be possible with the information about spermatogenic activity. Thus TESE planning will be possible for patients who went through treatment to provide spermatogenesis.

Trial registration number: NA.

P-090   Sperm DNA fragmentation and its role in Assisted Reproductive Technologies: analysis of 1056 cycles

M. Di Santo[1], N. Tarozzi[1], M. Nadalini[1], F. Pennetta[1], A. Borini[2]

[1]9.baby Family and Fertility Center, Reproductive Medicine IVF Laboratory Unit, Bologna, Italy
[2]9.baby Family and Fertility Center, Reproductive Medicine IVF Clinical Unit, Bologna, Italy

Study question: Is there a prognostic value of sperm DNA fragmentation (SDF) test on in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) reproductive outcome?

Summary answer: According to our data on 1056 cases, it can be stated that high SDF levels negatively affect both IVF and ICSI reproductive outcome.

What is known already: To date the link between SDF, male infertility and ART outcome has been extensively investigated by many authors. However, in 2015 the Practice Committee of American Society for Reproductive Medicine (ASRM) reported that data published regarding the relationship between SDF and ART outcome are not sufficient to routinely propose the use of SDF test. Moreover, once recognized a high SDF level, are we able to choose the 'healthy" spermatozoa among the entirely population?

Study design, size, duration: Retrospective observational study carried out between January 2004 and December 2015, on 1056 men undergoing to ART cycles in our Fertility Center. Total treatments included, as follow: IVF (N = 265), ICSI (N = 680) and intracytoplasmic morphologically selected sperm injection (IMSI) (N = 111). According to SDF levels, patients were divided into groups and compared taking into consideration the ART outcome of each treatment.

Participants/materials, setting, methods: DNA fragmentation was evaluated by terminal deoxynucleotidyltransferase-mediated fluorescein-dUTP nick end labelling (TUNEL) assay, performed on sperm suspensions after density gradient separation, in 1056 men undergoing to ART cycles within three months from SDF test. The threshold value chosen to differentiate between high and low SDF levels was 10%. The chi-square test was used to compare the ART cycles in terms of main outcome measures. Statistical differences were considered significant at $p < 0.05$ and $p < 0.01$.

Main results and the role of chance: 1)Considering IVF treatments, we observed that the sperm DNA damage exclusively affects the fertilization rate (FR). Our data reported that sperm samples with low SDF (N = 245) displayed a significant higher fertilization rate compared to samples with high SDF levels (N = 20), (69% vs 51%, $p < 0.01$).

2)Taking into account ICSI treatments we obtained a significant higher FR, implantation (IR) and pregnancy (PR) rate in patients with low SDF levels (N = 452) compared to patients with high SDF levels (N = 228); (FR: 77, 6% vs 71, 4%, $p < 0.01$; IR: 14% vs 7,7%, $p < 0,01$; PR: 24, 7% vs 14, 8%, $p<0,01$).

3)Finally, we wondered if the application of IMSI technique, in case of increased SDF, might be more helpful rather than ICSI procedure, in term of ART outcome. Results showed a significantly higher IR and lower pregnancy loss rate (PL) in IMSI treatments with high SDF levels (N = 81) compared to ICSI treatments with high SDF levels (N = 228); (IR: 13, 1% vs 7, 7%, $p < 0.05$; PL: 1, 5% vs 13, 8%, $p < 0.01$).

Limitations, reasons for caution: The study is referred to patients attending our Fertility Center. In many years we performed the TUNEL assay as method for detecting SDF. Nevertheless, this methodology is one of many available in laboratories worldwide. Therefore, our data do not lead to unquestionable results and can not be generally applied

Wider implications of the findings: The worthy aspect of our study is the considerable number of patients analyzed, in comparison to the number in other studies published. We mainly aimed to highlight the SDF role on ART outcome, further to suggest the possibility to perform IMSI as alternative approach in case of high SDF levels.

Trial registration number: none.

P-091   Effect of Seminal ORP Value on Embryo Quality and Clinical Pregnancy Rate

A. Ayaz[1], B. Balaban[2], S. Sikka[1], A. Isiklar[2], M. Tasdemir[2], B. Urman[2]

[1]Tulane University, Department of Urology, New Orleans, U.S.A.
[2]VKF American Hospital, Assisted Reproduction Unit, Istanbul, Turkey

Study question: Whether ORP in semen of men undergoing ART affects embryo quality during IVF and plays any role in predictive value for clinical pregnancy.

Summary answer: Semen ORP measurement can be used as an indicator of oxidative stress and help determine the successful embryo development during IVF.

What is known already: Excessive amount of oxidative stress can attack biological molecules such as membrane lipids, DNA and proteins affecting sperm function. Morphological abnormalities and poor motility are associated with unsuccessful ART affecting clinical pregnancy and live-birth rate. Although ORP can measure such oxidative stress, it is not known if it plays a role as determinant of successful clinical pregnancy.

Study design, size, duration: This prospective study was carried out in the VKF American Hospital, Assisted Reproduction Unit, Istanbul, Turkey. The study was approved by Koc University the institutional review board and patients signed a consent prior to participation. The 154 male patients who were visiting Andrology laboratory (between May 31st, 2016 and Jan 1st, 2017) were grouped in according to semen ORP values. IVF was performed using the semen samples by our routine established protocol.

Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of STD or chronic disease, use of any prescription drug or OTC medications or antioxidants. Semen samples were collected and assessed for routine parameters using the WHO-2010 guidelines. sORP was measured (mV) using the MiOXSYS system and normalized to concentration (mV/10^6 sperm/mL). Embryo was graded based on the quality (Grade 1 for best quality and Grade 5 is poor).

Main results and the role of chance: All semen samples were grouped as 'High ORP" and 'Low ORP" based upon seminal ORP cut-off value of 1.36 mV/10^6 sperm. Mean Grade 1 embryo quality in High ORP group (n = 81) and low ORP group (n = 26) was 2.88 ± 1.76 and 1.33 ± 0.47 respectively. In addition, Mean Grade 2 embryo in High ORP group was 2.47 ± 1.54 and in low group was 4 ± 1.63 accordingly. Clinical pregnancy rate (Mean 0.48; 19/40) was significantly higher ($p = 0.006$) in low ORP group compared to high ORP group (1/8) however there was no significant difference in embryo quality in both high and low ORP groups (Grade 1 embryo $p = 0.67$, Grade II G2 embryo $p = 0.33$). Also, mean mother age in two groups was not significantly different (low ORP = 37.2 years and high ORP = 35.2 years; $p = 0.23$). These

data suggest that ORP may play an important role in determining the success of clinical pregnancy irrespective of oocyte quality in women >35 yrs. of age.

Limitations, reasons for caution: The sample size was relatively small. Also, ORP is still an investigative tool and further multicenter clinical trials are needed before its establishment as a diagnostic tool in clinical practice.

Wider implications of the findings: These findings may have important diagnostic and prognostic implications for couples experiencing male infertility and undergoing assisted reproductive technique (ART). Further studies are warranted to explore the mechanism of increased ORP in a subset of couples (male factor, no female factor) undergoing ART to corroborate the significance of these findings

Trial registration number: Not applicable.

P-092   Incidence of symptoms associated with testosterone deficiency after TESE: a systematic review

J. Eliveld, M. Van Wely, A. Meißner, F. Van der Veen, S. Repping, A. M.M. Van Pelt

Academic Medical Center- University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands

Study question: Does TESE induce symptoms associated with testosterone deficiency?

Summary answer: Although there is a trend towards decreased testosterone after TESE, there is virtually no data on symptoms related to testosterone deficiency after TESE.

What is known already: Surgical testicular sperm extraction (TESE) is used as a technique to assist azoospermic men to become fathers. Studies on hypogonadism after TESE are limited and show contradictory results. To clarify this issue, we performed a systematic review on the symptoms of hypogonadism being, among other things, sexual dysfunction, decreased testis size, increased fat mass, loss of muscle mass and strength and depression.

Study design, size, duration: In this systematic review we used the databases Pubmed and Embase to search from inception to 12 December 2016. For the search, we combined subject headings with terms in title and/or abstract related to intervention, outcomes and participants and used no restrictions for study types.

Participants/materials, setting, methods: We included all peer-reviewed studies which measured clinical symptoms related to testosterone deficiency before and after any TESE technique in azoospermic men. The measurement before TESE was used as a control. For the analyses we used Review Manager 5.3 software.

Main results and the role of chance: With our search we identified 1525 citations. After independent screening by two individuals, we found 12 studies reporting on potential hypogonadism upon TESE of which 5 studies could be included for data extraction on symptoms of hypogonadism. Cohorts in these studies varied between 26 and 120 participants. Only one study reported on the incidence of erectile dysfunction 6 months after TESE and found that 13 out of 66 men (20%) developed new-onset erectile dysfunction. In these men a decrease of 17.4 nmol/L in testosterone was seen. Four other studies reported on potentially decreased testicular size. In three of these studies no or only a small decrease(<2 ml) was seen in testis size after TESE. One study reported a decrease in testicular size of >2 ml in 12 out of 120 men (10%) with a decrease in testosterone in only two men. No studies reported on any other testosterone deficiency related symptoms such as decreased libido, increased fat mass, and decreased muscle mass and strength. Analyzing all studies reporting on potential hypogonadism, we see an overall decrease in testosterone levels in NOA and OA patients of 3.3 nmol/L six months after TESE, which starts to recover nine months after TESE.

Limitations, reasons for caution: Included studies are very heterogeneous in TESE techniques used (multiple biopsies versus microdissection).

Wider implications of the findings: Although TESE temporarily affects hormone levels in azoospermic patients, limited data is available on whether it leads to a higher incidence of symptoms related to testosterone deficiency. More

large-scale monitoring needs to be performed to be able to assess these risks accurately. Only then patients can be counselled appropriately.

Trial registration number: not applicable.

P-093   Inflammasome complex gene expression and its relationship with infertility of male rats after spinal cord injury

M. Bazrafkan[1], B. Nikmehr[2], G. Hassanzadeh[2], A. Shahverdi[3], M. Marzban[4], S. Kiani[5], H. Choobineh[6]

[6]*Tehran university of medical sciences-School of Allied Medical Sciences, Zoonosis Research Center, tehran, Iran*

Study question: Evaluation of Inflammasome genes expression and their activity pattern in testis of spinal cord injury (SCI) rat models.

Summary answer: Testis is one of the sources of inflammasome genes which induces pyroptosis and resulted in reduction of sperm concentration and motility in SCI model.

What is known already: Many young men with spinal cord injury (SCI) suffer from infertility. Previous studies showed the low sperm concentration, motility and abnormal morphology in SCI infertile men. Some researchers suggested immunologic reasons for diminished sperm quality in SCI patients. They identified some inflammasome complex productions such as caspase-1 in sperm of these patients, but the class of upstream genes and the time of starting activity in this complex was not determined clearly.

Study design, size, duration: Mature male rats were used in this study. The rats were divided into four groups (n = 4): three surgery groups that SCI at level of T10 performed on them and one intact group as control. We scarified group one, a day after SCI surgery, group two, 3 days after and group 3 a week after surgery. Testes were collected. The most known inflammasome upstream genes expression includes NLRP1a, NLRP3, NLRC4, and AIM2 were assessed.

Participants/materials, setting, methods: Mature male wistar rats with 250-300 gr. body weight were used. The above- mentioned genes were examined by qrt-PCR. The data analyzed by The Kruskal-Wallis Test and Games Howel post hoc test to find the difference between various time points.

Main results and the role of chance: According to the statistical analysis test the gene expression level in NLRP3 (χ^2= 11.373,df=3, P-Value .010) and AIM2 (χ^2= 9.201,df=3, P-Value.027) showed significant difference (p < 0.05). No significant difference was detected in NLRP1a and NLRC4 genes expression between the test and control groups in any time points. In group 3 the expression of NLRP3 was significantly different in compare to control group (MD= -2.80, P =0.04) also in group one, the expression of AIM2 (MD= 1.73, P = 0.025) was significantly up regulated in contrast to control group. For the first time we find that expression of NLRP3 as the most known upstream gene of inflammasome complex up-regulates one week after SCI in the testis of rat model. Also we find that expression of AIM2 as another gene of infalmmasome complex up-regulates a day after injury. These up-regulations indicate initiation of inflammasome complex activity. The Inflammasome complex activity can induce pyroptosis (a model of Programmed cell death after formation of inflammasome complex). We suggest that pyroptosis can be the cause of low sperm motility and count in SCI rat models.

Limitations, reasons for caution: The main limitations of this study could be the low number of rats. Also, based on the ethical considerations in this study we only examined the effects of SCI in rat model but not in human.

Wider implications of the findings: Knowing the exact genes of inflammasome complex that express in testis after SCI and the exact time of

inflammasome up-regulation can be helpful for administration of anti inflamma-some drugs in exact time to suppress inflammasome complex formation, excessive pyroptosis and also improve sperm count and motility.

Trial registration number: it is basic science.

P-094   ICSI cycles with cryopreserved or fresh testicular sperm in patients with obstructive (OA) and non-obstructive (NOA) azoospermia: are there differences in outcome?

B. Mencaroni[1], D. Amadori[2], B. Scarselli[3], G.M. Colpi[4]

[1]Futura Diagnostica Medica P.M.A., IVF Laboratory, Firenze, Italy
[2]Futura Diagnostica Medica Pma, IVF Laboratory, Firenze, Italy
[3]Futura Diagnostica Medica Pma, Laboratory Director, Firenze, Italy
[4]Ises, Andrological Surgeon, Milano, Italy

Study question: Are there different outcomes between ICSI cycle using cryopreserved or fresh testicular sperm in patients with obstructive (OA) and non-obstructive (NOA) azoospermia?

Summary answer: Live birth, clinical pregnancy, clivage rate: No statistical differences. NOA significantly affects fertilization. Statistical increment in embryo top quality in NOA patients in frozen group.

What is known already: It was proved that cryopreserved testicular spermatozoa in patients with obstructive azoospermia (OA) and non obstructive azoospermia (NOA) maintains adequate characteristics of vitality and reaches excellent fertilization rate (Prins GS, 1999) as well as good pregnancy rate (KUPKER W, 2000)

on the other hand, the use of fresh sperm from tese has resulted in a large number of pregnancy in OA and NOA patients (Vloberghs et al, 2015). The use of fresh or testicular sperms are however still, much discussed (Verheyen G, 1997; Aoki et al, 2004; Mohamed K.M, 2008; Karacan et al, 2013; Ohlander et al, 2014).

Study design, size, duration: Retrospective analysis of 119 ICSI cycles between 2012-2016 in futura P.M.A.

GROUP 1: 31 fresh testicular sample (12 OA; 19 NOA)

GROUP2: 88 frozen-thawed testicular sample (47 OA; 41 NOA)

Inclusion criteria: Normal karyotype, patients undergoing testicular biopsy for OA and NOA, male age <45, female age <38, AMH>1,5 ng/ml

Exclusion criteria: Female age >38, poor ovarian reserve, male age >45

Main outcome: Fertilization rate, embryo quality, clivage rate, pregnancy rate, live birth rate.

Participants/materials, setting, methods: Groups were matched for fresh or frozen testicular sperm sample and for the presence of OA/NOA patients distinguished by histological classification.

Testicular biopsies were retrieved for freezing and later used or for fresh use at the day of pick-up.

Surgery/crioconservation was in-house or transferred from other centers.

Fertilization and embryo development were checked and best quality embryos were transferred.

For statistical analysis: Student's t-distribution, Mann–Whitney U test, analysis of covariance and logistic regression.

Main results and the role of chance: It is not a significant difference between fresh or frozen sperm sample in the clinical pregnancy rate ($P=0,7442$ in OA fresh vs OA frozen; $P=1,000$ in NOA fresh vs NOA frozen), in live birth rate ($P=0.227$ OA fresh vs OA frozen; $P=1.029$ in NOA fresh vs NOA frozen) but in 8 patients the pregnancys are in progress. The clivage rate doesn't change ($P=1$ NOA fresh vs NOA frozen and $P=0.2330$ in OA fresh vs OA frozen).

We find a significant difference in fertilization rate in cryopreserved group: the OA frozen group has an increment respect to the NOA frozen group ($P<0,001$). So the use of sperm from men with NOA significantly affects fertilization (Nicopoullos et al, 2004).

We find a different fertilization rate in OA fresh respect to OA frozen ($P=0.231$).

For the quality of embryos (gardner classification) we find a statistical increment in top quality embryo in NOA frozen group vs NOA fresh group ($P=0,0347$)

Data could be related to a known cryo damage to chromatin but in our study it didn't interfere with embryo quality considering that also tese sperm has less fragmentation respect to ejaculated (Esteves SC, 2015) and there isn't the problem of synchronization ovarian stimulation and biopsy surgery.

Limitations, reasons for caution: This work is a retrospective analysis so some informations are incomplete.

Wider implications of the findings: No differences were found in ICSI outcomes between cryopreserved and fresh testicular sperm.

The problem of synchronization ovarian stimulation and biopsy surgery may be resolved using the cryopreserved sample retrieved inside or transferred from other centers.

Another advantage is reducing the risk of failure spermatozooario recovery (Vehement et al, 2004).

Trial registration number: None.

Study question: Is seminal elastase more reliable than histological determination of hyperleucocytose to detect oxidative-DNA damage? Is it related with modifications of seminal environment?

Summary answer: Dosage of seminal elastase is more sensitive than histological determination of leucocytes for the detection of oxidative DNA damage of spermatozoa.

What is known already: Leucocytospermia is considered as a major factor to male infertility (decreased sperm motility and normal morphology).

For elastase, a protease secreted by activated polynuclear, the following correlations have been reported:—Positive with the number of leucocytes (but discussed),—Negative with the percentage of motile sperm or with intact DNA (which can explain a poorer blastocyst development rate and a higher number of arrested embryos),—Negative with seminal plasma volume and its citrate content.

There are few studies about the oxidative-dependent damage of DNA spermatozoa in relation with leucocytospermia. According to a recent work, DNA oxydative damage was not associated to leucocytes.

Study design, size, duration: In this retrospective study, elastase concentration ($n = 2037$) was assessed in 1714 men attending the Cochin hospital center for fertility problems between 2012 and 2015. The correlation of either elastase or leucocytospermia with peroxidase-stained leucocytes, sperm parameters ($n = 1921$), bacteriology ($n = 713$), seminal biochemistry ($n = 263$), oxidative DNA damage ($n = 167$) results were investigated.

Participants/materials, setting, methods: Sperm parameters were evaluated according WHO standard procedures. Semen leucocyte concentration was determined by peroxidase-stained leucocytes. This test was realized when round cells with $2n$ content, determined by flow cytometer with propidium iodide, was superior to $1.10^6/mL$. Elastase-inhibitor complex was assessed by immunoassay in seminal plasma. Biochemical seminal markers (zinc, acid phosphatase, citrate, fructose, α-glucosidase and carnitine) were assessed by spectrophotometry. DNA-base adducts formation was determined using flow cytometer by OxyDNA test.

Main results and the role of chance: Major significant correlations between polynuclear elastase and semen characteristics have been observed.

Levels of seminal elastase are:

1° positively correlated with peroxidase-stained leucocytes ($p = 1.9 \times 10^{-101}$), negatively correlated with sperm motility ($p = 3 \times 10^{-4}$).

2° positively correlated with 8OHdG ($p = 9 \times 10^{-4}$) in contrast to semen leucocytospermia determined by peroxidase-stained leucocytes.

3° negatively correlated with volume ($p = 1.10^{-3}$), markers of prostate secretion (citrate $p = 4.6 \times 10^{-5}$, zinc $p = 10^{-3}$ and acid phosphatase $p = 4.6 \times 10^{-6}$) and positively with pH ($p = 1.2 \times 10^{-14}$).

A cut-off of 377 ng/mL (ROC curve) allowed to predict leucocytospermia with a sensitivity of 92 % and a specificity of 81%.

The 90^e percentile in the population with « normal sperm parameters » ($n = 292$), according to the WHO criteria, was 730 ng/mL.

Among the 157 positive bacteriology, only 15,3% had an elastase concentration superior to 377 ng/mL: inflammation and infection are dissociated.

Limitations, reasons for caution: The lifestyle (BMI, tabac, antecedent of uro-genital infection), fertility background, ART outcome of this patients supported by our ART center were not taken into account.

Wider implications of the findings: Patients with increased seminal elastase concentration display reduction of sperm motility, high numbers of oxidized spermatozoa (perhaps due to a loss of the nucleus condensation related to a decreased prostatic zinc secretion?) which might have an impact on techniques of in-vitro fertilization and embryo development.

Trial registration number: Not applicable.

P-096   Relationship between urokinase plasminogen activator (uPA) concentration in seminal plasma and outcome of assisted reproduction treatments

J.C. Martinez-Soto[1], J. Gadea[2], M. Mollá[3], L. Fernandez[4], M. Nicolas[4], M. Trabalon[5], J. Landeras[4]

[1]IVI Murcia, Andrology, Murcia, Spain
[2]University of Murcia, Physiology, Murcia, Spain
[3]IVI Murcia, In vitro fertilization, Murcia, Spain
[4]IVI Murcia, Reproductive Medicine, Murcia, Spain
[5]IVI Murcia, Reproductive Medicine, Murcia, Slovenia

Study question: Are the concentration of urokinase plasminogen activator (uPA) in seminal plasma related to the outcomes in ART?

Summary answer: Higher values for uPa in seminal plasma were detected in the cases with pregnancy after IUI and IVF-ICSI ($p = 0.04$), than in failure of pregnancy

What is known already: The plasminogen/plasmin system functions as one of the most important extracellular protease systems in vivo.

Plasminogen-plasmin system has been related to different process of the male reproductive function, as spermatogenesis, sperm capacitation, and fertilization. Some authors have previously detected the presence of plasminogen activators as tPA and uPA in human seminal plasma as well as inhibitors of the plasminogen-plasmin system. uPA activity was correlated significantly with sperm parameters (count, motility and morphology) and fertility.However, the specific role and importance of uPA for the male reproductive function is not well known.

Study design, size, duration: This research was desing as a Case control study and it was carried out in collaboration with department of Physiology of Murcia, University of Murcia. Spain.

55 semen samples were analized in Instituto Valenciano de Infertilidad of Murcia during the period 2013-2014.

Participants/materials, setting, methods: Total uPA in seminal plasma were measured by ELISA test in 55 seminal samples (3o IUI+ 25 IVF/ICSI cases)). Aliquots were centrifuged at 300 g for 10 minutes and seminal plasma and spermatozoa were stored at -80°C until uPA evaluation.

Levels of uPA were correlationed with ART results by Pearson test. Receiver Operating Chacarcteristic curves (ROC) were used to evaluate predictive value of uPA in outcomes of ART

Main results and the role of chance: *IUI treatment.* IUI was used in 30 cases resulting, 20% ongoing pregnancy rate. We detected higher values for total uPA in seminal plasma (26.66 ± 1.61 vs. 20.29 ± 1.47 ng/ mL, $p = 0.04$,) in the cases with pregnancy than in the cases when pregnancy was not detected. Receiver Operating Characteristic (ROC) curves analysis to evaluate the predictive value of the fertility (pregnancy) of the total uPA in seminal plasma. We found area under the curve was 0.74 ± 0.10, $p < 0.05$ and the cut off value for predicting pregnancy of 26 ng/ml. the sensitivity was 67% and specificity was 78%.

ICSI Treatment. IVF-ICSI treatment was applied in 25 cases with 56%% pregnancy rate. When we studied the uPA concentration in cases with pregnancy vs. no pregnancy we found a higher difference 22.45 ± 0.82 vs 19.32 ± 1.40, $p = 0.04$) in total uPA concentration in seminal plasma in pregnancy group. ROC curves analysis to evaluate the predictive value of the fertility (pregnancy) of the uPA concentration in seminal plasma, area under the curve was 0.81 ± 0.09, $p < 0.05$ and the cut off value of 21,6 ng/ml. Sensitivity was 90% and specificity was 73%.

Limitations, reasons for caution: In next researches we should increased number of patients.

Wider implications of the findings: In this research we have founded total uPA in seminal plasma were higher in ART cycles with pregnancy versus non pregnancy. Total uPA could be a seminal biomarket in ART treatment in especially in ICSI treatment.

Trial registration number: Don't apply.

P-097   The impact of cigarette smoking on sperm nuclear protein and DNA integrity

H. Amor[1,2], N. Shelko[1], A. Zeyad[1], M. Hamad[1], H. Ben Ali[2], M.E. Hammadeh[1]

[1]University of Saarland, Obstetrics and Gynaecology, Homburg/Saar, Germany
[2]Laboratory of Molecular Biology, Cytogenetic & Reproductive medicine, University hospital Farhat Hachad Sousse

Study question: Does cigarette smoking affect histone H2A, H2B, protamine and DNA integrity of human spermatozoa?

Summary answer: Cigarette smoking affects the sperm protein (H2A, H2B and protamine) and increase the DNA damage

What is known already: Condensation of chromatin during spermatogenesis, and its decondensation at the time of fertilization are essential for successful fertilization. Several mechanisms have been proposed for the presence of DNA damage in ejaculated sperm like excessive production of reactive oxygen species (ROS) in the ejaculate.

Cigarette smoking itself contains high levels of ROS. Smoking metabolites may induce an inflammatory reaction in the male genital tract with a subsequent release of chemical mediation of inflammation that can recruit and active leukocytes, which can generate high levels of ROS in semen that may impair spermatogenesis, resulting in the production of abnormal spermatozoa.

Study design, size, duration: Prospective controlled trail.

Participants/materials, setting, methods: The present study carried out at the department of Obstetrics and Gynaecology, University of Saarland, Germany. 54 patients: 35 smokers and 19 non-smokers were included in this study. Semen samples were prepared according to WHO guideline 2010 and sperm nuclear protein were extracted from each semen sample using acid-urea –PAGE and Western blot. Chromatin condensation was assessed by Chromomycine CMA3 staining and DNA fragmentation by TUNEL assay.

Main results and the role of chance: The sperm concentration, vitality, motility, membrane integrity, chromatin condensation, DNA fragmentation, Histone (H2A) and Histone (H2B), Protamine 1 and Protamine 2 of smokers were (51.87 ± 5.05 mill/ml; $41.04 \pm 2.49\%$; $29.67 \pm 2.47\%$; $59.24 \pm 1.79\%$, $36.96 \pm 2.33\%$ and 25.29 ± 5.0 %; 219.8 ± 16.35 ng/10^6 sperm; 292.27 ± 58.2435 ng/10^6 sperm; 425.6 ± 14.56 ng/10^6 sperm and 354.9 ± 11.28 ng/10^6 sperm and the corresponding values for non- smoker group were (84.27 ± 6.01 mill/mL; $59.00 \pm 3.33\%$; $46.83 \pm 4.12\%$; $71.30 \pm 3.16\%$; $20.95 \pm 1.35\%$, $12.47 \pm 1.41\%$; 156.4 ± 12.6 ng/10^6 sperm; 109.1 ± 43.70 ng/10^6 sperm, 425.8 ± 16.26 ng/10^6 sperm and 412.8 ± 16.24 ng/10^6 sperm respectively). In smoker group (count, vitality, motility, chromatin condensation, and membrane integrity, H2A, H2B and Protamine 2) were significantly lower than non –smoker group. Chromatin condensation and DNA fragmentation were significantly higher in smokers. The value of protamine1 was similar in both groups

Limitations, reasons for caution: The size number of the sample

Wider implications of the findings: The finding of geat clinical value as the P1/P2 ratio could be used as a sensitive parameters.

Trial registration number: Basic Science.

P-098   Selection of spermatozoa with higher chromatin integrity through a microfluidics device

A. Parrella, N. Pereira, S. Chow, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We tested a simple method to enrich spermatozoa with higher progressive motility and superior chromatin status in men with normal and abnormal semen parameters.

Summary answer: A microfluidics device was able to isolate spermatozoa with higher progressive motility and the lowest incidence of chromatin fragmentation in oligo- and normo-spermic semen.

What is known already: Semen analysis is currently used as a method to screen for male factor infertility. Standard selection methods provide a cleaner and safer specimen for insemination with enhanced progressive motility albeit without any input on the genomic integrity of the spermatozoon. We learned that sperm DNA fragmentation is linked to motility and therefore a method that is capable of guaranteeing a richer proportion of the most progressive spermatozoa may also provide cells with the highest chromatin integrity.

Study design, size, duration: From October 2016 to January 2017, seminal samples of normozoo- (n = 10) and oligozoospermic men (n = 3) were simultaneously processed by density gradient centrifugation (DGC) and by a new microfluidic sperm sorter (MFSS) chamber to allow selection of the most forwardly progressive motile sperm portion. Terminal deoxynucleotidyl transferase dUTP Nick End Labeling (TUNEL) was carried out on the raw specimen and on the differently selected aliquots to assess sperm chromatin integrity (SCI).

Participants/materials, setting, methods: Consenting men had their ejaculates screened for infertility by standard semen analysis according to WHO 2010 criteria. Standard DGC, centrifugation and a MFSS chamber were used to isolate motile spermatozoa based on cell motility and fluid dynamics. SCI was assessed by TUNEL on at least 500 spermatozoa under fluorescent microscopy considering a $\geq 15\%$ threshold.

Main results and the role of chance: The mean age for the men was 36.5 ± 8 years. The average semen parameters for the normozoospermic men was: concentration $71.5 \pm 25 \times 10^6$/mL, motility of $44.8 \pm 4\%$ and morphology of $2.9 \pm 1\%$. After DGC and MFSS the total motility was $86.4 \pm 5\%$ and $98 \pm 1\%$, respectively ($P < 0.001$) while the progressive motility was $84.7 \pm 5\%$ and 97.6 ± 2 %, respectively ($P < 0.001$). The original sperm morphology of 2.9% became 4.0% after MFSS. In these men, the average SCI was 14.7 % in the raw sample; however, following DGC, the SCI decreased to 8.8% and after MFSS processing it reduced to 2.4% ($P < 0.001$). The average semen parameters for the oligozoospermic men was: concentration $18.7 \pm 28 \times 10^6$/mL, motility of $6.3 \pm 5\%$, and a morphology $2.0 \pm 1\%$. Following enrichment by DGC the motility became $9.7 \pm 5\%$ and following MFSS processing the motility was $98.3 \pm 3\%$. The progressive motility changed from an initial value of $4.0 \pm 3\%$ to $7.7 \pm 5\%$ with DGC and $98.3 \pm 3\%$ with MFSS. The average SCI on these men was 26.5% in the raw sample, 22.6% in the DGC specimen, and following MFSS it decreased to 3.5% ($P < 0.001$).

Limitations, reasons for caution: This analysis is a pilot study on a small number of subjects. However, if confirmed, this microfluidic method, capable of selecting the portion of spermatozoa with the most progressive motility together with the highest level of chromatin integrity, may yield spermatozoa with superior embryo developmental competence for reproductive treatment.

Wider implications of the findings: SCI appears to be related to the kinetic characteristic of the human spermatozoa. MFSS yielded the highest progressively motile spermatozoa characterized by high DNA integrity. Couples with unexplained infertility and unable to achieve a pregnancy due to a concealed male factor may benefit from MFSS to improve their reproductive outcome.

Trial registration number: Not Applicable.

P-099   Sperm progressive motility and strict morphology have a negative correlation with DNA fragmentation

M. Bilinski, D. Lorenzi, H. Uriondo, F. Fulco, G. Alvarez, S. Papier, C. Alvarez Sedo

CEGYR Reproductive Medicine and Genetics, Reproductive Biology and Genetics, Buenos Aires, Argentina

Study question: Is there any seminal parameter that significantly correlated with high levels of sperm DNA fragmentation?

Summary answer: It was shown that strict morphology, progressive motility and vitality had a negative correlation with DNA fragmentation.

What is known already: In the last decade, the evaluation of sperm DNA fragmentation has become as an important method to assess semen quality. Several authors have reported a negative correlation between high DNA fragmentation levels and assisted reproductive technology (ART) outcomes. Considering a population with male factor, we have previously reported that elevated sperm DNA damage is associated with advance male age and oxidative stress.

Study design, size, duration: This is a retrospective cohort study. The sample size was 684 semen samples (2014-2016). All seminal analysis were performed at the same Andrology laboratory and sperm DNA fragmentation assessment was always blind to the seminal parameters.

Participants/materials, setting, methods: Six hundred and four patients who were undergoing ART were selected. Samples were collected by masturbation after sexual abstinence for 2-5 days. After semen liquefaction, semen analysis was performed (concentration, progressive motility, vitality, strict morphology and polymorphonuclear neutrophils). Motile sperm were selected by swim-up according to the procedures established by the World Health Organization (2010). Sperm DNA fragmentation was assessed over motile sperm by TUNEL assay. For statistical analysis Pearson´s correlation and ANOVA were performed.

Main results and the role of chance: The correlation between TUNEL sperm concentration was: R = -0.29, sperm motility R= -0.58, strict morphology R= -0.43, vitality R= -0.44 and PMN R= 0.10. All the correlations were statistically significant ($p < 0.05$). When correlations were compared, sperm motility, morphology and vitality were significantly higher than the others, but not were different between them. DNA fragmentation levels were 10.8 ± 8.2 in normozoospermic men (N: 397), 17.3 ± 9.9 in oligozoospermic men (N: 28), $26.8 \pm 8.0*$ in asthenozoospermic men (N:36) and $21.1 \pm 10.1*$ in men with teratozoospermia (N:100) (*$p < 0.05$). When two or more sperm anomalies were found, e.g. asthenoteratozoospermia and oligoasthenoteratozoospermia, DNA fragmentation increased up to $30.2 \pm 10.5*$ and $32.2 \pm 8.5*$, respectively.

Limitations, reasons for caution: In some Andrology laboartories, sperm DNA fragmentation assay is perfomed in raw samples, we believe that is most important to evaluate DNA damage only in motile (alive) spermatozoa.

Wider implications of the findings: These kind of patients (astheno, terato, asthenoteraro and OAT) had higher levels of DNA damage in compared with normozoospermic and oligozoospermic men, this could be considered as an alert to suspect high levels of DNA damage.

Trial registration number: None.

P-100   Role of Gender Selection in ART

N. Nikprelevic, S. Cheung, C. O'Neill, S. Chow, Z. Rosenwaks, G. Palermo

Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We attempt to address an explicit request of infertile couples to select spermatozoa of a specific gender.

Summary answer: Individual selection of spermatozoa post enrichment yielded the desired gender in the extreme majority of cases and this proportion was maintained in the resulting embryos.

What is known already: Several techniques have been developed to successfully select for X- or Y-bearing spermatozoa. Centrifugations methods and layering techniques, as well as the use of electrophoretic devices, have all been previously tested. The most effective method to date was through flow cytometry, which was capable of achieving a selection of 90% X- and 80%. Although successful, this method was expensive and required exposing spermatozoa to a fluorescent dye. We experimented with a method to allow spermatozoa to select themselves and generate embryos in couples being treated with ICSI.

Study design, size, duration: Over a course of 3 years, we processed by density gradient ejaculates from 21 couples being treated by ICSI. Fluorescent in situ hybridization was used to assess the proportion of X- and Y- bearing spermatozoa prior to and following selection. Single spermatozoa from the gender-enriched fraction were selected for injection according to an empirical head morphology. Preimplantation genetic diagnosis (PGD) results and pregnancy outcomes were recorded. Additionally, 26 couples were treated in 48 IUI cycles.

Participants/materials, setting, methods: A total of 47 couples were enrolled in our IRB study. A combination of gradient formulations was used for the ICSI and IUI treatments. During the ICSI procedure, an individual sperm selection was also implemented by carefully assessing spermatozoon. We confirmed the successful selection of the desired gender by performing cytogenetic analysis with 9 chromosome FISH on at least 1000 cells for each specimen.

Main results and the role of chance: A total of 47 couples (sperm concentration $66.7 \pm 27 \times 10^6$/ml, $46.4 \pm 5\%$ motility, normal morphology). Prior to selection, average total aneuploidy for our subjects was $3.4 \pm 2\%$, compared to a normal value of <1.6%. After selection, our method consistently yielded 81.4% for X- and 78.0% for Y-bearing spermatozoa. In 21 couples treated by ICSI, GS enrichment was followed by pickup of individual spermatozoa selected according to their head morphometry. These couples achieved an average fertilization rate of 79.6% (164/206) and cleavage rate of 98.1%. Of these couples, 11 elected for PGS on the resulting embryos. PGS analysis evidenced that 3/3 (100%) couples selecting for male and 6/8 (75%) couples selecting for female obtained embryos of their desired gender. All embryos were cryopreserved. So far, 5 couples had their embryos thawed (n = 11), 4 for female and 1 for male. Out of the remaining ICSI couples, of those that had an embryo replacement, 7 selected for female and

1 for male. Only 1 couple reported an ongoing pregnancy of female gender. No one else reported a pregnancy. In 26 couples with an average maternal age of 37.7 ± 3yrs undergoing IUI, post sperm gender selection achieved 4 ongoing pregnancies. Thus far, 1 couple delivered the desired baby girl.

Limitations, reasons for caution: Our findings suggest that although it is possible to skew a spermatozoa population towards a specific gender, results are not definite despite taking into consideration sperm head morphometry. In this population with higher incidence of sperm aneuploidy, PGS on the conceptus can help identify euploid embryos of the desired gender.

Wider implications of the findings: Multi-gradient gender selection methods, combined with individual spermatozoa identification by empirical head morphometry, can consistently help identify X- or Y-bearing spermatozoa. If proven reliable, this method to individually select spermatozoa of a particular gender may alleviate sex-linked disorders as well as aid with family planning in a morally accepted manner.

Trial registration number: Not Applicable.

P-101   Sperm nuclear structure in infertile patients with "pinhead sperm" syndrome

A. Braham, H. Ghedir, K. Mhalhel, M. Zidi, A. Saad, S. Ibala-romdhane

Farhat Hached University Hospital- Sousse- Tunisia, Department of Cytogenetic and Reproductive Biology- Farhat Hached University Hospital- Sousse- Tunisia, Sousse, Tunisia

Study question: The impact of a nuclear spermatic quality analysis in patients presenting with "pinhead" sperm defect could assess the chances of success in assisted fertilization?

Summary answer: Infertile men with "Pinhead sperm" have an impaired nuclear sperm which obviously affects the fertilizing sperm power.

What is known already: "Pinhead sperm" or "acephalic sperm" syndrome is a rare but severe form of human teratozoospermia, refers to the condition in which ejaculate contains mostly sperm flagella without heads. The familial incidence and the typical phenotype strongly suggest the genetic origin of the syndrome. Ultrastructral studies of acephalic spermatozoa suggest that this condition results from defects in formation of the connecting piece of spermatozoa during late spermiogenesis. Spontaneous fertilization cannot occur with these sperm and ICSI is the only way in which embryos can be obtained. Otherwise, few data regarding the nuclear integrity of acephalic spermatozoa were reported in the literature.

Study design, size, duration: This is a case control study carried out on 4 Tunisian infertile patients with "Pinhead sperm" syndromeand 20 fertile men with normal semen profiles included as a control group. Patients were recruited between January 2010 and March 2016.

Participants/materials, setting, methods: Semen samples were analyzed according to the World Health Organization criteria (2010). Chromatin condensation was assessed by aniline-blue Staining. Sperm DNA fragmentation was evaluated by terminal desoxynucleotidyl transferase mediated deoxyuridine triphosphate biotin nick-end labelling (TUNEL) assay and chromosome abnormalities by fluorescence *in situ* hybridization (FISH) for chromosomes X, Y and 18.

Main results and the role of chance: Medical history, hormonal levels, lymphocyte karyotype and molecular analyses of Y chromosome microdeletion were normal. Sperm analysis showed numerous isolated motile tails and fewer isolated heads. The mean DNA fragmentation index was significantly higher in patients compared to the controls (35 ± 6.21 vs 10.41 ± 3.77). The aniline blue-reacted spermatozoa rate was also high in comparison to the controls ($63.66 \pm 6,027$ vs 11.80 ± 5.7). The rate of total sperm aneuploidy was higher in patients compared to the controls (3.74 ± 0.68 vs 1.48 ± 0.22) with a predominance of sex chromosomes disomy ($1.86 \pm 0.73\%$ vs $1 \pm 0.3\%$).

Limitations, reasons for caution: A limitation of this study is the low number of patients with "Pinhead sperm" considering the rarity of this syndrome.

Wider implications of the findings: Our results confirm the importance of sperm chromosomal aneuploidy, chromatin condensation and DNA fragmentation analysis for patients with "Pinhead sperm" syndrome in order to adopt the best course of treatment for these patients and to predict the chances of success in assisted reproductive technology(ART).

Trial registration number: not applicable' for non-clinical trials.

P-102 Oral antioxidant therapy improves sperm quality in patients with abnormally high levels of apoptotic spermatozoa

A. Leza[1], E. Rocafort[1], I. Vilella[2], L. Medrano[1], J. Sarasa[2], M. Enciso[2], J. Aizpurua[1]

[1]IVF Spain, Reproductive Medicine, Alicante, Spain
[2]iGLS, Genetics Department, Alicante, Spain

Study question: To determine whether two months of oral antioxidant treatment could improve sperm quality in neat sperm samples with abnormally high levels of apoptosis.

Summary answer: Oral antioxidant therapy during two months significantly reduces apoptosis levels in sperm samples improving clinical results.

What is known already: Traditional semen analysis is not always sufficient for adequate male infertility diagnosis. In consequence, recent studies have focused on the comprehensive evaluation of sperm features. Apoptosis is a process that induces cellular, morphological and biochemical alterations leading the cell to suicide without an inflammatory response. Despite apoptosis occurs continuously in the testicle, it is known that high apoptosis levels have a negative impact on embryo development and pregnancy outcomes. Several strategies such as magnetic activated cell sorting (MACS) have been proposed to reduce apoptotic sperm levels, however the antioxidant therapy seems to be an easier solution to this problem.

Study design, size, duration: Unicentric and retrospective study including 156 sperm samples from patients undergoing egg donation treatment at our center between January 2014 and September 2015. The influence of oral antioxidants such as vitamins, diclofenac and Seidiferty in human sperm samples with 2 days of sexual abstinence, after two months of therapy is explored in this study.

Participants/materials, setting, methods: Apoptosis was assessed by flow cytometry using Annexin-V-FITC/PI assay in the first visit and two months later at the start of treatment.

When apoptosis level was in normal range ($\leq$20%), patients did not take any medication (control group,n = 34). When altered on the first visit, they initiated the intake of vitamins (group 1,n = 23), vitamins and diclofenac (group 2, n = 73), Seidiferty® (group 3,n = 8) or vitamins, diclofenac and Seidiferty® combined (group 4,n = 17). Apoptosis levels of the groups were statistically compared.Main results and the role of chance:

When assessing the effect of the oral antioxidant treatment on the study groups, a significant reduction of apoptosis levels were found in all groups (group 1: 20.54% to 14.82%, p = 0.025; group 2: 21.42% to 13.45%, p = 0.001; group 3: 25.27 to 8.64%, p = 0.012; group 4: 28.42% to 11.52%, p = 0.002). Results show that the administration of antioxidant treatment to patients producing sperm samples with altered levels of apoptosis improves sperm quality significantly, reducing the number of apoptotic spermatozoa in the ejaculate.

Moreover, in the control group we could find a significant increase in the apoptosis level from 7.82% in the first visit to 13.91% (p = 0.006). Although the level of apoptosis from control group patients remains in the normal range, the absence of medication leads to an increase in the number of apoptotic spermatozoa present in the ejaculate.

Limitations, reasons for caution: The retrospective and unicentric nature of the study, together with the limited number of samples may be reasons for caution. Further studies should be performed to evaluate the effects of oral antioxidant treatment in other sperm quality parameters.

Wider implications of the findings: This study demonstrates that the evaluation and treatment of sperm samples with pathologic levels of apoptotic spermatozoa prior to the completion of the fertility treatment may improve embryo development and clinical outcomes.

Trial registration number: Non applicable.

P-103 Sperm count upon switch from valproic acid to other antiepileptic drugs of male subfertile patients

I. Georgiou[1], S. Markoula[2]

[1]University of Ioannina, Medical School- Laboratory of Medical Genetics and Human Reproduction, Ioannina, Greece
[2]Ioannina University Hospital, Department of Neurology -, Ioannina-, Greece

Study question: The aim of the study was to determine whether switching from valproic acid to other antiepileptic drugs improves the sperm counts of male subfertile patients.

Summary answer: There is significant improvement of the sperm count and sperm parameters after switching from valproic acid to other antiepileptic drugs.

What is known already: Apart from epilepsy per se and its role on hypothalamic-pituitary-gonadal axis function, antiepileptic drugs (AEDs) may also have an important impact on hormonal regulation, affecting peripheral endocrine glands, hormones' protein binding and metabolism.Valproic acid (VPA) is a widely used AED, whose adverse reactions in fertility are not limited to women. Effects of VPA on male reproductive health occur early during treatment, with increase in serum testosterone, free androgen index, androstendione and dehydroepiandrosterone sulfate.

Study design, size, duration: Observational study of adult subfertile epilepsy male patients, long term treated with VPA, recruited in a period of three years.

Participants/materials, setting, methods: Seventeen subfertile male patients, followed up at the University Department of Neurology were referred for fertility management at the Assisted Reproduction Unit, Department of Obstetrics and Gynecology. A sperm count was conducted while they were treated with VPA and six months after switching to another AED. Pregnancies, after switching, were also reported.

Main results and the role of chance: A significant improvement of the sperm count was observed in eleven patients (65%) and spontaneous pregnancies were reported in three of the patients.

Limitations, reasons for caution: This is an observational study without blind controls in patients with epilepsy; effective seizures control upon switch is a potential confounding factor of the sperm count improvement

Wider implications of the findings: Epilepsy is a common disorder affecting people with high prevalence in the young age. Epilepsy and AEDs may affect family planning and cause infertility problems. Fertility specialists treating subfertile patients with epilepsy have to be familiarized with issues emerging from certain AEDs and refer their patients for antiepileptic treatment reconsideration.

Trial registration number: None.

P-104 Sperm DNA Fragmentation and Semen Parameters in a cohort of Brazilian Infertility Patients

C. Alvarenga[1], S. Cortezzi[2], F. Affonso[3], C. Abreu[3], B. Cezarino[4]

[1]Faculdade De Medicina Da Usp, UROLOGIA, São Paulo - SP, Brazil
[2]Faculdade de Medicina do ABC, Post Graduation, Santo André, Brazil
[3]LAB Medicina Masculina, Laboratory Department, São Paulo, Brazil
[4]LAB Medicina Masculina, Clinical Department, Sao Paulo, Brazil

Study question: Is there a correlation between sperm DNA fragmentation (SDF) in a cohort of Brazilian infertility patients and their lifestyle and semen parameters, such as sperm morphology, concentration, and motility?

Summary answer: Patients showed high levels of SDF regarding aging, sexual abstinence and lower sperm parameters. No association between alcohol or cigarette consumption and SDF was found

What is known already: Sperm DNA integrity has emerged as an important parameter of sperm quality in the prognosis of infertility and in the assisted reproductive outcomes. There are controversial studies related to an adverse effect of sperm DNA damage on fertility. These studies emphasize that the discrepancy is due to the various methods used for evaluating the cut-off value of SDF, due to different detection methods, studied population, and type of assisted reproductive procedure.

Study design, size, duration: Two hundred and one patients undergoing a private andrology clinic for fertility evaluation were subjected to routine sperm analysis in a cross-sectional study. Personal habits (alcohol consumption and cigarette smoking) were also verified. Patients were stratified into groups regarding age, sexual abstinence, semen parameters, lifestyle habits, and sperm DNA fragmentation.

Participants/materials, setting, methods: Samples were assessed according WHO 2010. SDF was assessed by sperm chromatin dispersion (SCD) test.

Linear correlation was conducted using Spearman's coefficient. Quantitative variables with normal and asymmetric distribution were respectively compared according to Student's t-test or Mann-Whitney/Kruskal-Wallis test. Results were considered to be statistically significant when p < 0.05

Main results and the role of chance: Older men showed higher SDF than younger patients in two different analysis (p = 0.021; p= 0.0221). Sexual abstinence time was related to SDF (p = 0.045), with 3 days of abstinence with the higher index (15.8%). With respect to sperm concentration, oligozoospermic men presented more SDF in distinct analysis (p= 0.014; p = 0.012). When considering the cut-off value of 30% for SDF, there was an inverse correlation between SDF rate and sperm concentration (p = 0.0021). Total sperm motility was significantly related to SDF (p < 0.0001). When comparing different patients with rates below or above 40% of total motility, astenospermic group presented a higher SDF (p = 0.0003). Comparing patients with DNA fragmentation below or above 30%, higher SFD rates were related to lower motility (p = 0.0008). Regarding Kruger sperm morphology, there was a negative correlation with SDF (p = 0.016). Patients with ≥ 30% SDF had lower number of morphologically normal sperm (p = 0.014). Our data does not support an association between alcohol consumption (p = 0.82) or cigarette smoking (p = 0.93) and SDF.

Limitations, reasons for caution: Our results do not support that lifestyle habits such as alcohol consumption or cigarette smoking are related to high sperm DNA fragmentation, maybe due to the small number of heavy consumers in the sample analyzed (17.2% and 15.1%, respectively).

Wider implications of the findings: The analyzed cohort of Brazilian infertility patients showed high levels of SDF related to aging, sexual abstinence and lower sperm parameters such as concentration, motility and morphology

Trial registration number: Not applicable, due to the cross-sectional design of the study.

P-105 Curcumin protects human sperm DNA against ROS after freeze-thawing process

M. Santonastaso[1], F. Caprio[2], M.D. D' Eufemia[3], A. Natella[3], C. Trotta[3], L. Rocco[4], N. Colacurci[3]

[1]Università degli Studi della Campania "Luigi Vanvitelli", Dpt. of Woman-Child and General and Special Surgery, Naples, Italy
[2]Università degli Studi della Campania "Luigi Vanvitelli", Dpt. of Women-Child and General and Specialist Surgery, Naples, Italy
[3]Università degli Studi della Campania "Luigi Vanvitelli", Dpt. of Women-Child and General and Specialist Surgery, Naples, Italy
[4]Università degli Studi della Campania "Luigi Vanvitelli", DEP. OF SCIENCE AND TECHNOLOGY ENVIRONMENTAL AND BIOLOGICAL PHARMACEUTICAL, Caserta, Italy

Study question: To examine if curcumin could contrast the ROS-mediated alterations to the motility, viability and DNA integrity of human spermatozoa after a freeze-thawing process.

Summary answer: The addition of curcumin in freezing medium improves the quality and DNA integrity of cryopreserved human semen.

What is known already: The mechanism of reduction of fertilizing capacity of cryopreserved spermatozoa is not still completely understood. ROS influence the sperm function as well as its potential fertility after freeze thawing. Higher production of ROS causes sperm cells immobility and damages DNA. Antioxidant systems are the major defense approach against ROS during semen cryopreservation. Curcumin is one of the natural antioxidants which act as an anti-inflammatory,antitoxic and anticancer agent for medical treatment.With regard to its biological, pharmacological and antioxidant activities, curcumin has been shown to improve frozen-thawed goat, bovine and boar semen qualities. No previous study has been performed on cryopreserved human semen.

Study design, size, duration: Semen samples from 150 men were obtained by masturbation following 3–5 days sexual abstinence from June to December 2016. After liquefaction, the samples were examined for sperm concentration, viability, and motility according to WOH. Semen were divided into 3 groups: one group of frozen-thawed samples without addition of curcumin as negative control and two groups of semen samples with addition of curcumin (10 and 20 μM) in freezing medium.

Participants/materials, setting, methods: The semen freezing was conducted in accord to the manufacturer's instructions (Quinn's Advantage™ Sperm Freeze).Sperm parameters, such as progressive motility and concentration were analyzed with Makler camber while sperm viability and morphology were evaluated by Eosin- Nigrosin Test and by Testsimplets® pre-stained slides respectively.Sperm DNA fragmentation was evaluated by TUNEL Test and the intracellular ROS level was assessed by DFC Assay. The data were analyzed using the unpaired Student's t-test and considered significant if p-value≤0.05.

Main results and the role of chance: None significant differences were found between negative group and group supplemented with 10 μM curcumin. There was a significantly higher percentage of progressive motility in the 20 μM curcumin groups than in the negative group (p ≤0.05). Statistically significant difference in intracellular ROS levels and DNA damage have been observed in 20 μM curcumin group also. In particular, ROS percentage and DNA damage was significantly higher in semen thawing without curcumin compared sperm curcumin supplemented in frozen medium. The supplementation of curcumin at 20 μM in the freezing medium yields better frozen-thawed human semen qualities in terms of progressive motility and DNA fragmentation linked to a ROS reduction when compared with control and other treatment group.

Limitations, reasons for caution: None

Wider implications of the findings: The present study demonstrates the beneficial effect of adding curcumin during cryopreservation on the qualities of frozen-thawed human semen. We suggest that human sperm is able to uptake substances such as antioxidants and utilize them for protecting its plasma membrane and DNA from intracellular ROS during cryopreservation.

Trial registration number: None.

P-106 ART outcome of non-obstructive azoospermia in terms of testicular sperm number by micro-TESE through 16 years experience

A. Yoshida[1], K. Sano[2], K. Seida[2], Y. Umeikawa[2], M. Tanaka[2]

[1]Kiba Park Clinic, Tokyo, Japan
[2]Kiba Park Clinic, IVF Laboratory, Tokyo, Japan

Study question: Is there any difference of ART outcome after ICSI with frozen-thawed testicular spermatozoa of non-obstructive azoospermia in terms of obtained testicular sperm number?

Summary answer: The normal fertilization rate, the implantation rate and the delivery rate per ET in the tiny amount of sperm group were significantly lower.

What is known already: The introduction of ICSI has revolutionized the treatment of severe male infertility. ICSI using testicular spermatozoa has been commonly applied in the treatment of obstructive azoospermia (OA) and non-obstructive azoospermia (NOA). Moreover, the ART outcome of NOA is significantly lower than that of OA. However, the number of reports regarding the ART results in terms of obtained testicular sperm number retrieved from testes in NOA patients is still small.

Study design, size, duration: This is a retrospective study of ART outcome in 529 cycles (5,693 oocytes) with ICSI using testicular spermatozoa in NOA patients from 1999 to 2014 in our clinic.

Participants/materials, setting, methods: Sperm number was calculated after sperm preparation before ICSI. Tiny amount of sperm (TAS) was defined less than one sperm in one field of view under 400 magnifications. Meanwhile small amount of sperm (SAS) was defined more than one sperm in one field of view under 400 magnifications. The ART results including the fertilization rate, the implantation rate, the delivery rate and the mean birth weight were compared between TAS and SAS groups.

Main results and the role of chance: The wife's average age, the husband's average age and the number of the oocytes retrieved were comparable between TAS and SAS groups (the wife's average age; 35.3 ± 4.2 vs 35.5 ± 4.6, the husband's average age; 37.9 ± 6.4 vs 39.0 ± 7.9, the number of the oocytes retrieved; 10.2 ± 7.1 vs 10.4 ± 7.8). However, the normal fertilization rate in TAS group (59.5%) was significantly lower than that in SAS group (68.9%). The average number of embryo transferred was comparable between the two groups (1.6 ± 0.6 vs 1.7 ± 0.8). However, the implantation rate, the clinical

pregnancy rate (FHB) per ET and the delivery rate per ET in TAS group were significantly lower than those in SAS group (the implantation rate; 14.8% vs 23.6%, the clinical pregnancy rate per ET; 19.8% vs 31.2%, the delivery rate per ET; 14.3% vs 26.3%). The mean birth weight, the pregnancy week at term and the congenital abnormality rate were comparable between the two groups (the mean birth weight; 3014.6 ± 334.6 g vs 2703.8 ± 682.0 g, the pregnancy week at term; 38.0 ± 2.4 vs 38.0 ± 2.6, the congenital abnormality rate; 2.6% vs 3.4%).

Limitations, reasons for caution: Genetic counseling and informed consent should be given prior to ICSI with NOA patients.

Wider implications of the findings: The results of this study showed that the normal fertilization rate, the implantation rate the clinical pregnancy rate per ET and the delivery rate per ET were low when the obtained testicular sperm number by micro TESE was very small in NOA patients.

Trial registration number: N/A.

P-107 Temporal trends of semen quality among infertile Greek couples undergoing oocyte donation cycles between 2007 and 2016 in a single IVF centre. A retrospective study

K. Ravanos[1], Y. Panagiotidis[1], A. Papatheodorou[1], M. Goudakou[1], D. Pavlidou[1], A. Gkountis[1], S. Petousis[1], N. Prapas[1], Y. Prapas[1,2]

[1]IAKENTRO fertility centre, IVF laboratory, Thessaloniki, Greece
[2]Institut Médical de Champel, Infertility center, Geneve, Switzerland

Study question: Do semen parameters of male partners of infertile Greek couples undergoing oocyte donation cycles in a single IVF centre exhibit statistical significant changes over the last 10 years?

Summary answer: Semen concentration increased but without upward trend. Sperm motility and sperm concentration <20million/mL showed an absence of significant change. Rapid progressive motile sperm deteriorated significantly

What is known already: Temporal global trends of sperm quality remains a matter of debate. Earlier studies suggest a geographical and time related decline in sperm quality parameters while more recent reports failed to reveal a statistical significant change or temporal trend. Such controversies are attributed to the selection bias of the population studied, failure to adjust for confounding factors and different statistical tools employed for analyses. It is widely believed that exposure to endocrine disruptors during fetal life can damage testicular function, leading to testicular cancer and impairment of the reproduction.

Study design, size, duration: This is a retrospective, descriptive study using data registered in a single IVF centre located in Thessaloniki Greece during the period 2007-2016. Data regarding sperm concentration and sperm motility were processed and analyzed from a total of 1113 participants with a mean age of 43.8 (SD, 6.1) years that fulfilled the inclusion criteria.

Participants/materials, setting, methods: The study population included male partners of infertile Greek women living in the greater area of Thessaloniki and undergoing oocyte donation treatment for the first time in a single IVF centre. Semen analyzed was a fresh ejaculate delivered by masturbation. Patients excluded were those with a frozen sperm sample, with obstructive azoospermia, with a history of cryptorchidism and genital cancer or consumption of steroids and procreative drugs.

Main results and the role of chance: Analyzing 1113 semen samples over a period of ten years, the main outcomes were: mean sperm concentration increased significantly between 2007 and 2015 (39.5million/ml versus 59.1million/ml; $P < 0.001$) but without forming a visible upward trend over the years, mean total motility remained statistically unchanged (56% versus 49.8%; $P = 0.239$) as well as the percentage of sperm concentration of less than 20million/mL (23.5% versus 24.4%; $P = 0.249$), whereas mean of rapid progressive motile sperm decreased significantly (41.1% versus 30%; $P < 0.001$), forming a visible downward trend.

Limitations, reasons for caution: This is a retrospective study where the population studied was not adjusted for several confounding factors. Sample size exhibited annual variations and the participants were of advanced age, therefore a degree of selection bias can not be exclude. Prospective, large-scale, population-based studies are needed in order to confirm our results.

Wider implications of the findings: To our knowledge, there is only one study, evaluating possible trends of semen quality in the Greek population published in 1996 and concluding a significant temporal decline in seminal volume and count. The present study ends this long paucity of data, providing evidence that disprove the earlier findings.

Trial registration number: Not applicable for non-clinical trials.

P-108 Do childless sperm donors have a different profile than those who have children? Assessment of the first recruitments

T. Chougar, L. Ferreux, C. Chalas, P. Leblanc-Ronat, N. Mendes, C. Squires, C. Dudkiewicz-Sibony, O. Rosenblum, A. Condat, J.P. Wolf, V. Drouineaud

Université Paris Descartes- Sorbonne Paris Cité- Faculté de Médecine- Assistance Publique– Hôpitaux de Paris AP- HP- Hôpital Universitaire Paris Centre- Centre Hospitalier Universitaire CHU Cochin, Service d'Histologie-Embryologie-Biologie de la Reprod,

Study question: Has the change in donor legislation in France affected the profile and motivations of men wanting to be sperm donors?

Summary answer: Childless donors showed a different profile than donors who have conceived. Altruism was the most important motivation and sperm cryopreservation rarely motivated their donation process.

What is known already: In France, sperm donation proceeds through voluntary, anonymous and unpaid donation. Donors must be under 45 years old, and until 2015, only men who have procreated could donate their sperm. Following a change in the law (Law of Bioethics 2011, Decree 2015), childless men now also have the possibility to donate their gametes, and unlike donors having procreated, they are offered sperm cryopreservation. Studies carried out previously in sperm donors having procreated, showed that most of them were in agreement with anonymity, sensitized by a couple requesting donor insemination, and that altruism most often motivated their approach.

Study design, size, duration: This was a retrospective descriptive study that looked at 82 men who approached the CECOS of Paris Cochin between the October 2015 and August 2016, i.e. just after the change in legislation (October 2015). A total of 82 sperm donors with or without offspring and aged 18-44 were included.

Participants/materials, setting, methods: Two groups were compared: 41 sperm donors with offspring and 41 childless sperm donors. Socio-demographic characteristics, motivations, attitudes toward anonymity and sperm cryopreservation (childless donors only) were analyzed in the two groups. Additionally, sperm parameters were compared between childless sperm donor and father sperm donors.

Main results and the role of chance: Childless sperm donors were significantly younger than donors with offspring (33.4+/-7.0 vs 36.2+/- 5.0 p = 0.04) and were less likely to be in a relationship than father-donors (26.8% vs 85.4% respectively; p < 0.001). The childless sperm donors were more likely to have a wish for a child than the donors with children. No difference was found between the two groups regarding anonymity and disclosure to their relatives. Childless donors were mostly sensitized by media or promotional campaigns (p = 0.009), while donors with children were mostly sensitized by infertile couples requesting sperm donor insemination in their family circle (p = 0.002). Altruism was the most important source of motivation among the donors without offspring (78.0%) and was more frequent than the other sources of motivation compared to the donors with offspring (53.6%) (p = 0.02). Sperm cryopreservation was a source of motivation in only 4.9% (2/41) of childless donors. In the above mentioned group, 43.9% (18/41) of men were approved for a donation and among them 66.6% (12/18) refused sperm cryopreservation for themselves. The exclusion rate was similar in the two groups (21.9% vs 17.1% respectively) as well as the drop-off rate (21.9% vs 36.6% respectively). No difference was found between the two groups regarding sperm parameters.

Limitations, reasons for caution: As this was a retrospective study, there is a chance for the introduction of bias.

Wider implications of the findings: We have shown that differences exist between sperm donors with and without offspring regarding age, family status, childbearing motivation and recruitment mode. Surprisingly, sperm self-cryopreservation, which is proposed as a reward, is not that successful among

the childless donors and altruism is always the main motivation for sperm donation.

Trial registration number: Not applicable.

P-109 Testis development in the absence of SRY: chromosomal rearrangements at SOX9

S. Jellad[1], R. Ben Mefteh[1], M. Basly[1], M. Chibani[1], M. Chaabouni[2], R. Rachdi[1]

[1]Military Hospital, Unit of Reproductive Biology, Tunis, Tunisia
[2]Charls Nicolle Hospital, Department of genetics, Tunis, Tunisia

Study question: to describe and analyze several pathophysiological mechanisms put forward to explain a rare case of a 46 xx male man with male phenotype and azoospermia.

Summary answer: Even in absence of SRY, complete male differentiation may occur, possibly driven by overexpression of SOX9 in the gonadal ridge

What is known already: 46, xx disorders are congenital conditions in which, in the presence of a female karyotype, the development of gonadal and anatomical sex is atypical, ranging from various degrees of ambiguous genitalia to phenotypic males with azoospermia. These conditions are poorly characterized, at least in subjects whose DNA does not contain SRY, the gene triggering testis differentiation in mammals.

Study design, size, duration: A case report, A 34 year old man with complete masculinization who was referred to our institution because of a history of primary infertility.

Participants/materials, setting, methods: Repeated semen analysis, endocrinological data, testicular biopsy, karyotype analysis, Fluorescent in situ hybridization, polymerase chain reaction and Array CGH analysis.

Main results and the role of chance: Physical examination showed normal male secondary sexual characteristics and bilateral gynecomastia. Repeated seminal analysis showed complete azoospermia. Endocrinological data showed lower testosterone levels and testicular biopsy confirmed germinal cell aplasia. Peripheral blood culture for chromosome studies revealed 46xx chromosome complement. Fluorescent in situ hybridization (FISH) and polymerase chain reaction (PCR) analyses excluded the presence of SRY gene. Array CGH analysis showed partially overlapping 17q24.3 duplications about 500 kb involving the gene desert region upstream of SOX9, inherited from a normal father.

Limitations, reasons for caution: The duplication is inherited by a healthy and fertile father.This suggests that a copy gain of the region does not affect sex development and fertility in 46, xy subjects, where SOX9transcription is anyway activated during gonadal development.

Wider implications of the findings: In the absence of SRY, The Reversal Sex duplication causes increased expression of SOX9 in undifferentiated gonadal cells. The duplication could alter Sox9 expression by increasing the dosage of one or more gonadal specific enhancers located within the minimal duplicated interval defined as reversal sex.

Trial registration number: not applicable.

P-110 The impact of male factor infertility (MFI) on early- and late-morphokinetic parameters: retrospective analysis of 2868 time-lapse (TL) monitored embryos

I. Souter[1], G. Christou[2], I. Dimitriadis[1], M.L. Brock[2], S.T. McLellan[2], P. Bhowmick[2], C.L. Bormann[1]

[1]Harvard Medical School- Massachusetts General Hospital, Obstetrics/Gynecology/ Reproductive Endocrinology and Infertility, Boston- MA, U.S.A.
[2]Massachusetts General Hospital Fertility Center, Obstetrics/Gynecology/ Reproductive Endocrinology and Infertility, Boston- MA, U.S.A.

Study question: Is there an effect of male factor infertility on either early- and/or late-morphokinetic parameters obtained during embryonic culture to blastocyst stage in a TL-monitored incubator?

Summary answer: Times from either pronuclei fading (tPNf) or 5-cells to early blastulation (periods: PSB and P5SB, respectively), were prolonged in MFI compared to non-MFI embryos.

What is known already: Studies suggest that optimal values of certain morphokinetic parameters correlate with an embryo's ploidy status and potential for blastocyst development and implantation. TL-morphokinetics might be affected not only by inherent embryonic traits but by both external factors (laboratory, culture) and patient-related characteristics, as well. Evidence of paternal influence on embryonic genome activation, early embryonic development, and blastocyst formation in-vitro has been reported. However, the potential impact of paternal factors and male infertility diagnosis, if any, on early- and late-morphokinetic parameters, remains unclear.

Study design, size, duration: Data from 2868 embryos (MFI: 1239, non-MFI: 1629 embryos) derived from 419 IVF cycles (IVF/ICSI: 267, and IVF/conventional insemination: 152) and cultured to the blastocyst stage in a TL-monitored incubator, were retrospectively reviewed. 383 women ≤38 years of age undergoing IVF at a major academic center between 09/2013 and 09/2016 were included.

Participants/materials, setting, methods: MFI embryos were compared to those derived from non-MFI patients, in regards to the following early- and late-morphokinetic parameters: time period from i) tPNf to 1st cytokinesis (P1), ii) 2- to 3-cells (P2), iii) 3- to 4-cells (P3), iv) 4- to 5-cells (P4), v) P5SB, and vi) PSB.

Statistics: t-test, chi-square were used as appropriately. $P < 0.05$ was considered statistically significant.

Main results and the role of chance: Groups did not differ in baseline characteristics (age, BMI, basal-FSH, AMH, antral follicle counts) but more MFI patients required ICSI (94.3 vs. 40.8%, MFI vs. non-MFI, $p < 0.001$). Time periods PSB and P5SB lasted significantly longer in MFI compared to non-MFI embryos [mean(SD): 75.6(8.7) vs. 73.8(9.2), $p < 0.001$; 51.7(10.9) vs. 49.3 (10.8), $p < 0.001$, respectively]. This difference persisted even when analyzing *usable* (either transferred or frozen blastocysts) separately from *discarded* embryos [*usable*: 72.6(7.0) vs. 71.2(7.7), p: 0.004; and 47.4(8.1) vs. 45.7(8.3) hours, for PSB and P5SB, respectively; and *discarded*: 78.9(9.2) vs. 77.1(9.8), p: 0.006; and 56.5(11.6) vs. 53.5(12.0) hours, $p < 0.001$; for PSB and P5SB, respectively).

All other time periods did not differ significantly between the two groups when either: i) all embryos were included (P1: 2.9(1.6) vs. 2.9(2.0), P2: 9.5(4.8) vs. 9.7(4.7), P3: 2.8(4.4) vs. 2.8(4.4), and P4: 9.2(6.2) vs. 9.9(6.3) hours, for MFI vs. non-MFI, respectively), or ii) *usable* (P1: 2.6(0.6) vs. 2.7(0.6), P2: 10.5(3.3) vs. 10.2(3.2), P3: 1.9(3.4) vs. 1.9(3.3), and P4: 10.6(4.3) vs. 10.7(4.5) hours, for MFI vs. non-MFI, respectively), and iii) *discarded* embryos (P1: 3.0(2.1) vs. 3.1 (2.4), P2: 8.7(5.6) vs. 9.2(5.7), P3: 3.6(4.9) vs. 3.7(5.0), and P4: 8.0(7.1) vs. 9.3 (7.5) hours, for MFI vs. non-MFI, respectively) were analyzed separately.

Limitations, reasons for caution: Limitations include the retrospective design and a potential effect of the fertilization method. To account for the latter and decrease possible bias, times were normalized to a common starting time-point irrespective of fertilization method. Only women ≤38 years were included, so results may not be generalizable to women >38 years.

Wider implications of the findings: The possible effect of MFI on embryonic development was more pronounced from the late cleavage to blastocyst stage, causing a prolongation of both time-periods to early blastulation. No difference was noted in early-morphokinetic parameters, a finding suggestive of a possible late paternal effect visible after paternal genome activation.

Trial registration number: Not applicable.

P-111 Evolutionary-like selection on-a-chip: Using microfluidics to isolate the fittest sperm

T. Chinnasamy[1], J. Kingsley[2], N.G. Durmus[3], P.J. Turek[4], M.P. Rosen[5], B. Behr[6], L.M. Steinmetz[7], E. Tüzel[2], U. Demirci[1]

[1]Bio-Acoustic MEMS in Medicine (BAMM) Laboratory, Canary Center at Stanford for Cancer Early Detection, Department of Radiology
[2]Department of Physics, Worcester Polytechnic Institute, Worcester
[3]Department of Biochemistry, School of Medicine, Stanford University
[4]The Turek Clinic, San Francisco, CA, USA
[5]Department of OBGYN, University of California San Francisco School of Medicine, San Francisco, California
[6]Department of Obstetrics and Gynecology, School of Medicine, Stanford University
[7]Department of Genetics, School of Medicine, Stanford University

Study question: To develop a microfluidic device for selective sorting of motile, morphologically normal sperm with high DNA integrity for ICSI applications.

Summary answer: Microfluidic chip sorted human sperm showed higher motility, morphologically normal and DNA integrity compared to unsorted or traditionally sorted sperm.

What is known already: The path that sperm take through the female reproductive system has been conserved for millions of years. This suggests that this sperm journey has significant evolutionary importance. In fact, we know very little about how this reproductive journey influences or "filters" sperm quality for fertilization. We hypothesize that evolutionarily important attributes of sperm are improved by this sperm journey. We sought to partially mimic this complex pathway using microfluidics by creating various three-dimensional geometries within microscopic channels. Geometric selection sets were developed based on known hydrodynamic principles that guide the inter-action between sperm and surrounding periodic structures.

Study design, size, duration: Sperm sorting analysis was performed using de-identified discarded human semen samples from REI Laboratory, Stanford School of Medicine, Stanford University. All the sperm processing experiments were performed within 1 to 3 hours after the semen samples were collected. The unprocessed semen sample was injected into microfluidic device to sort highly motile sperm. Similarly, unprocessed semen sample was also subjected to traditional swim-up method to compare the sperm sorting efficiency.

Participants/materials, setting, methods: The sperm sorting microfluidic chip consists of inlet, outlet chamber and a middle channel featuring pillars (10 dia.), which are variably spaced to facilitate the transport of the motile sperm into the outlet chamber. Initially, the device was filled with sperm washing med-ia, and the semen sample was injected to the channel inlet. Followed by the incubation at 37 °C for 10-30 min, outlets imaged and sperm trajectories were analyzed using CASA.

Main results and the role of chance: All the sorted sperm samples were analyzed using ImageJ CASA plugin system for sperm motility, trajectory kinetics and percentage of motile sperm. Further, the sorted sperm and unprocessed semen were subjected to morphology and DNA integrity analysis. The results showed that sperm sorted by the microfluidic device have higher motility (98%) as compared to sperm sorted in swim-up approach (65%), and unprocessed semen (43%). Similarly, higher percentage of morphologically normal sperm (51%) was observed for sperm sorted using the microfluidic chip compared with sperm sorted using swim-up (25%), blank channel (37%) and raw semen (11%). Further, DNA integrity of sperm sorted by microfluidic chip was higher compared to sperm sorted using swim-up and raw semen samples. The higher overall sperm quality sorted by the microfluidic chip method is due the unique space constrained pillar geometry in chip, which does not only sort but direc-tionally navigates the motile sperm.

Limitations, reasons for caution: The developed microfluidic sperm sorting device is optimized with specific channel dimension and pillar geometry that are able to isolate the functional sperm with a shorter duration (10 minutes). On the other hand, sperm sorting duration can be increased for handling the sam-ple with lower sperm motility or count, e.g. azoospermia.

Wider implications of the findings: This approach has implications for developing user-friendly, standardized and improved sperm selection methods for assisted reproduction.

Trial registration number: No Trial done in this study.

POSTER VIEWING SESSION
EMBRYOLOGY

P-112   Performing oocyte denudation for ICSI without delay does not compromise cycle outcomes

O. Naji[1], N. Moska[2], A. El-Shirif[2], M. Khalil[2], H. El-Ashkar[2], A. Gambaro[2], Y. Dajani[2], Y. Khalaf[2], V. Bolton[2], T. El-Toukhy[2]

[1]London, United Kingdom,

[2]Guy's and St Thomas' Foundation Trust, Assisted Conception Unit, London, United Kingdom

Study question: Is there a benefit from delaying oocyte denudation before ICSI in order to achieve better reproductive outcomes?

Summary answer: There is no significant difference in fertilisation and preg-nancy rates between early vs. delayed denudation of the oocyte in fresh non-donor ICSI cycles.

What is known already: There is increasing pressure on IVF laboratories to work more efficiently in order to meet the rising demands on ART services. Before the ICSI procedure, oocyte denudation of the corona-cumulus-complex (CCC) must be performed. The presence of CCC has been suggested to improve oocyte cytoplasmic maturation and embryonic metabolism. Various studies have been conducted to evaluate the optimal timing of denudation with-out reaching definitive conclusions.

Study design, size, duration: Prospective cohort observational study of 2052 fresh non-donor ICSI treatment cycles carried out between January 2015 and October 2016.

Participants/materials, setting, methods: ICSI was performed following controlled ovarian stimulation (COH); oocyte retrieval was undertaken 36-hours after maturation trigger injection. Patients were divided into two groups: group I (n = 1064) had the oocytes denudation within 2-hours of retrieval, and group II (n= 988) within 2-5 hours. Timings were recorded on an automated radio-frequency laboratory database. StatView-software for statistical analysis was used to compare fertilisation/ pregnancy rates, and the mean number of embryos transferred/ cryopreserved between the two groups.

Main results and the role of chance: We found no effect of the denudation time on ICSI outcomes. After controlling for confounding variables, groups I and II were comparable in terms of mean patient age (35.5 vs. 35.6 years, P 0.9), number of previous treatment cycles (1.6 vs. 1.5, P 0.3) and the total dose of gonadotropins used (2767 vs. 2790 IU, P 0.7). There was no significant differ-ence with regard to the mean number of oocytes retrieved (11.1 vs. 11.2, P 0.8), and the number of oocytes injected with sperm (9 vs. 8.8, P 0.6). The sperm used were ejaculated in 94 vs. 93.4% (P 0.9), while surgically retrieved in 6 versus 5.2% (P 0.9) in groups I and II, respectively. The post sperm prepar-ation motility was 89 vs. 88% (P 0.24). The mean number normally fertilised oocytes was 6.1 vs. 6 in group I and II, respectively (P 0.6), while the number of embryos transferred was 1.7 versus 1.6 (P 0.5). The number of surplus embryos cryopreserved at the blastocyst stage was 2.3 versus 2.1 (P 0.12). The preg-nancy, clinical pregnancy and implantation rates were 38 versus 37, 31 versus 30 and 29 versus 27 in groups I and II, respectively, P 0.5, 0.4, 0.2).

Limitations, reasons for caution: This is the first study conducted pro-spectively on a large number of participants. However we evaluated time points up to 2 hours then between 2 and 5 hours post oocyte retrieval. Assessing hourly intervals of retrieval-denudation timings may be more informative.

Wider implications of the findings: The lack of a significant impact of the denudation time on ICSI-outcome has important implications; a delay may pre-sent logistical challenges in the laboratory and avoidable financial constrains. Reducing the time over which ICSI is completed can streamline the workload and allow more patients to access the treatment.

Trial registration number: N/A.

P-113   Sperm-specific Phospholipase-C-isoform zeta (PLCζ) is the physiological trigger of calcium oscillation in mammalian eggs

A. Hachem[1], J. Godwin[2], M. Ruas[1], H.C. Lee[3], M.F. Buitrago[4], G. Ardestani[3], A. Bassett[5], S. Fox[6], P. De Sutter[4], B. Heindryckx[4], R. Fissore[3], J. Parrington[1]

[3]University of Massachusetts, Veterinary and animal sciences, Massachusetts, U.S.A.
[4]University of Ghent, Department for Reproductive Medicine, Ghent, Belgium
[5]University of Oxford, Pathology, Oxford, United Kingdom
[6]University of Oxford, Medical science, Oxford, United Kingdom

Study question: What is the physiological agent of calcium oscillation and egg activation in mammals?

Summary answer: Sperm-specific Phospholipase-C-isoform zeta (PLCζ) is the physiological trigger of calcium oscillations in mammals. However, calcium oscillation-independent fertilisation can still occur, albeit at greatly reduced efficiency.

What is known already: Calcium oscillation is initiated after sperm entry into the oocyte in mammals. A series of calcium spikes triggers cortical reactions to block polyspermy, resumption of the second meiotic division, and metabolic activation of the egg that precedes the first embryonic cell division. This process has been proposed to be caused by a sperm-specific PLCζ. PLCζ acts by catalysing the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) within the membrane of the oocyte to generate inositol 1,4,5-trisphosphate (InsP3). InsP3 binds to its receptor on the endoplasmic reticulum causing Ca^{2+} to be periodically released from the internal stores as Ca^{2+} spikes.

Study design, size, duration: CRISPR/Cas9 gene editing tool was used to knockout the *Plcz1* gene in mice. Two strategies were employed targeting different exons of *Plcz1*: one used Cas9^{WT} endonuclease with single sgRNA, the other used Cas9^{D10A} nickase with two paired sgRNAs. From selected F0 animals showing frameshift-producing deletions, two mutant *Plcz1* mouse lines were produced: *Plcz1*^{em1Jparr} generated using Cas9^{D10A} nickase (22-nucleotide deletion in exon 3), and *Plcz1*^{em2Jparr} generated using Cas9^{WT} endonuclease (17-nucleotide deletion in exon 5).

Participants/materials, setting, methods: To study the effect of the mutation on spermatogenesis and other sperm parameters, testicular tissue was examined by sectioning and staining methods, while epididymal sperms were evaluated in terms of viability, motility and hyperactivation, and the ability to induce acrosome reaction. For egg activation and calcium imaging, mouse eggs were incubated with Ca^{2+}-sensitive fluorescent dye, and fertilized by ICSI. Calcium spikes were registered as the 340/380 nm excitation ratio of fluorescence.

Main results and the role of chance: Histological analysis of PLCζ knockout male testes indicated no defects in spermatogenesis. Epididymal sperm showed standard viability, motility and hyperactivity parameters, which reflects their ability to undergo capacitation. Additionally, the ability of PLCζ-null sperm to undergo the acrosome reaction in response to either progesterone or ionomycin was undistinguishable from sperm of wild type animals. Collectively, these results demonstrate that loss of PLCζ has no apparent detrimental effects on spermatogenesis or parameters associated with the sperm's ability to bind and fuse with the egg. However, calcium oscillation studies post ICSI procedure showed that injecting PLCζ-null sperm from either line had failed to induce calcium oscillations ($P < 0.0001$). Such calcium oscillations were however triggered by subsequent injection of *Plcz1*^{WT} cRNA. Remarkably however, some eggs fertilized by PLCζ-null sperm can develop, albeit at greatly reduced efficiency (two-cell stage: $P < 0.01$; blastocyst: $P < 0.01$), and after a significant time-delay. Suggesting that in PLCζ's absence, eventual, spontaneous egg activation can occur via an alternative route. The study also showed evidences of increased level of polyspermy in oocytes fertilised with PLCζ-null sperm ($P < 0.05$), due to the role of calcium oscillations in egg cortical reaction.

Limitations, reasons for caution: Deciphering whether egg activation is calcium dependent or independent is technically challenging due to the difficulty in extending calcium recordings as there is a reduction in oocyte viability. Nonetheless, we have shown that loss of calcium oscillation reduces the rate of fertilization.

Wider implications of the findings: This is the first demonstration that *in vivo* fertilization without calcium oscillations can result in offspring. PLCζ-null sperm now make it possible to resolve long-standing questions in fertilization biology, and test the efficacy and safety of artificial egg activation stimuli used to treat egg activation deficiency in human infertility.

Trial registration number: N/A.

P-114 Embryonic progesterone receptors: Do they have a role in the implantation and post-implantation development?

F.J. Huang[1], W.H. Chan[2], Y.D. Hsuuw[3], K.C. Lan[4], P.Y. Lin[4], H.J. Chiang[4], Y.J. Lin[4], Y.R. Tsai[5], Y.T. Su[4]

[5]Chiayi Chang Gung Memorial Hospital, Department of Obstetrics and Gynecology, Chiayi, Taiwan R.O.C.

Study question: Do progesterone receptors in the blastocysts have a physiological role in the implantation and post-implantation development?

Summary answer: The implantation and post-implantation development of mouse blastocysts in vitro were adversely affected by blocking progesterone receptors (PR) using PR blockers.

What is known already: The effects of progesterone depend on the existence of their specific receptors. Although PR mRNA was not found in oocytes, fertilized eggs and cleaving embryos, the expression level began to appear at the blastocyst stage. The embryonic expression of PR genes in the blastocyst suggests a possible functional requirement for PR at this stage of development. These results provide a basis for determining the direct role of progesterone in pre-implantation and post-implantation embryo development.

Study design, size, duration: The physiological function of the PR was evaluated by using the PR blockers. Mice blastocysts were cultured for 8 days to evaluate the morphological development. 700 blastocysts were collected from the ICR female mice for the in vitro culture. 100 blastocysts were collected for the immunocytochemical assay to detect the PR in the pre-implantation embryos.

Participants/materials, setting, methods: This was an in vitro experimental study involving the use of mouse blastocysts and the model of in-vitro 8-day culture. Under the RU-486 treatment, implantation and post-implantation development were evaluated daily. The differential staining of blastocysts following the treatment of RU-486 was performed to investigate its effects on the cell proliferation and apoptosis. The PR proteins in the pre-implantation and post-implantation embryos were detected through the immunocytochemical assay.

Main results and the role of chance: The PR proteins were immunostained in the pre-implantation embryos, especially at the early post-implantation stage; the implanted blastocysts and early egg cylinder stage embryos. Following the treatment of RU-486 at the concentration of 10^{-9} M or 10^{-7} M, the development from the implanted blastocysts to early somite stage in vitro 8-day culture was not affected in comparison to control group. However at the concentration of 10^{-5} M of RU-486, the development of later egg cylinder stage and early somite stage was severely affected (39.2 vs 56.4%; 24.5 vs 40.5%; treated vs control). The cell number in the inner cell mass of blastocysts following the 48-hr treatment with RU-486 was adversely inhibited. Conversely, the inhibition of trophectoderm proliferation was mild affected. In conclusion, the dose-dependent adverse effects of PR blocker on the implantation and post-implantation development were demonstrated clearly. Reviewing the literatures, this is the first study to show the physiological role of PR in the blastocysts and post-implantation embryo development.

Limitations, reasons for caution: Considering the ethical and technical limitations inherent to the use of human embryos for implantation studies, the mouse model was used as an approach for exploring the potential role of embryonic PR on the implantation and post-implantation embryo development. Nevertheless, the extrapolation of these results to humans requires further investigation.

Wider implications of the findings: This study presents clear evidence on the potential role of embryonic PR on the implantation and post-implantation embryo development. These new findings could contribute to the physiological knowledge of human embryo culture for the clinical applications in in-vitro –fertilization protocol.

Trial registration number: Not clinical trial.

P-115 Is there any correlation between oocyte polarization microscopy findings with embryo time lapse monitoring in ICSI program?

A. Faramarzi[1], M.A. Khalili[2], A. Agha-Rahimi[2]

[1]Clinical and Research Center for Infertility, Clinical and Research Center for Infertility - Shahid Sadoughi University of Medical Science, Yazd, Iran
[2]Research and Clinical Center for Infertility- Shahid Sadoughi University of Medical Sciences- Yazd- Iran, Research and Clinical Center for Infertility, Yazd, Iran

Study question: Is there a relationship between the presence of the meiotic spindle (MS) and zona pellucida (ZP) birefringence of MII oocytes with morphokinetic variables of embryos?

Summary answer: High ZP birefringet and visualized MS oocytes have different morphokinetic behavior compared with low ZP birefringet and no visualized MS oocytes.

What is known already: Oocyte quality, especially optimal cytoplasmic and nuclear maturity is one of the most important variables determining the developmental potential of embryos. In an effort to optimize the outcomes of ART treatment, a noninvasive method, polarization microscopy imaging, for evaluating ZP birefringence and MS visualization has been adjudged as predictor factor for oocyte quality. To our knowledge, reports on possible impact of ZP birefringence and MS on early embryo morphokinetic are so limited.

Study design, size, duration: This prospective study on 54 patients performed between November 2015and October 2016. After injection, 478 MII oocytes were cultured in time-lapse incubator. The morphokinetic behavior of each embryo was monitored until day 3.

Participants/materials, setting, methods: Using a polarized microscopy, the ZP birefringence and presence of MS in MII oocytes were evaluated pre ICSI. Also, morphokinetic variables (absolute and relative time points, including time to 2nd PB extrusion (ESPB), pronuclei appearance (PNA), PN fading (PNF), time to 2 cells (t2), t3, t4, t5, t6, t7, t8, S1 (t2-PNF), S2 (t4-t3), CC2 (t3-t2) and CC3 (t5-t3) as well as abnormal cleavage patterns of 368 embryos were analyzed with time lapse monitoring (TLM).

Main results and the role of chance: t5 occurred earlier in high birefringent ZP compared with low birefringent oocytes (p = 0.001). In addition, t2 happened later in invisible MS compared to visible MS oocytes (p = 0.01). The rates of reverse cleavage as well as reverse and direct cleavages were significantly less in oocytes with high birefringent and visible MS, respectively (p = 0.005, p = 0.001 and p = 0.001).

Limitations, reasons for caution: The limitations of this study were small sample size plus lack of data on the implantation and pregnancy outcomes. Therefore, future studies are warranted to validate findings of the present study.

Wider implications of the findings: The present study focused on the ZP birefringence and MS integrity of the oocytes and its relationship with morphokinetic parameters and atypical cleavage using TLM. It seems that embryo selection based on polarization microscopy imaging can ameliorate good morphokinetc embryos with high implantation potential for single embryo transfer program.

Trial registration number: None.

P-116 Spermatozoa piRNA levels correlate to sperm concentration and fertilization rate after ICSI

Y. Ye[1], L. Cui[2]

[1]Women's Hospital- School of Medicine- Zhejiang University, Reproductive Endocrinology, Hangzhou, China
[2]Women's Hospital- Zhejiang University School of Medicine, Department of Reproductive Endocrinology, Hangzhou, China

Study question: Is there any relationship between spermatozoa PIWI-interacting RNAs (piRNAs) levels and semen parameters? Does spermatozoa piRNAs play a role in fertilization and embryo development after intracytoplasmic sperm injection (ICSI) treatment?

Summary answer: Spermatozoa piRNA levels correlate with sperm concentration and fertilization rate after ICSI.

What is known already: Sperms contain several small noncoding RNAs, such as microRNAs (miRNAs), piRNAs and endogenous small interfering RNAs. Several transcripts present in human spermatozoa and zygote are absent in unfertilized oocytes, suggesting that spermatozoa deliver these transcripts to oocyte during fertilization and that they may play a role in subsequent zygote and embryonic development. piRNAs are mainly expressed in pachytene spermatocytes and spermatids, suggesting direct roles in spermatogenesis. The concentration of seminal plasma piRNAs are altered in infertile patients with azoospermia and asthenozoospermia compared with fertile control. Next generation sequencing revealed that 20121 piRNAs are present in human testis.

Study design, size, duration: Retrospective observational study was performed in 186 patients undergoing ICSI from April 2014 to May 2015.

Participants/materials, setting, methods: Participants includes couples who underwent first ICSI cycles in our University affiliated IVF unit with the diagnosis of male factor infertility. The levels of three piRNAs (hsa-piR-31704, hsa-piR-39888 and has-piR-40349) in spermatozoa were measured by real time RT-PCR. The relationship between semen parameters and spermatozoa piRNA levels was investigated. And the effect of piRNA expressions on fertilization and embryo development after ICSI treatment was assessed.

Main results and the role of chance: Spermatozoa levels of piR-31704 and piR-39888, but not piR-40349 were decreased in male factor infertility group as compared with control group (piR-31704, P = 0.027; piR-39888, P = 0.041). And these two piRNAs were expressed at higher levels in patients with normal sperm concentration compared with subnormal sperm concentration group (piR-31704, P = 0.042; piR-39888, P = 0.047), while there were no correlation between the three piRNAs levels in spermatozoa and the rates of sperm progressive motility and normal sperm morphology. There were significant increases of spermatozoa piRNAs levels from the group with higher 2PN rates (piR-31704, P = 0.002; piR-39888, P < 0.001; piR-40349, P < 0.001), but there was no correlation between spermatozoa levels of these three piRNAs and the rates of embryo early cleavage, Day-3 good-quality embryo and pregnancy.

Limitations, reasons for caution: Only ICSI cycles using ejaculated sperms were included in our study. And we only evaluated the levels of three piRNAs which were most abundantly expressed in human testis.

Wider implications of the findings: The present study demonstrated a paternal effect of piRNA on fertilization, which has not been reported before. After prospective confirmatory studies are performed, piRNAs may be used as indicator of fertilization to provide male infertility patients proper treatment before they undergo ICSI cycles.

Trial registration number: no.

P-117 Dehydroepiandrosterone sulphate (DHEAs) supplementation: A promising non-invasive futuristic strategy for oocyte activation in IVF cycles

B.N. Chimote[1], N. Nath[2], N.M. Chimote[3]

[1]Vaunshdhara Clinic & Assisted Conception Centre, Embryology- Endocrinology, Nagpur, India
[2]Vaunshdhara Clinic and Assisted Conception Centre, Biochemistry- Endocrinology, Nagpur, India
[3]Vaunshdhara Clinic and Assisted Conception Centre, Embryology- Endocrinology, Nagpur, India

Study question: To investigate if baseline Day3 serum DHEAs levels in PCOS/Non-PCOS women undergoing IVF could be indicative of oocyte activation and its competence to undergo fertilization.

Summary answer: DHEAs levels in Baseline serum strongly correlate with number of MII oocytes and fertilization rates thus implicating its significant role in augmenting oocyte activation

What is known already: The sulfonated steroid DHEAs is considered to be a storage reservoir for DHEA and an inactive component in follicular steroidogenesis. However recently, DHEAs has been implicated in generation of calcium oscillations necessary for oocyte activation and its impending fertilization. Due to its unique chemical properties, this 'androgen' behaves so much like an anti-androgen that it has been proposed to be an important, potentially major endogenous estrogen in the body. Lower fertilization rates have been reported in elderly/poor responder women as well as PCOS women. Therefore, we hypothesized that DHEAs may play a significantly major role in oocyte activation and fertilization.

Study design, size, duration: In lieu of our previous study with FF DHEAs, we prospectively estimated baseline D3 serum DHEAs levels in all women (PCOS/non-PCOS, poor/average/high responders; n = 680) undergoing antagonist stimulation protocol from August 2014- December 2016 at our private infertility centre. Out of these, n = 46 cycles had total fertilization failure (TFF). So, n = 634 cycles were evaluated for fertilization rates and embryo development to blastocyst stage. DHEAs level in day3 serum sample was measured by Radio-immuno assay (RIA) method.

Participants/materials, setting, methods: Cycles were initially classified on the basis of ovarian response into poor (<5 eggs retrieved), average (5-15 eggs retrieved) and hyper-responders (>15 eggs retrieved). Women were then classified into PCOS (n = 102) and Non-PCOS (n = 532) groups and each of these groups were subsequently divided into Low, Medium and High Baseline DHEAs Groups respectively (PCOS: n = 26, <100 µg/dL; n = 50, 100-191 µg/dL; n = 26, > 191 µg/dL. Non-PCOS: n = 140, <98 µg/dL; n = 256, 98-179 µg/dL; n = 136, > 179 µg/dL). Statistical analysis was done using Prism VI software.

Main results and the role of chance: Low and Medium groups of Non-PCOS women differed significantly in mean number of MII oocytes (6.7 and 7.0 vs. 8.8,p = 0.03), Fertilization (63 and 67 vs. 81%,p < 0.0001), Cleavage (61.5 and 64 vs. 80,p < 0.0001) and Blastocyst formation (25 and 29 vs. 39%, p = 0.01) rates compared to High day3 DHEAs group, whereas there was no such statistical difference in these parameters between low vs. medium groups (p > 0.05). Among the PCOS group, number of MII oocytes (22.07 and 22.15 vs. 25.1, p = 0.02), Fertilization (59 and 55 vs. 69%,p = 0.0003, 0.03), Cleavage (59 and 54 vs. 68%,p = 0.0006, 0.03) and Blastocyst formation rates differed significantly when compared between low and high vs. medium but not between low vs. high day3 DHEAs groups. Fertilization rates correlated with day3 DHEAs levels (Pearson r = 0.22, 95%CI=0.14-0.29). After correcting for very high levels of DHEAs in PCOS women at which also low fertilization rates were observed, Pearson r = 0.52. Lower threshold of day3 DHEAs for fertilization was >95 µg/dL whereas upper threshold limit was <270 µg/dL (ROC$_{AUC}$ = 87.48, p < 0.0001, Sensitivity 71.92%, Specificity 78.08%). These results suggest that while high baseline DHEAs levels (95-270 µg/dL: PCOS/Non-PCOS) are conducive, very low (<95 µg/dL:PCOS/Non-PCOS) and very high levels (>270 µg/dL:PCOS), are detrimental for oocyte activation, fertilization and embryonic development.

Limitations, reasons for caution: Larger multicentric studies are required to establish the exact metabolic role of DHEAs in the process of generation of calcium oscillation and oocyte activation. Extensive research is necessary to arrive at a threshold physiologic, ovarian (not adrenal) dose of DHEAs that will be sufficient for oocyte activation in IVF cycles.

Wider implications of the findings: Mechanical, chemical, electrical methods of oocyte activation with calcium ionophores, recombinant PLCζ, mitochondrial insertion have been employed for oocyte activation. However, these are invasive or may cause unknown epigenetic effects. Therefore, understanding oocyte physiology, metabolism and endocrine pathways may prove to be more effective for oocyte activation with DHEAs supplementation.

Trial registration number: Not applicable.

P-118 Clinical outcomes of day 5 morula transfer are acceptable when no blastocysts are available after prolonged embryo culture

I. Virant - Klun, J. Kmecl, L. Bacer-Kermavner, B. Valentincic-Gruden, J. Mivsek, M. Stimpfel, S. Korosec, E. Vrtacnik-Bokal

University Medical Centre Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia

Study question: How do morula and blastocyst transfers on day 5 differ in terms of pregnancy rate and outcome in the in vitro fertilization programme?

Summary answer: On day 5, the outcome of morula transfer is poorer than that of blastocyst transfer but is acceptable in terms of pregnancy rates and outcomes.

What is known already: It is not evident what is the clinical outcome of morula transfers, when no blastocysts are available. Rare studies have shown that day 5 morulae may result in an acceptable pregnancy rate (Wilson et al., 2004), although no pregnancy outcome has been reported. A significant proportion of morulae on day 5 are euploid, and the majority of them progress to the blastocyst stage by day 6 (Kort et al., 2015). Compacted morula transfer on day 5 may be a good alternative to day 6-7 blastocyst transfer (Su et al., 2016) in delayed embryos not to miss the implantation window.

Study design, size, duration: In this retrospective study we compared the clinical outcomes of early and expanding/expanded blastocyst and compacted morula transfers (if no blastocysts were available) after prolonged embryo culture to estimate the clinical outcomes of delayed embryos. The study included

694 compacted morula and 3007 blastocyst (246 early and 2761 expanding/expanded blastocysts) transfers performed between January 2011 and September 2015; the transfers were compared in terms of clinical pregnancy outcome, and newborn characteristics at birth.

Participants/materials, setting, methods: In women aged 24-43 years one or two optimal embryos were transferred into the uterus on day 5: blastocysts (early or expanding/expanded) or compacted morulae (if no blastocysts were available) based on Gardner and Schoolcraft scoring system. The factors affecting the developmental stage of transferred embryos and clinical outcomes (pregnancy and birth characteristics) of morula and blastocyst transfers were compared using the statistical tests (Chi-Square, Mann-Whitney U test, logistic regression) with significance set at p < 0.05.

Main results and the role of chance: The compacted morulae were transferred in 18.7%, early blastocysts in 6.6%, and expanding/expanded blastocysts in 74.7% of transfers. The developmental stage of transferred embryos was connected to female age (p < 0.001; OR 0.960; 95%CI 0.940-0.980) and endocrine disturbances (p = 0.012; OR 0.765; 95%CI 0.621-0.942), number of oocytes (p < 0.001; OR 1.072; 95%CI 1.051-1.092), ICSI (p < 0.001; OR 0.666; 95%CI 0.540-0.822), and sperm motility (p = 0.003; OR 1.007; 95%CI 1.002-1.011). The clinical pregnancy rate increased with increasing developmental stage of embryos (13.5%, 28.0%, and 44.1%); after morula transfer the pregnancy rate was significantly lower than after early and expanding/expanded blastocyst transfer (p < 0.01) but acceptable. There were no significant differences in ectopic pregnancy (1.0%, 1.4%, and 0.7%), miscarriage (25.5%, 31.9%, and 22.8%), and twin pregnancy (18.0%, 16.3%, and 14.1%) rates regarding the developmental stage of transferred embryos. The monozygotic twin pregnancy occurred after the transfer of a single expanding/expanded blastocyst (0.8% of pregnancies) but not in earlier stages. At birth, there were no differences in gestational age. The mean birth weight of singleton newborns (n = 797) did not differ significantly: 3203.4 g (range: 760-4470) after morula transfer (n = 55), 3201.5 g (range: 1050–4260) after early blastocyst transfer (n = 36), and 3202.8 g (range: 620–5310) after expanding/expanded blastocyst transfer (n = 706).

Limitations, reasons for caution: The results of this study show acceptable pregnancy and birth rates after transfer of compacted morulae on day 5, if no blastocysts are available. The analysis of the health status of babies born after morula transfer has been undertaken in our centre to make relevant conclusions.

Wider implications of the findings: In spite of several advantages, there are some negative aspects of prolonged embryo culture: a relatively low proportion of embryos developing to the blastocyst stage and a higher embryo transfer cancellation rate. This may be improved by morula transfer in couples without blastocysts on day 5 after prolonged embryo culture.

Trial registration number: This retrospective study was approved by the National Medical Ethical Committee; the clinical trial registration number is not needed.

P-119 Live birth delivery predictors of ICSI cycles with ejaculated sperm

A.M. Pinto[1], M. Sousa[2], J. Silva[3], P. Viana[3], M. Cunha[3], N. Barros[3], C. Oliveira[4], J. Teixeira da Silva[4], P. Xavier[4], A. Couceiro[4], A. Barros[5]

[2]*Institute of Biomedical Sciences Abel Salazar- UMIB- Univ. Porto, Microscopy- Lab. Cell Biology-, Porto, Portugal*
[3]*Centre for Reproductive Genetics A. Barros, IVF Lab, Porto, Portugal*
[4]*Centre for Reproductive Genetics A. Barros, IVF Clinics, Porto, Portugal*
[5]*Centre for Reproductive Genetics A. Barros- Faculty of Medicine- University of Porto-I3S, Director, Porto, Portugal*

Study question: To assess whether some critical factors in intracytoplasmic sperm injection (ICSI) cycles can be used to predict the likelihood of live birth delivery (LBD).

Summary answer: In ICSI with ejaculated sperm, several cut-offs of demographic, stimulation, embryological and clinical characteristics were found associated with an increased likelihood of live birth.

What is known already: Although numerous studies have tried to establish predictive clinical factors associated with a higher likelihood of attaining a live birth, there is still no consensus.

Study design, size, duration: Retrospective evaluation of 3844 treatment cycles using homologous ejaculated sperm and intracytoplasmic sperm injection, conducted at the Centre for Reproductive Genetics A. Barros between 2003 and 2014 (11 years).

Participants/materials, setting, methods: The 3844 ICSI cycles were divided in two groups according with their outcomes and compared regarding demographic, stimulation, embryologic, clinical and newborn (NB) characteristics: 993 cycles (25.8%) with NB and 2851 cycles (74.2%) without NB. Seropositive, anejaculation, retrograde ejaculation, preimplantation genetic diagnosis and Y chromosome microdeletions cases were excluded.

Main results and the role of chance: Higher LBD rate was associated to the following factors. Demographic: lower age and lower bFSH levels. Stimulation: lower total dose of gonadotropins, time of stimulation and dose of HCG, higher number of follicles and estradiol levels. Embryologic: higher number of aspirated oocytes and mature oocytes, and higher rates of embryo cleavage, high quality embryos and blastocysts.

Based on the present results and on those of the literature it is possible to suggest the following cut-off associated with a higher likelihood of LBD. Female age $\leq$ 35y; time of infertility $\leq$ 5y (ideal: < 2y); bFSH $\leq$ 10 IU/L; both antagonist and agonist protocols, as well as rFSH and HMG, gave similar outcomes, and thus the decision for one or another should be patient personalized; estradiol levels 2000-4000 pg/ml (3000-4000 pg/ml if women <38y; 2000-3000 pg/ml if women > 38y); number of follicles $\geq$ 4 (maximum: 14); number of aspirated oocytes $\geq$ 4 (maximum: 15); number of mature oocytes $\geq$ 4 (maximum: 15); number of high quality embryos $\geq$ 3; day 3 single embryo transfer when women <35y; day 3 double embryo transfer when women > 35y; single embryo transfer of blastocysts; no relation between spermiogram values and LBD.

Limitations, reasons for caution: This study included only ICSI cycles with ejaculated sperm. Additionally, seropositive, anejaculation, retrograde ejaculation, preimplantation genetic diagnosis and Y chromosome microdeletions cases were excluded. Thus, findings should remain restricted to this kind of patients.

Wider implications of the findings: From the analysis of a large series of 3844 ICSI cycles, data revealed critical demographic, stimulation and embryological factors, and cut-offs for live birth delivery are suggested. These findings are considered relevant for clinical guidance and patient information regarding the likelihood of achieving a live birth delivery.

Trial registration number: None.

P-120   Fresh embryos versus all-freezing embryos transfers strategies: nuances of a meta-analysis

F. Dieamant[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], V.A. Comar[1], M.C. Mattila[1], L.D. Vagnini[2], A. Renzi[2], B. Petersen[2], A. Nicoletti[1], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis- Research and Training, Research, Ribeirao Preto, Brazil

Study question: Can cryopreservation of all embryos with subsequent embryo transfers (ALL/FREEZE-ET) promote improvements in clinical ART outcomes compared to fresh embryo transfers (FRESH-ET)?

Summary answer: The all-frozen embryo transfer strategy does not have an advantage compared to fresh embryo transfer if the mean number of oocytes collected was <15.

What is known already: Meta-analysis is a powerful tool and considered the highest in the evidence-based pyramid, but their strength depends on the quality of randomized controlled trails (RCTs) analyzed. Recently, a RCT including high-responders patients, and favorable to the use of the All/Freeze-ET was retracted of the literature access (Aflatoonian,2010). This retracted RCT composes a relatively recent meta-analysis (Roque,2013) concerning of the beneficial effects of cryopreservation and subsequent frozen-embryo transfer, but with the removal of the previously mentioned study, the prior meta-analysis (Roque,2013) loses its power to assist in medical decision when the All/Freeze-ET should be used or not in clinical practice.

Study design, size, duration: A systematic review based on electronic searches in databases (PubMed, EMBASE, Web of Science, SCOPUS, and Cochrane Central Register of Controlled Trials; Keywords: all-freezing; poor-/normal-/high-responder; clinical outcomes; collected oocytes) up to December/2016 were conducted to identify RCTs that compare the ART outcomes of fresh versus elective frozen embryo transfer. The primary outcome was ongoing pregnancy rate (per woman randomized). Secondary outcomes included clinical pregnancy rate (per patient randomized) and miscarriage rates (from clinical pregnancy).

Participants/materials, setting, methods: Four RCTs (Shapiro et al.,2011a;Shapiro et al.,2011b;Chen et al.,2016;Vuong et al.,2016) were included as targets for data extraction and meta-analysis involving 2,549 women. Data were combined for meta-analysis using the StatsDirect statistical software. Dichotomous data were expressed as relative risk (RR) with a 95% confidence interval (CI). The measure of heterogeneity was evaluated using the Cochran's Q and I^2 tests. Study data were combined using a random-effects model. P-values<0.05 were considered statistically significant.

Main results and the role of chance: The results of this meta-analysis were divided into two parts: Part I- All trials where the mean of the collected oocytes was > 12 and <21; and Part II- Three studies where the mean number of oocytes retrieved was > 12 and <15.

Part I:

(1) Ongoing pregnancy rates: FRESH-ET: 44.3% (568/1282) versus ALL/FREEZE-ET: 48.3% (612/1267) with statistically significant differences (RR=1.09; 95%CI=1.01-1.19; P = 0.03). Heterogeneity: I^2=0%; Cochran Q=2.0, P = 0.57.

(2) Clinical pregnancy rates: FRESH-ET: 55.1%, (491/891) versus ALL/FREEZE-ET: 59.2% (519/876) with no significant differences (RR=1.12; 95%CI=0.97-1.31; P = 0.13). Heterogeneity: I^2=34.5%; Cochran Q=3.05, P = 0.22.

(3) Miscarriage rates: FRESH-ET: 13.1% (68/519) versus ALL/FREEZE-ET: 10% (52/519) with no significant differences (RR=0.71; 95%CI=0.51-1.01; P = 0.05). Heterogeneity: I^2=0%; Cochran Q=0.16, P = 0.92.

Part II:

(1) Ongoing pregnancy rates: FRESH-ET: 43.8% (534/1220) versus ALL/FREEZE-ET: 47.6% (574/1207) with no significant differences (RR=1.09; 95%CI=1.00-1.19; P = 0.052). Heterogeneity: I^2=0%; Cochran Q=1.90, P = 0.39.

(2) Clinical pregnancy rates: FRESH-ET: 55.1% (457/829) versus ALL/FREEZE-ET: 58.8% (480/816) with no significant differences (RR=1.15; 95%CI=0.88-1.49; P = 0.30). Heterogeneity: Cochran Q=2.6, P = 0.11.

(3) Miscarriage rates: FRESH-ET: 13.8% (63/457) versus ALL/FREEZE-ET: 10.0% (48/480) with no significant differences (RR=0.71; 95%CI=0.50-1.01; P = 0.06). Heterogeneity: Cochran Q=0.16, P = 0.69.

Limitations, reasons for caution: Data regarding clinical/ongoing pregnancy rates were included without data on live births. In addition, all trials included patients who were considered normal/high-responders; therefore, these results may not be held for the poor-responders. More RCTs are required to evaluate whether the all-freezing strategy can influence the clinical outcomes.

Wider implications of the findings: The all-freezing strategy could be favourable when high numbers of oocytes were collected, signalizing one association between higher COS and the consequent impairment of endometrial receptivity. However, when the number of oocytes collected was <15, the all-freezing strategy does not appear to be advantageous.

Trial registration number: Not applicable. The local Research Ethics Committee approved the study.

P-121   Glycan profile of blastocyst spent culture medium varies in implantation success vs failure: a potential non-invasive viability assay

W. Shi[1], J. Shi[2], X. Xue[2]

[1]Northwest women and children's Hospital, Assisted Reproduction Center, Xi'an, China
[2]Northwest women and children's Hospital, Assisted Reproduction Center, Xi'an, China

Study question: Is there any difference of glycan profile in blastocyst spent culture medium between implantation success and failure group?

Summary answer: The gycopattern and expression levels in blastocyst spent culture medium showed significant statistical difference between successful implantation and failure implantation.

What is known already: Current methods of pre-implantation selection of embryo mainly are subjective and inefficient. Glycan profile may reflect health condition and interaction capability of embryo with uterus, however currently there has not been any report on glycan profiling for prediction of embryo viability and implantation rate. Glycan profile can be assessed in spent culture medium non-invasively.

Study design, size, duration: This was a case-control study to compare the difference of gycopattern and expression levels in the blastocyst spent culture medium grouped according to the implantation results. A total of 78 cases (success vs failure, 39 samples each) of blastocyst spent culture medium were analyzed by lectin array (37 lectins). The lectins with difference were chosen to further verify by sample microarray stained with specific lectin and lectin blot.

Participants/materials, setting, methods: The patients were enrolled underwent single blastocyst transfer on day 5 in fresh IVF/ICSI cycles. A total of 78 cases of blastocyst spent culture medium were analyzed. The half of one sample in each group was pooled and spotted on the lectin microarray. Another half of one sample was produced as sample microarray to further verify by sample microarray stained with specific lectin.

Main results and the role of chance: The blastocyst spent culture medium (success vs failure) was detected by lectin microarray (37 lectins) (Fig 2). 10 lecins (AAL, NPA, UEA-I, MAL-I, LCA, PHA-E+L, GNA, DBA, BPL, LTL) showed the significant difference of NFLs fold change (>1.5-fold or <0.67-fold) (Table 1). In the blastocyst culture medium with successful implantation, 6 specific glycans (NPA, UEA-I, MAL-I, LCA, PHA-E+L, GNA) showed up-regulation and 4 (AAL, LTL, DBA, BPL) showed down-regulation. LCA specific glycan structure showed the highest change fold of up-regulation (ratio=3.900). LTL failed to be detected in blastocyst culture medium microarray. The other 9 lectins were followed by blastocyst culture medium microarray analysis and lectin blot analysis (Fig 3). All 9 lectins showed the significant statistical difference in blastocyst spent culture medium between successful implantation and failure implantation. Of these, the difference of UEA-I, LCA and GNA were the most significant with p < 0.001.

Limitations, reasons for caution: Successful implantation is a complex process involves reciprocal interactions between blastocyst and uterus. The current study does not assess the uterus factors such as endometrial receptivity. In addition, the results are affected by numerous risk factors which may cause bias in the results in spite of exclusion of special cases.

Wider implications of the findings: The results suggest that the change of glycan profile in spent culture medium may led to a novel non-invasive assessment assay of embryo viability. These results may be helpful to understand about glycobiology of embryo implantation.

Trial registration number: ChiCTR-DOD-15006743

P-122 the relationship between embryo gender and morphokinetics parameters analyzed by time-lapse imaging in human embryo

H. Hattori[1], Y. Nakajo[1], N. Aono[1,2], H. Igarashi[1], K. Kyono[1,2]

[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan

Study question: The gender-related differences in embryo morphokinetics are still not well known. Does the gender difference of human embryo affect embryo morphokinetics parameters?

Summary answer: In early stage embryo, the male showed significantly earlier development and shorter cell cycles than the female. These results suggested that embryo gender affects morphokinetics.

What is known already: Many studies have reported that there might be gender-specific differences in human embryo development. Most studies have indicated that male embryos showed earlier development than female embryos. However, there are few studies that confirmed the gender-related differences in embryo development analyzed by TL imaging.

Study design, size, duration: This study is a retrospective observational study, conducted at Kyono ART Clinic in Japan from June 2013 to January 2016. It was approved by the Ladies Clinic Kyono Ethics Committee. A total of 65 euploid embryos from 53 patients were included in this study.

Participants/materials, setting, methods: Following ICSI, all embryos were monitored by TL system and morphokinetics parameters were analyzed. The data from 34 infants conceived by TL monitored embryo transfer and 31 discarded blastocysts that were confirmed normal karyotype by next-generation sequencing were analyzed. Chi-squared and Mann-Whitney U tests were used for statistical analysis.

Main results and the role of chance: There was no significant difference in parental age between embryo genders. The gender ratio in the infants and the embryos were 41.1% and 48.4% male respectively, and there were no differences in the gender ratio of both groups. Male embryos showed significantly faster morphokinetics parameters such as time of cleavage to 5-cell (t5) (t5: 48.7 ± 6.6 vs. 51.8 ± 5.1, P = 0.045) and the third cell cycles (cc3=t5-t3) (cc3: 13.2 ± 2.8 vs. 14.6 ± 2.1, P = 0.023) than female embryos. Although male embryos showed faster morphokinetics parameters from time of cleavage to 6-cell (t6) to time of expanded blastocyst (tExpand) than female embryos, yet the results did not reach statistical significance.

Limitations, reasons for caution: Unlike previous studies, our study could not show gender-specific development patterns such as faster blastocyst formation in male embryo. There is a possibility that our results have been influenced by small sample size of our study.

Wider implications of the findings: We found a strong relationship between embryo gender and development speed in early stage embryo. At the 4 to 8-cell stage, genome impression pattern is drastically changed because the embryo produces its own genome. Our results indicate that this phenomenon called zygotic gene activation has an effect on sex chromosomes.

Trial registration number: None.

P-123 Evaluation of efficacy of GM-CSF in embryo culture for frozen embryos on embryo development and pregnancy outcomes

S. Zafardoust, A. Mohammadzadeh, F. Fatemi, S. Jouhari, A. Karimi, A. Shahbakhsh, M. Barchinezhad, Z. Fathi, M.R. Sadeghi

Avicenna research institute, avicenna infertility clinic, Tehran, Iran

Study question: Does presence of GM-CSF in the embryo culture medium influence a thawed embryo's ability to grow and implant?

Summary answer: It is suggested that presence of GM-CSF in embryo culture of thawed embryos, has not effects on blastolation and implantation

What is known already: Naturally, there are GM-CSF (granulocyte macrophage-colony stimulation factor) and another growth factors in the female reproductive tract and they play a physiologic role in normal blastocyst development and embryo implantation. Ziebe showed that the incidence of blastulation in human embryos is increased when GM-CSF is present in the culture medium and was seen to significantly increase in implantation and survival of transferred embryos to week 12 gestation and live birth rate(2013). Herein, we attempted to evaluate the effect of adding GM-CSF in thawed embryo's media culture to determine the blastulation rate, implantation and clinical pregnancy rates

Study design, size, duration: The present randomized clinical trial was performed in Assisted Reproduction and Infertility Clinic affiliated to Avicenna Research Institute, Tehran, Iran, from February 2015 to January 2017, with a total of 90 patients. 10 patients were excluded from the final analysis due to different reasons.Blastocyst formation rate, Implantation and clinical pregnancy rates were the primary outcome measures

Participants/materials, setting, methods: Randomly, frozen embryos were thawed and cultured in control medium (n = 40,Vitrolife,USA) or test medium (n = 40, BlastGen,Denmark) containing 2 ng/mL GM-CSF. Pregnancy was tested by measuring serum beta-hCG levels 16 days after embryo transfer. The implantation rate and Clinical pregnancy was defined as the presence of

gestational sac and fetus with a heartbeat by vaginal ultrasonography at 7 weeks of pregnancy

Main results and the role of chance: Although the age of patients, the mean number (P = 0.155) and the quality of thawed embryos were similar in the two groups, there was not significantly differences in blastocyst (28.9% vs. 30.9%, P = 0.932), early blastocyst (9.2% vs. 8.9%, P = 0.716) and compact embryos (18.5% vs. 24.4%, P = 0.405) formation between two groups. Pregnancy (40% vs.32.5%, P = 0.642) and implantation (32.5% vs. 30%, P=1.000) rate did not have significant differences

Limitations, reasons for caution: Culture mediums that were used in this study were from different companies. It is better to design another studies with more patients and adding GM-CSF for another development stages of embryos

Wider implications of the findings: The present findings suggested that the presence of GM-CSF in culture medium after 3th day of development has not effect on blastulation in thawed embryos

Trial registration number: IRCT 2014021611430 N4.

P-124 Identification of a novel long intergenic noncoding RNA gene palying vital roles during porcine early embryonic development through genome-wide analysis

J. Li[1], G. Huang[2]

[1]Chong Qing Reproductive and Genetic Institute, Chong Qing Reproductive and Genetic Institute, chongqing, China
[2]Chong Qing Reproductive and Genetic Institute, Chong Qing Reproductive and Genetic Institute, Chong Qing, China

Study question: How does long intergenic noncoding RNA (lincRNA) regulate the gene expression network, and its subsequent effects on embryonic development in pig.

Summary answer: After genome-wide analysis, we identified a novel lincRNA palying vital roles during porcine early embryonic development.

What is known already: Many events are crucial for the whole embryonic development during the cleavage stage, including nuclear reprogramming, zygote genome activation (ZGA), and the first cell fate specification. Although a few have been mechanistically characterized, lincRNAs have emerged as a new field in biology, playing significant roles in many biological functions, including X chromosome inactivation, imprinting, cell apoptosis and cell cycle control, immune response, and mitochondria regulation. However, the underlying molecular mechanisms related to lincRNAs remain unclear. Overall, lincRNAs and/or their transcripts program various biological functions via epigenetic and nonepigenetic, mechanisms at the pre-transcriptional, transcriptional, and post-transcriptional levels.

Study design, size, duration: Five RNA-seq data sets from the NCBI SRA database were analyzed for predicting potential lincRNAs. The zygote microinjected with a novel linc-RNA locked nucleic acid (linc-RNA-LNA), control-LNA (negative control) and none (control) were used to evaluate the pronucleus formation, cleavage rate and blastocyst formation rate.

Participants/materials, setting, methods: RNA-seq data were analyzed by TopHat version 2.0.9, CNCI and CPAT were used to predict the coding potential. The expression pattern of these novel transcripts were analyzed by real-time quantitative PCR (qPCR). LincRNA depletion were performed through LNA microinjection at 3 h after ICSI. Nucleus stage, DNA damage and cell death were evaluated by EdU, γ-H2AX and Annexin-V assay. Pronucleus formation and pronucleus fusion were assessed at 12 h and 21-24 h after ICSI by Immunofluorescence staining.

Main results and the role of chance: Here we identified 7,618 novel lncRNAs from 4,776 loci based on published RNA-seq data. These lincRNAs show low exon number, short length, low expression level, tissue-specific expression and cis-acting, which is consistent with previous reports in other species. By weighted co-expression network analysis, we identified 5 developmental stages specific co-expression modules. A novel lincRNA depletion caused the developmental arrest at 1-cell stage. Then, we compared the nucleus stage among the three groups. Major of zygotes have entered or passed mitotic stage at 21 h after ICSI in control and negative control groups. Zygotes divided and entered the 2-cell stage at about 24 h after 24 h after ICSI. However, the male and female pronuclei begin to migrate toward each other,

but fusion did not occur in linc-RNA-LNA group. Meanwhile, we detected more DNA damage and cell death signals in the linc-RNA-LNA group. Futhermore, depletion of the lincRNA in one blastomere of the 2-cell embryo have no effect on the following cleavage, indicating that the lincRNA might only function in the first cell-cycle during embryonic development.

Limitations, reasons for caution: Findings in porcine may not be fully representative of human. Further functional studies are needed to explain the molecular mechanism.and determine the clinical significance.

Wider implications of the findings: Our study provide the first lincRNA profiles of procine early embryonic development. In particular, it is the first study reporting the function of lincRNA during porcine early embryonic development.

Trial registration number: NO.

P-125 Effects of direct cleavage on embryo development and clinical outcomes

M. Takahashi[1], Y. Nakajo[1], H. Hattori[1], N. Aono[1,2], M. Koizumi[1], M. Toya[1], M. Doshida[1], H. Igarashi[1], M. Machida[2], T. Hashimoto[2], K. Kyono[1,2]

[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan

Study question: How often does direct cleavage (DC) of embryo occur? Does the timing of DC of embryo affect blastocyst formation rate and pregnancy rate?

Summary answer: The frequency of DC was 20%. Blastocyst rate of DC at the first-cleavage was low. Pregnancy rate was the same regardless of the DC timing.

What is known already: Recently, time-lapse (TL) imaging has revealed the relationship between morphokinetic parameters of human preimplantation embryo and clinical outcomes. DC, defined as one blastomere into three daughter blastomeres at cell cleavage, was observed with large variations in frequency, ranging from 8.3% to 26%. It has also been reported that embryos with DC showed lower implantation rate than embryos with normal cleavage pattern.

Study design, size, duration: This study is a retrospective observational study, which was conducted at Kyono ART clinic in Japan from August 2013 to March 2016. It was approved by the Ladies Clinic Kyono Ethics Committee. A total of 494 human embryos observed by TL imaging system were included in this study.

Participants/materials, setting, methods: Ninety-nine embryos which underwent DC were divided into three groups by timing of DC (first cleavage, second cleavage, and third cleavage or later). Blastocyst formation rate and pregnancy rate of each group were analyzed.

Main results and the role of chance: The total incidence of DC per embryo was 20.0% (99/494). With regard to timing of direct cleavage, the first cleavage was 46.5% (46/99), the second cleavage was 39.4% (39/99) and the third cleavage or later was 14.1% (14/99). Blastocyst formation rate of embryos with DC at the first cleavage, the second cleavage and the third cleavage or later were 10.9% (5/46), 43.6% (17/39) and 50.0% (7/14) respectively. The embryos with DC at the first cleavage showed significantly lower blastocyst formation rate than embryos with DC at other timings (p < 0.01). Fifteen blastocysts which underwent DC were transferred, and 6 blastocysts (40%) implanted. There was no significant difference in pregnancy rate among the three groups. Pregnancy outcomes were 2 live births, 2 ongoing pregnancies and 2 miscarriages.

Limitations, reasons for caution: Our results might be influenced by the small sample size of our study. To clarify the safety and efficacy of DC embryo transfer, euploidy of DC embryos should be assessed.

Wider implications of the findings: Our findings have shown that DC embryos have a potential to develop to blastocyst, although blastocyst formation rate was low, especially at the first cleavage. If DC embryo develops to blastocyst, DC embryos could be selected as an option for transferred embryos.

Trial registration number: None.

P-126 The role of amino acid metabolism in bovine inner cell mass development and pluripotency

V. Najafzadeh[1], R. Martinus[2], B. Oback[3]

[1]AgResearch Limited, Reproductive Technologies, Hamilton, New Zealand
[2]Waikato University, Biological Sciences, Hamilton, New Zealand
[3]AgReseach Limited, Reproductive Technologies, Hamilton, New Zealand

Study question: To investigate if the metabolism of candidate amino acids (AAs) is crucial for bovine inner cell mass (ICM) development and pluripotency

Summary answer: Bovine ICM develops without several AAs but requires threonine dehydrogenase (TDH) activity.Its inhibition stimulates autophagy and increases histone 3 lysine 4 trimethylation (H3K4me3) in blastocysts.

What is known already: Mouse ICM and ICM-derived pluripotent stem cells (PSCs) specifically need threonine and ICM-restricted TDH to produce the methyl donor S-adenosylmethionine (SAM). Depleting threonine (ΔT) or TDH decreases SAM levels, limits H3K4me3 and induces autophagy in PSCs. By contrast, human PSCs do not survive without lysine (ΔK), leucine (ΔL), tryptophan (ΔW) or methionine (ΔM). In cattle, bona fide embryonic PSCs have not been isolated.

Study design, size, duration: Experiments were conducted on *in vitro* fertilised preimplantation bovine embryos, individually cultured in chemically defined, protein-and glutamin-free synthetic oviduct fluid (gSOF) with essential (E) and non-essential (NE) AAs. Selective AA depletion or pharmacological TDH inhibition, using the specific QC1 inhibitor, was applied from the morula to the blastocyst stage (day 5 to 8) in single embryo culture. SOF with and without E/NE_AAs served as positive and negative controls, respectively.

Participants/materials, setting, methods: For AA drop-out experiments, 2509 embryos were scored for embryo development according to the International Embryo Transfer Society morphological grading guidelines. For TDH inhibition experiments, 658 embryos were analysed for embryo development, cell numbers (Hoechst/ Propidium iodide staining), lineage-specific marker expression (quantitative PCR), histone trimethylation (immunofluorescence quantification) and autophagy (Autophagy Detection Kit, Abcam #139484). Statistical significance was determined using Fisher's exact test for development and t-tests for cell numbers, gene/protein expression and autophagy.

Main results and the role of chance: Depleting one (ΔT, ΔM), two (ΔMT, ΔCM, ΔCT; ΔIL, ΔIK, ΔKL), three (ΔCMT, ΔIKL) or six ($\Delta HPRVWY$) EAAs did not affect ICM formation, even when NEAAs were also removed for ΔT and ΔM groups. However, depleting another six ($\Delta CIKLMT$), nine (+CMT, +IKL), eleven EAAs (+T, +M) or all twelve EAAs impaired blastocyst development (P < 0.05). As no clear EAA candidate emerged from this targeted screen, we focused on TDH. *TDH* mRNA was present at similar levels in trophectoderm (TE) and ICM. Exposure to the TDH inhibitor QC1 reduced ICM and TE cell numbers ~2-fold (P < 0.005). This cell loss was due to increased autophagy (P < 0.05). Hypoblast (*PDGRFα*), pluripotency-related epiblast (*NANOG, FGF4* and *SOX2*) and TE (*CDX2*) markers were not altered in the QC1 group compared to DMSO controls. QC1-treated ICM and TE nuclei were specifically hypermethylated at H3K4me3 (P < 0.05), while H3K9me3 and H3K27me3 were not affected.

Limitations, reasons for caution: Conclusions drawn from pharmacological inhibition rely on specificity of the inhibitor for TDH enzyme and need to be complemented by genetic evidence, using both gain- and loss-of-function approaches. Furthermore, isolated bovine ICM cells require complex culture conditions and do not robustly propagate in chemically defined, protein-free medium.

Wider implications of the findings: Our findings highlight differences in amino acid dependency between bovine, mouse and human ICM cells. Such species-specific connections between metabolism, epigenetics and pluripotency regulation may help understand why bona fide bovine embryonic PSCs have not been isolated yet.

Trial registration number: NA.

P-127 Rapid warming method can improve the survival rate of slow freezing with cryovial carriers

X. Shun[1], J.X. Liu[1], G.N. Huang[1]

[1]Chongqing Maternity and Children Health Care Hospital, Reproductive and Genetics Institute, Chongqing, China

Study question: The survival rates for slow freezing are lower, especially when cryovials are used as carriers. Can rapid warming improve the survival rate for slow freezing with cryovials?

Summary answer: The rapid warming can improve the survival and intact survival rates for slow freezing even if cryovials are used as carriers.

What is known already: The rapid warming can improve the survival rate when cryostraws are used as carriers.

Study design, size, duration: The first part presents a retrospective design. This part involves 90 cycles which underwent frozen embryo transfer between January 2015 and October 2016. The second part is a prospective design which includes 79 embryos from three pronuclear (3PN).

Participants/materials, setting, methods: Cycles underwent slow freezing and frozen embryo transfer from January 2015 to October 2016 were defined as traditional group (90 cycles, 288 embryos). Cryovials with 2 ml volume was the carriers. The thawing method followed the traditional protocol. Embryos derived from 3PN were included in modified group, which were frozen by slow freezing and thawed using the rapid warming, based on the method described by Parmegiani (Parmegiani et al., 2014).

Main results and the role of chance: The survival and intact survival rates in modified group were 88.61% (70/79) and 59.49% (47/79), respectively, which were significantly higher than that in traditional group (64.58% (186/288) and 25% (72/288), respectively, P = 0.000). Different temperature of water bath was used in modified group, there were no significant differences in terms of the survival rates for different temperature (88.24%, 88.89%, 88.89% for 37°C, 38°C, 39°C, respectively).

Eight cycles in traditional group were canceled for embryo transfer because of the failure of embryo survival. Eighty two cycles received embryo transfer. The implantation and clinical pregnancy rates were 36.59% and 28.95%, respectively. From November to December in 2016, there were 11 cycles in which the rapid warming method was used, five of them were clinical pregnancy.

Limitations, reasons for caution: The limitation of this study was the small sample size. We should notice that embryos in modified group derive from 3PN. Larger, clinical trials are needed.

Wider implications of the findings: Slow freezing using cryovials is a hard challenge compared with cryostraws because of the high volume of cryovials. This study proves the efficiency of rapid warming method on slow freezing even if cryovials are used.

Trial registration number: no.

P-128 Effect of trophectoderm projection on blastocyst development in relation to hatching, pregnancy, and miscarriage rates

Y. Matsui[1], Y. Kaneko[1], S. Tsuchiya[1], A. IIzumi[1], K. Itakura[1], A. Wada[1], K. Nishimura[1], T. Ozaki[2], Y. Araki[3], Y. Araki[3], M. Nishimura[2]

[1]Nishimura Women's Clinic, ART laboratory, Hamamatsu, Japan
[2]Nishimura Women's Clinic, Medical Doctor, Hamamatsu, Japan
[3]The Institute for Advanced Reproductive Medical Technology, Laboratory, Maebashi, Japan

Study question: Whether frequencies of trophectoderm projections are greater with conventional IVF or ICSI is unclear. Relationships between the TPs site and pregnancy, miscarriage rates remain unclear.

Summary answer: Incidence of TPs was higher in ICSI than conventional IVF (c-IVF). However, similar pregnancy and miscarriage rates occurred in vivo irrespective of c-IVF or ICSI.

What is known already: We believe TPs represent a response to a spontaneous trigger from inside the blastocyst to its exterior, which initiates hatching. These projections display amoeboid-like movement, suggesting that they actively seek an implantation site. However, only morphological features of TPs have been characterized, and biological actions remain unclear. Relationships to pregnancy and miscarriage also remain unclear.

Study design, size, duration: Study I This study compared the incidence of TPs in relation to hatching in c-IVF and ICSI cycles. Experimental vitrified-warmed

blastocysts (n = 112) were allocated to two groups (TPs present or absent), and were retrospectively compared between groups.

Study 2 This was a retrospective clinical study of 944 embryo transfer cycles in 712 clinic patients who received a single vitrified-warmed blastocyst. Finally, pregnancy and miscarriage rates were compared during January 2014 and July 2016.

Participants/materials, setting, methods: Experimental vitrified-warmed blastocysts were surplus embryos. Time-lapse cinematography was used to observe the presence of TPs in them. All embryos were graded using three 3AA or 4AA per person according to the Gardner criteria.

In the clinical retrospective study, blastocysts were categorized according to the presence of TPs (TPs(+) group: 213 embryos, TPs present; TPs(-) group: 731 embryos, TPs absent). Pregnancy and miscarriage rates were retrospectively compared from time-lapse cinematography. Statistical analysis was the χ^2 test.

Main results and the role of chance: The incidence of TPs was significantly higher in embryos inseminated by ICSI compared to c-IVF, (ICSI: 51/56, 91%; c-IVF: 25/56, 45%; $p < 0.01$). The successful hatching rate was significantly lower with ICSI than with c-IVF (ICSI: 11/56, 20%; c-IVF: 29/56, 52%; $p < 0.01$). In addition, the hatching rate was significantly lower when TPs were present (14/76, 18%) than in non-TPs embryos (26/36, 72%; $p < 0.01$).

With regard to the clinical study results, no significant differences were found between groups in terms of the pregnancy rate (TPs(+) group: 125/213, 58.7%; TPs(-) group: 402/731, 55.0%) or miscarriage rate (TPs(+) group: 23/125, 18.4%; TPs(-) group: 66/402, 16.4%). We hypothesized that in vivo hatching would occur naturally by assisting protease activity in the uterus. These results suggest that the presence of TPs has no effect on pregnancy rates in clinical settings.

However, the TPs site position around the inner cell mass(ICM) was associated with an increased miscarriage rate (6/12, 50.0%) compared to the from-elsewhere group (17/113, 15.0%; p < 0.01) and non-TPs (66/402, 16.4%; p < 0.01).

Limitations, reasons for caution: It is more necessary to study the mechanism producing of TPs, and relation between TPs site and implantation and miscarriage.

Wider implications of the findings: We report here a new finding of TPs action that it is no direct relation between projection and implantation. This appears to be the first discussion reported worldwide.

Trial registration number: Not applicable.

P-129 Mitotic pulses and cell apoptosis are the two major factors contributing to collapse of blastocoel cavity

D. Hlinka[1], B. Kalatova[2], K. Vybiralova[2], L. Svobodova[2], B. Zborilova[3], S. Lazarovska[4]

[1]Prague Fertility Centre, Embryology, Prague 9, Czech Republic
[2]Prague Fertility Centre, Embryology, Prague, Czech Republic
[3]Fertimed, Embryology, Olomouc, Czech Republic
[4]Prague Fertility Centre, Gynaecology, Prague, Czech Republic

Study question: What are the causes of collapses occurring during blastocyst development and should they be always regarded as a negative phenomenon?

Summary answer: Collapses resulting from physiological cell changes during mitosis should not be considered as negative marker. However, the negative impact of apoptosis-induced collapses can be expected.

What is known already: Studies have found that collapse-expansion cycles may decrease implantation potential of blastocysts. Embryos exhibiting weak contractions should be preferred for transfer since blastocysts with strong collapses usually fail to hatch. Undergoing collapses are accompanied by an efflux of blastocoel fluid but the cause(s) and exact mechanism of blastocoel contraction and recovery is still not known. It can be speculated that collapse is a consequence of compromised embryo viability arising from poor oocyte/sperm quality or it may be an artefact of extended in vitro cultivation.

Study design, size, duration: Retrospective cohort study conducted at private fertility clinic from May 2016 to January 2017. The blastocoel collapses were analyzed in time-lapse images of 308 blastocysts (118 hatching and 190

expanded non-hatching blastocysts) resulting from ICSI fertilization of own/donated oocytes.

Participants/materials, setting, methods: A total of 59 ICSI patients were included in this study. Time–lapse images (Primovision) were taken every 30 min. for 115 hrs. **CATI** software (**C**ognitive **A**utomation of **T**ime-lapse **I**mages) was used to detect cleavages up to 9 cells and blastocoel expansion/collapse(s)/reexpansion. The mitotic cycles beyond 9 cells and the abnormal cleavages were annotated manually. Apoptotic collapses were confirmed by the presence of apoptotic cells underoing lysis in blastocoel. Trophectoderm was evaluated according to Gardner scoring.

Main results and the role of chance: The mean values (hrs) of mitotic cycle timing observed during 115 hrs of cultivation period (in 308 embryos) were: t2:25, t3:36, t4:37, t5:50, t8:56, t9:72, t17:85, t33:96, t65:105, t129:112. 76% (no. 235) of embryos cleaved normally and in 24% (no. 73) some kinds of abnormalities were detected.The collapses were detected in 63% of embryos (no. 194). 49 % (no. 96) of these collapses were considered as mitotic pulses and 51 % (no. 98) as apoptotic collapses. 26% (no. 80) of analyzed embryos were evaluated as low cell number trophectoderm (TE) group (Gardner TE: B, C).

Significantly more embryos with abnormal cleavages (34 vs. 1%) were detected in a group of embryos with collapses when compared to no-collapse group.Significantly more embryos with abnormal cleavages (59 vs. 11%, total no. 308) were detected in low cell number TE group (Gardner TE: B, C) when compared to normal TE group (Gardner TE: A).Significantly more embryos with apoptotic collapses (75 vs. 37%, no. 194) were detected in low cell number TE group when compared to normal TE group.Significantly more embryos with apoptotic collapses (69 vs. 41%, no. 194) were detected in abnormally cleaved embryos when compared to correctly cleaved group.

Limitations, reasons for caution: Inexact apoptotic cell identification: limited value of subjective noninvasive detection of apoptotic cells. Not sufficient time-lapse data: just one focal plane was captured and analyzed. Limited period of embryo observation: some apoptotic cells may undergo lysis after finishing of cultivation.

Wider implications of the findings: The presence of apoptotic cells in TE was proven in many studies. We have described the impact of apoptotic cells on collapse occurrence and reduction of TE cells. Apoptosis-induced collapses can be considered as negative marker unlike the collapses described here as mitotic pulses induced by cell changes during mitosis.

Trial registration number: Not applicable.

P-130 Age and oocytes retrieved as predictors of blastocyst formation

M. Perez[1], M. Carbonaro[2], K. Calvo[2], C. Brignardello[2], H. Miiechi[3], G. Botti[4], C. Morente[5], M.E. Mackey[6]

[1]PROAR, Embryology, Rosario, Argentina
[2]PROAR, Embriology, Rosario, Argentina
[3]PROAR, Clinician, Rosariio, Argentina
[4]PROAR, Clinician, Rosario, Argentina
[5]PROAR, Medical Director, Rosario, Argentina
[6]PROAR, Statistics, Rosario, Argentina

Study question: The objetive of the study is to calculate the probability of having at least 1 expanded blastocyst on day 5 in women undergoing ICSI relative to age and injected oocytes

Summary answer: Probability of obtaining 1 expanded blastocyst on day 5 is about 80% in women under 35 years in contrast of 40% for women over 40

What is known already: Blastocyst-stage transfer has more known advantages than cleavage-stage transfer. According to a recent Cochrane Review, blastocyst-stage transfer is associated with higher live birth rates compared with cleavage-stage transfer with no reduction in clinical pregnancy rate and miscarriage rate. However, the major disadvantage of extended culture is the risk that no blastocysts will be available for transfer on day 5.

Study design, size, duration: This study was a retrospective cohort study analysis of 329 ICSI cycles with blastocyst transfer completed between January 2014 and December 2015

Participants/materials, setting, methods: Patients were classified in 3 groups according to age. Group1: < 35 years, Group2: 35–39 years, Group3: ≥40 years. Each group was divided in 3 subgroups according to the number of injected oocytes, a: ≤4 M2, b: 5–9 M2, c: ≥10 M2. The probability of obtaining at least 1 expanded blastocyst was calculated for each age group. Data analyses were performed using Fisher test. A P-value of < 0.05 was considered to be statistically significant.

Main results and the role of chance: The probability of obtaining at least 1 expanded blastocyst was 82% (IC95% 0.73–0.88), 65% (IC95% 0.57–0.72) and 46% (IC95% 0.33–0.60) for group 1(n = 109), 2 (n = 166) and 3 (n = 54) respectively. When each group was divided according to the injected oocytes the results were:

G1a(n = 9): **67%** (IC95% 0.30–0.93),G1b(n = 46): **78%** (IC95% 0.64–0.89), G1c(n = 54): **87%** (IC95% 0.75–0.95)

G2a(n = 43): **40%** (IC95% 0.25–0.56),G2b(n = 68): **65%** (IC95% 0.52–0.76),G2c(n = 55): **86%** (IC95% 0.73–0.94)

G3a(n = 19): **42%** (IC95% 0.20–0.67),G3b(n = 26): **39%** (IC95% 0.20–0.59),G3c(n = 55): **78%** (IC95% 0.40–0.97)

Overall, blastocyst formation increase 25% and 76% when comparing G1 vs G2 (RR:1.25 IC95% 1.09–1.45) and G1 vs G3 (RR:1.76 IC95% 1.31–2.38) respectively.

Not statistically differences could be found when comparing different quantities of injected oocytes among the youngest group G1c vs G1b RR 1.11 (IC95% 0.92–1.34) G1c vs G1a RR 1.31(IC95% 0.81–2.10).However, in the middle age group the probability of quality blastocysts increase when more oocytes are available to inject G2c vs G2b RR 1.32(IC95% 1.07–1.62) G2c vs G2a RR 2.16(IC95% 1.47–3.18). In the oldest group the probability increase as the injected oocytes increase but not statistically differences could be found when comparing more than 10 vs less than 4 G3c vs G3b RR 2.02(IC95% 1.11–3.68) G3c vs G3a RR 1.85(IC95% 0.98–3.48).

Limitations, reasons for caution: The main strength of this study is the sizable sample of patients over 40 years with more than 10 oocytes and less than 4. For this reason the results in this group are in the limit of the statistical significance. Clinical outcomes after transfer of these blastocysts were not calculated

Wider implications of the findings: Blastocyst formation is associated with maternal age being 80% for patients under 35 and 40% for patients over 40. Total number of quality blastocysts increased as injected oocytes rose for all groups, however this finding seems to be not relevant for young patients but regain importance as the age rose.

Trial registration number: Not applicable.

P-131   High reliability of morphokinetic annotations among embryologists

M. Martinez Garcia[1], J. Santaló[2], A. Rodríguez[1], R. Vassena[1]

[1]Clínica EUGIN, EUGIN, Barcelona, Spain
[2]Universidad Autónoma de Barcelona, Biología Celular- Fisiología e Immunología, Barcelona, Spain

Study question: Are morphokinetic measurements of time lapse videos comparable among operators?

Summary answer: There is little variation among morphokinetic measurements taken by different operators when analyzing the same time lapse videos.

What is known already: Morphokinetic analysis of preimplantation embryo development is a complementary method of embryo assessment increasingly used in IVF laboratories. Time-lapse videos of embryo development are usually viewed by trained embryologists and the times at which certain cellular events occur manually annotated. Such annotations form the basis for embryo selection algorithms, whish are used to rank the embryos for transfer. The reliability of morphokinetic annotations is dependent on both the quality of the video, and the training of the embryologists. Only one study so far reported the reliability of morphokinetic annotations among 3 embryologists; larger studies are needed to address this further.

Study design, size, duration: Prospective study carried out between October 2015 and June 2016. Six senior embryologists with an experience in classic morphology-based evaluation of several years individually annotated the same 93 videos of preimplantation development, corresponding to 18 IVF/ICSI cycles, recorded by a Primo Vision® System.

Participants/materials, setting, methods: Times of second polar body extrusion, appearance and disappearance of pronuclei, and cleavages of embryo development (times from 2-cell to 5-cell stage: t2, t3, t4, t5) were annotated. Each embryologist was blinded to the annotations of the others. Intra- and inter-observer agreement was evaluated by computing intra-class correlation coefficients (ICCs).

Main results and the role of chance: In the inter-observer analysis, most ICCs obtained were higher than 0.80, indicating a high degree of concordance: t2: 0.93; t3: 0.80; t4: 0.89; t5: 0.90; disappearance of two pronuclei: 0.98. However, the ICCs obtained from second polar body extrusion and the appearance of two pronuclei annotations was lower: 0.49 and 0.56 respectively, indicating an average degree of concordance. The ICCs obtained from the intra-observer analysis were mostly higher than 0.80 (t2: 0.96; t3: 0.89; t4: 0.88; t5: 0.86; disappearance of two pronuclei: 0.96). Similiarly to the interobserver's, the intra-observer ICCs obtained for the second polar body extrusion and the appearance of two pronuclei annotations were 0,77 and 0,66 respectively. These results indicate that the measures of embryonic development times annotated by analyzing time-lapse videos are highly reliable both intra observer and among observers.

Limitations, reasons for caution: The developmental stages from 6-cells to blastocyst were not evaluated; since some morphokinetic algorithms use times past the 6 cell stage in their calculations, further studies should be carried out to understand the variations among operators in these cases.

Wider implications of the findings: Time-lapse measurement should be as objective as possible, especially for the first cleavages of embryo development, because they are often measured to define algorithms to assess the embryonic implantation potential. Our results show that measurements using Primo Vision® System are consistent and reliable within and among different operators.

Trial registration number: NA.

P-132   The implantation chance of an euploid blastocyst may not correlate with its morphological grading at all

L.C. Demirel[1], G. Tuysuz[2], E. Donmez[2], F. Tulek[2], B. Gökcan[2], S. Aydoğdu[2], Z. Salar[2]

[1]Memorial Atasehir Hospital- IVF Department, Atasehir - Istanbul, Turkey
[2]Ataşehir Memorial Hospital, IVF Unit, İstanbul, Turkey

Study question: Do better morphology scores of blastocysts mean a better chance of implantation when euploid blastocyst are being transferred, or vice versa?

Summary answer: The implantation and ongoing pregnancy chance of an euploid blastocyt may not correlate with its morphological grading at all.

What is known already: The ploidy status of the blastocysts is known to affect their implantation potential. It is not known weather the implantation and ongoing pregnancy chance of an euploid blastocyst is affected by its morphological grading.

Study design, size, duration: This is a retrospective study of 88 blastocysts transferred between March 2013 and November 2016, that have been tested as euploid by comprehensive chromosome screening (CCS) on aCGH or NGS genetic platforms. The cycles included were either single or double embryo transfer cycles in which case, either both or none of the embryos had implanted. The blastocyst morphology was evaluated according to standard Gardner's classification system.

Participants/materials, setting, methods: 88 euploid blastocysts were from 74 patients undergoing preimplantation genetic screening for recurrent IVF failures, habitual abortion and advanced maternal age. The implantation and ongoing pregnancy rates of each embryo were analysed with respect to the genetic platform, weather the transfer was a fresh or frozen ET, and the expansion status, inner cell mass (ICM) and trophectoderm morphology of the blastocyst at the time of the transfer, by univariate analysis.

Main results and the role of chance: The implantation rate (IR) of euploid blastocysts did not differ between aCGH and NGS platforms (60.7 % vs 40.7 %,

respectively; p = 0.134). It also did not differ if the transfer had been a fresh or frozen one (55.8 % vs 52.8 %, respectively; p = 0.953).

The IR did not differ significantly with regard to the degree of blastocyst expansion; being 0 % for 1, 25 % for 2, 50 % for 3, 62.5 % for 4 and 5 and 25 % for 6 (p = 0.375). IR of euploid blastocysts also did not differ in different inner cell mass (ICM) and trophectoderm cathegories (53.9 % for A, 54.5 % for B, 100 % for C, p = 1,000 and 56.2 % for A, 42.9% for B and 100 % for C, p = 0.471; respectively). The lack of correlation persisted for all comparions when the ongoing pregnancy rate was chosen as the outcome parameter instead of IR (aCGH vs NGS, p = 0.743; fresh vs frozen, p = 0.854; different expansion classes, p = 0.383; ICM morphology, p = 0.697; trophectoderm morphology, p = 0.720)

The ongoing pregnancy chance of the euploid blastocysts did not differ among different blastocyst expansion scores, inner cell mass and trophectoderm morhology cathegories.

Limitations, reasons for caution: Low occurence number in certain subgroups of blastocyst morphology may introduce a statistical bias, therefore continuation of such a study with a greater number of cases is warranted for a stronger conclusion statement.

Wider implications of the findings: CCS may be the ultimate route of embryo selection and once an embryo is found to be euploid, blastocyst morphology may not be so influential on the outcomes.

Trial registration number: -.

P-133   Comparison of blastocyst expansion morphokinetics in euploid versus aneuploid embryos from infertility patients

D. Huang[2], M. Leung[2], C. Yin[2], T. Kosasa[2], C. Huang[3], C. Arnette[3], H.J. Ahn[4], T. Huang[1]

[1]Pacific IVF Institute, Department of Obstetrics and Gynecology and Women's Health- John A. Burns School of Medicine, Honolulu- Hawaii, U.S.A.
[2]Pacific IVF Institute, Department of Obstetrics and Gynecology and Women's Health of the John A. Burns School of Medicine, Honolulu- Hawaii, U.S.A.
[3]Advanced Reproductive Center of Hawaii, Department of Obstetrics and Gynecology and Women's Health of the John A. Burns School of Medicine, Honolulu- Hawaii, U.S.A.
[4]Office of Biostatistics and Quantitative Health Science, University of Hawaii- John A. Burns School of Medicinie, Honolulu- Hawaii, U.S.A.

Study question: Can the morphokinetics of blastocyst expansion distinguish euploid from aneuploid embryos and provide a basis for embryo ranking and selection for transfer?

Summary answer: Of several morphokinetic parameters obtained from time-lapse imaging, blastocyst expansion dynamics best distinguished euploid from aneuploid embryos.

What is known already: Without preimplantation genetic screening (PGS), the laboratory must rank embryos for transfer based on morphology. Compared to traditional grading, time-lapse imaging offers new possibilities, but applying this approach to embryo selection remains controversial. Blastocoel expansion rate is a new metric recently described using donor egg embryos having known positive implantation data (Huang et al., 2016); however, there is no information describing expansion in autologous embryos from infertility patients or how expansion correlates to karyotype after PGS. Results reported here describe these features and suggest how expansion metrics can be applied to embryo selection.

Study design, size, duration: This was a retrospective observational study initially involving 188 (non-donor) blastocysts biopsied from 34 infertility patients having preimplantation genetic screening for aneuploidy. The study period involved sequential biopsy cases from June 2014- June 2016 using a single laboratory (Genesis Genetics).

Participants/materials, setting, methods: The median age of study patients was 35.0 yrs (sd = 5.7). Retrievals averaged 9.6 mature and 7.1 fertilized eggs. After ICSI, embryos were cultured in an Embryoscope (Vitrolife) with laser hatching on D3 and biopsy on D5-D6. Blastocoel expansion was defined as the cross-sectional area of trophectoderm enclosed space both within and herniated outside of the ZP (in u^2) and measured hourly for 10 hours beginning at blastocyst formation (Tb).

Main results and the role of chance: Of 188 blastocysts from 34 PGS cycles analyzed, 89 (47.3%) were euploid and 99 (52.6%) aneuploid. The euploids' expansion slope (756.3) was statistically higher than for aneuploids (503.3) beginning 6 hours from Tb (p < 0.004). A scatter plot correlating Tb with expansion cross sectional area (CSA) at 8 hours from Tb showed a similar distribution of euploids and aneuploids at an intermediate expansion CSA of 15,000–20,000u^2 (euploid = 58%; aneuploid = 54%). In contrast, a greater percentage of all euploids (29%) showed more robust expansion > 20,000u^2 versus aneuploids (12%). Conversely, a higher proportion of all aneuploids (32.3%) expanded more slowly (< 15,000 u^2) versus euploids (12.3%). Based on these findings, individual blastocyst expansion slopes were used to rank embryos for hypothetical transfer within each patient's cohort. The percent euploid was highest in embryos ranked 1 or 2 (61.7% and 62.5%). Euploidy decreased in embryos ranked 3 or 4 (34.4% and 30.7%). Notably, 27/34 (79.4%) patients had at least one euploid embryo ranked 1 or 2, and in 14/34 (41.1%) patients, both embryos ranked 1 and 2 were euploid. No clear differences between euploid and aneuploid embryos were apparent in several earlier morphokinetic parameters (t2, t3, t4, t5, t6, Tsb, Tb).

Limitations, reasons for caution: This was a retrospective observational study. It is also limited by the sample size of both patients and blastocysts. In addition, this is the first application of a new metric of blastocyst expansion to biopsied embryos which limits wider comparison of results and power analysis.

Wider implications of the findings: Morphological selection of single embryos for transfer remains challenging. Results are the first to describe a new metric of blastocyst expansion rate in embryos from infertility patients undergoing PGS. Results suggest that expansion rate correlates with euploidy and describe its application to embryo ranking for transfer with or without PGS.

Trial registration number: No trial registration.

P-134   Relationship between early division in embryo and their ploidy status. A retrospective review

M.F. Chew, S.Y. Chen

Tropicana Medical Centre, IVF Lab, Petaling Jaya, Malaysia

Study question: Is there any correlation between early cleavage (EC) and ploidy status of embryo in different female age groups?

Summary answer: Embryos that showed early division had significantly lower risk of being aneuploid compared to non-early cleavage (NEC) or non-syngamy (NS) embryos, regardless patient age.

What is known already: The aneuploidy formation in human embryos can be meiotic or mitotic origin. The relationship between timings of early mitotic divisions and ploidy status of embryo was reported in previous studies, where delay in cleavage division were correlated with aneuploidy. Some time-lapse studies showed that the timing of first cleavage division is not age-related.

Study design, size, duration: This is a retrospective study from January 2015 until November 2016, with 165 ICSI+PGD cases were included during this period of study. EC embryos were compared to NEC and NS embryos respectively, subdivided into two age groups (≤35 year-old and > 35 year-old).

Participants/materials, setting, methods: EC assessment was performed on normally fertilized embryos at 25–27 hours post-injection. EC (2 cells), NEC (no sign of cleavage) and NS embryos (remained 2-pronuclei) were cultured separately. Biopsy was performed at either cleavage or blastocyst stage. Biopsy criteria: ≥6cells embryo scored grade 1–3 quality (in-house grading system, grade 1 = best, grade 5 = worst); full blastocyst scored AA to BB quality (Gardner's grading system). Array CGH for chromosome screening. Fisher's exact for statistical analyses (significant level at < 0.05).

Main results and the role of chance: A total of 755 biopsied embryos (327 Day 3 embryos and 428 blastocysts) were included in this study: 314 were EC embryos, 441 were NEC embryos at which 213 were NS embryos. The proportion of EC embryos in patients ≤35 year-old (35.8%) was slightly higher compared to patient > 35 year-old (31.0%) but this was not significant, p = 0.0567. In general, the proportion of euploid embryos from EC group (57.3%) was significantly higher than NEC group (45.4%), regardless of their age group; p = 0.0015. In patient ≤35 year-old, the percentage of euploid embryos from EC group was significantly higher than NEC group, 61.9% vs 51.5%, similar event was found in patient > 35 year-old, 44.6% vs 29.7%; p = 0.023 & p = 0.0389,

respectively. Meanwhile, the ploidy status of NS embryos were also investigated. The proportion of NS embryos from patients > 35 year-old was slightly higher than patient ≤35 year-old, 39.5% vs 35.9%, p = 0.1643. Our study showed that the percentage of aneuploid embryos found in NS group was statistically higher compared to EC group (60.5% vs 42.7%, p = 0.0001); this was most significant in patient ≤35 year-old (56.4% vs 38.1%, p = 0.0005) in comparison to patient > 35 year-old (70.5% vs 55.4%, p = 0.0829).

Limitations, reasons for caution: The retrospective nature of the study may be a source of undetected bias. There patients have various indications requiring PGS and may not reflect the general subfertile population. Besides, inconsistency during early cleavage assessment and the subjectivity in selecting embryos that fit our criteria for biopsy is our limitation.

Wider implications of the findings: Our observation shows that EC embryos are related to lower aneuploidy rate and should be given the priority for transfer or freezing. By performing routine EC checking, we believe it can optimize the selection of potential euploid embryos for patients as an alternative to PGS.

Trial registration number: None.

P-135 Magnetic-activated cell sorting of non-apoptotic spermatozoa improves the good quality blastocyst rate in women over 30 years old: a prospective study on sibling oocytes

M. Stimpfel, T. Fevzer, I. Verdenik, B. Zorn, E. Vrtacnik-Bokal, I. Virant-Klun

University Medical Centre Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia

Study question: Does magnetic-activated cell sorting (MACS) of non-apoptotic spermatozoa improve the outcome of intracytoplasmic sperm injection (ICSI) in couples treated due to teratozoospermia?

Summary answer: If MACS-selected non-apoptotic spermatozoa are used for ICSI, the rate of good quality blastocyst is improved, but only in women older than 30 years.

What is known already: MACS selection of non-apoptotic spermatozoa enables the selection of more quality and functional spermatozoa for ICSI. Besides the selection of only non-apoptotic spermatozoa, these spermatozoa also have a lower level of DNA fragmentation. Previous studies have indicated that using such spermatozoa for an in vitro fertilization procedure improves the fertilization rate, embryo quality and pregnancy rates. Despite these improvements, there is still no general consensus about using MACS selection of non-apoptotic spermatozoa in IVF or indications for it.

Study design, size, duration: Our prospective sibling-oocyte study included 26 couples who were treated in 2016 with ICSI due to male infertility, more precisely due to teratozoospermia (defined by strict Kruger criteria). The women in the couple included in the study were not older than 36 years (mean age 31.3 ± 2.4 years) and were required to have a normal ovarian response after controlled ovarian hyperstimulation (at least 8 mature MII oocytes).

Participants/materials, setting, methods: The semen sample preparation was performed using two-layer density gradient (40%/100%) centrifugation method. Then the 100% fraction was divided into two parts, where the first part was washed and swim-up performed and the second part was washed, processed with MACS® ART Annexin V System (Miltenyi), washed again and swim-up performed. With each part of prepared spermatozoa, half of mature MII oocytes were fertilized. To determine the differences between these two groups, multivariate analysis was performed.

Main results and the role of chance: The comparison of MACS-selected and non-selected spermatozoa showed that the percentage of morphologically normal spermatozoa was statistically lower in selected non-apoptotic spermatozoa (P = 0.025). When looking closer into morphologically abnormal spermatozoa, there were significantly more spermatozoa with abnormal tails (P = 0.013) and a trend towards more spermatozoa with an abnormal neck and midpiece in MACS-selected non-apoptotic spermatozoa (P = 0.057). On the contrary, there were significantly more spermatozoa with abnormal heads in unselected population (P = 0.015), which indicates MACS selection could have positive effect on the population of spermatozoa used for ICSI procedure. This positive effect was further observed when these spermatozoa were used

for fertilization with ICSI. More precisely, the good quality blastocyst rate was improved with MACS-ICSI in women over 30 years old (33.3% vs. 75.0%, P = 0.028), but in patients aged 30 years or less, there was no difference (69.2% vs. 50.0%, P = 0.336). Despite the good quality blastocyst rate was improved with MACS-ICSI, the overall blastocyst rate was comparable (ICSI vs. MACS-ICSI; 44.8% vs. 41.3%). No significant difference was observed in terms of the good quality day 3 embryo rate (58.4% vs. 62.4%), and pregnancy rate (33.3% vs. 31.3%).

Limitations, reasons for caution: The limitations of the study are in the relatively low number of included couples, but the study is still in progress. Achieved pregnancies must also be followed in order to evaluate the miscarriage and birth rate.

Wider implications of the findings: Non-apoptotic sperm selection could be of benefit to infertile couples treated due to teratozoospermia having previously blastocysts of poor quality, in order to improve the quality of embryos, but only when women are older than 30 years of age.

Trial registration number: The study was approved by the Slovenian Medical Ethical Committee.

P-136 Blastocyst Morphology (ICM and TE) stipulates endometrial receptivity during implantation window period and strongly correlates with 17-hydroxyprogesterone (17-α-OHP) as well as pregnancy outcome

N. Chimote[1], N. Nath[2], B. Chimote[3]

[1]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology & Reproductive Endocrinology, Nagpur, India*
[2]*Vaunshdhara Clinic and Assisted Conception Centre, Biochemistry, Nagpur, India*
[3]*Vaunshdhara Clinic and Assisted Conception Centre, Embryology- Endocrinology, Nagpur, India*

Study question: To investigate if blastocyst morphology correlates with the hormone 17- α-hydroxyprogesterone and whether this correlationship has any bearing on pregnancy outcome in IVF cycles.

Summary answer: Blastocyst morphology (Inner cell mass/trophectoderm) correlates with 17-α-hydroxyprogesterone (17-OHP) formation as well as pregnancy outcome and dictates endometrial receptivity during implantation window in IVF cycles.

What is known already: The endometrium prepares itself for implantation in every menstrual cycle. The hormones estrogen and progesterone have been known to enhance endometrial receptivity. The endometrium becomes receptive strictly during a window period, outside of which frame, it remains non-receptive for this highly dynamic and multifactorial phenomenon. We therefore speculated that blastocyst entry in uterus must be coinciding with a sequence of reactions including conversion of progesterone to its hydroxylated metabolite, 17- α-hydroxyprogesterone. Since same dose of progesterone is supplemented to all women before transfer in IVF cycles, its conversion to 17-OHP must hold the key for successful implantation and ensuing pregnancy.

Study design, size, duration: Prospective analysis of 17-Hydroxyprogesterone levels on day of embryo transfer (dET) in 181 women undergoing antagonist stimulation protocol at our private infertility centre from April 2015-April 2016. All women received elective single blastocyst transfers on day5 after OPU. 17-α-OHP was measured in serum by RIA method. Blastocyst stage and morphology: Inner cell mass (ICM) and Trophectoderm (TE) were graded as per Gardner's Blastocyst gradation system. Statistical analysis was performed using Graph pad prism V software.

Participants/materials, setting, methods: Women were classified into 3 groups (top, average, poor) respectively on the basis of ICM (grade 3: n = 92, grade 2: n = 76, grade1: n = 13) and TE cells (Grade 3: n = 78, grade 2: n = 88, grade 1: n = 15). Hormones estrogen (E2), progesterone (P), hydroxyprogesterone (17-α-OHP) and pregnancy outcome were intercompared between the groups. Endometrial thickness (ER) and echopattern (ER grade) were measure ultrasonographically on dET. Clinical Pregnancy rate (CPR) and Live birth rate (LBR) were main outcome measures.

Main results and the role of chance: Women with ICM grade 3, 2, 1 differed significantly (One way ANOVA) w.r.t following parameters: TE (p < 0.0001); E2/dET (p < 0.0001); OHP/dET (p = 0.0046); E2/d14ET (p = 0.04); OHP/d14ET

(p = 0.0007); CPR (p = 0.0008) and LBR (p = 0.0015). However there was no statistically significant difference in P/dET (0.4); P/d14ET (p = 0.49) as well as Endometrial thickness on dET (p = 0.53); endometrial echopattern dET (p = 0.52). ICM correlated significantly with OHP/dET (Pearson r = 0.24, p = 0.0011); CPR (Pearson r = 0.27, p = 0.0002) and LBR (Pearson r = 0.24, p = 0.0005).

Women with TE grades 3, 2, 1 showed significant differences w.r.t ICM (p < 0.0001); E2/dET (p = 0.0081); OHP/dET (p < 0.0001); E2/d14ET (p = 0.04); OHP/d14ET (p = 0.03). However there was no significant difference between the groups in endometrial thickness (p = 0.57); endometrial echopattern (p = 0.82); P/dET (p = 0.94); P/d14ET (p = 0.39). Although CPR and LBR were higher in the TE grade3 group compared to others, the difference was not statistically significant (p = 0.1, 0.13 respectively). TE correlated strongly with OHP dET (Pearson r = 0.42, p < 0.0001) but weakly with CPR (Pearson r = 0.14, p = 0.05) and LBR (Pearson r = 0.15, p = 0.05).

These results indicate that morphological and hormonal modifications including formation of 17-α-OHP from progesterone occur simultaneously during implantation window period. These parameters together influence pregnancy outcome irrespective of the endometrial thickness and echopattern. ICM correlates more than TE with pregnancy outcome.

Limitations, reasons for caution: Not all morphologically top embryos lead to pregnancy. On the other hand, some morphologically poor embryos do successfully implant. Therefore, a deeper understanding into the finer aspects of morphological assessment, hormonal investigations and their correlationship is required. More detailed, multicentric studies are required to comprehend this complicated human implantation process.

Wider implications of the findings: Rather than relying on ultrasound finding of endometrial thickness and echopattern on dET, it is better to assess hormonal parameters before transfer. This may give us a better indication of endometrial receptivity and therefore to decide whether to transfer embryo in same or next natural cycle and increase pregnancy rates.

Trial registration number: Not applicable.

P-137   The regulatory roles of polyamines/let-7 signaling in embryo dormancy and activation in mice

R. Cheng[1], **W. Liu**[1], **Z. Niu**[1], **R.T.K. Pang**[1], **E.H.Y. Ng**[2], **W.S.B. Yeung**[2]

[1]The University of Hong Kong, O&G, Hong Kong Island, China
[2]Queen Mary Hospital- Li Ka Shing Faculty of Medicine- The Univeristy of Hong Kong, O&G, Hong Kong Island, China

Study question: Does the balance of polyamines and let-7 determine whether blastocysts should implant or become dormant?

Summary answer: The blastocysts implant when polyamine is high but become dormant when that of let-7 is high.

What is known already: Polyamines are required for embryonic development as embryos lack of Ornithine decarboxylase (ODC1), the rate-limiting enzyme in the biosynthesis of polyamines, cannot survival after E7.5. Deprivation of polyamines significantly decreases implantation sites in mice and mink. Let-7 is up-regulated in dormant blastocyst and its forced-expression inhibits embryo implantation in vivo.

Study design, size, duration: The expression of ODC1 in dormant and estrogen-activated embryos was detected. The effects of polyamines on the expression of let-7 in dormant embryos, uterine primary epithelial and stromal cells were determined. The possible involved molecular mechanisms between them were explored. The influence of polyamines in activating dormant embryos in vitro was studied. The Kaplan-Maier survival curves of electroporated blastocysts with or without pre-let-7a during ex vivo culture was depicted.

Participants/materials, setting, methods: ICR female mice aged 6–8 weeks were used in this research. The expression of let-7 was detected by qPCR and the expression of Odc1, eIF5A, Lin28 and c-Myc was detected by immunostaining/western blotting. D4 blastocysts were electroporated with pre-let-7a and dormant blastocysts were cultured in the presence/absence of polyamines. All experiments were repeated more than 3 times and at least 5 embryos used in each group.

Main results and the role of chance: The expression of Odc1, Spermine Synthase, eIF5A and c-Myc in both embryos and the uterine epithelial cells was up-regulated after estrogen injection. While let-7a expression in primary epithelial and stromal cells was downregulated. Polyamines positively regulated the expression of eIF5A, Lin28 and c-Myc, but negatively regulated let-7 expression in both blastocysts and JEG3 cells. However, let-7 overexpression has little effect on the expression of ODC1 in embryos, primary epithelial and stromal cells. These results implied that polyamines may regulate the expression of let-7 via eIF5A/Lin28/let-7 axis and this regulation is unidimensional. Polyamines increased implantation rates and outgrowth of blastocysts in vitro. Proliferation (EdU) and nascent translation (HPG), markers of dormant embryo activation, were elevated by polyamines in dormant embryos. Blastocysts with let-7a over-expression can survive up to Day 13 and still have the ability to implant and give rise to live-born mice.

Limitations, reasons for caution: The balance between polyamines and let-7 has an important regulatory role in embryo implantation and dormancy. The molecular mechanisms involved in the balance needs to be explored. The applicability of this result in other animals and the utility of manipulations of this balance in assisted reproduction warrant further investigation.

Wider implications of the findings: Our data shows that polyamines activate dormant blastocysts in vitro and let-7 induces embryo dormancy. The balance between polyamines and let-7 is important for embryo implantation and dormancy. This study will shed light on the understanding of embryo dormancy in other animals and provide possible explanations for human implantation failure.

Trial registration number: No.

P-138   MicroRNAs in day three embryo culture media as non-invasive biomarkers of implantation and live birth

M.V. Geraldo[1], **R.C.S. Figueira**[2], **D.P.A.F. Braga**[3], **A.S. Setti**[4], **E. Ono**[4], **E. Borges Jr.**[5]

[1]University of Campinas, Structural and Functional Biology Department - Biology Institute, Campinas - São Paulo, Brazil
[2]Fertility Medical Group, IVF Laboratory, São Paulo, Brazil
[3]Fertility Medical Group, Scientific Research, São Paulo, Brazil
[4]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Research, São Paulo, Brazil
[5]Fertility Medical Group, Clinical Departament, São Paulo, Brazil

Study question: Are microRNAs (miRNAs) detected in the culture media of individual in vitro produced embryos potential biomarkers of embryo implantation and live birth?

Summary answer: The miRNA signature may be a tool to predict the embryo implantation and live birth.

What is known already: In spite of remarkable improvements in in vitro fertilization (IVF) since it was established, its efficiency, measured as the live birth rate, is usually low. Successful improvements to IVF depend on the ability to select the most viable embryos for transfer, which remains a challenge. MicroRNAs are small non-coding RNAs that post-transcriptionally regulate gene expression through mRNA degradation or inhibition of translation. MicroRNAs can be detected in the extracellular environment, such as biological fluids. Circulating miRNAs are already used as diagnostic and prognostic markers of several diseases; however, its utility as a biomarker of embryo implantation is still unknown.

Study design, size, duration: This case-control study included spent culture media from 36 blastocysts transferred on day five. Samples, collected on day three, were split into groups according to the implantation: Positive-Implantation-Group (n = 18) or Negative-Implantation-Group (n = 18). For the first analysis, samples were pooled in three sets for each group and the expression of microRNAs was compared between the groups. To check if miRNAs could be detected in individual samples, in a second analysis, ten more samples were tested.

Participants/materials, setting, methods: Samples from culture media were derived from patients undergoing intracytoplasmic sperm injection (ICSI), in a private university-affiliated IVF center. Samples were collected between January/2015 and November/2015 and were included exclusively samples

from high-quality blastocysts. The Positive-Implantation-Group included exclusively samples from patients with 100% implantation diagnosis. Seven miRNAs (*miR-21, miR-142-3p, miR-19b, miR-92a, miR-20b, miR-125a, and miR148a*) selected according with the literature, was tested. For the second analysis, 10 more samples were tested for *miR-21* and *miR-142-3p*.

Main results and the role of chance: All blastocysts from the Positive-Implantation-Group lead to live births. From the seven tested miRNAs (*miR-21, miR-142-3p, miR-19b, miR-92a, miR-20b, and miR-125a*), expression of four (*miR-21, miR-142-3p, miR-19b, and miR-92a*) could be detected in spent media from pooled samples. Three miRNAs (*miR-21, miR-142-3p, and miR-92a*) were differently expressed between the groups. A significant increased expression of *miR-142-3p* could be noted in the Negative-Implantation-Group (p < 0.001). For other two miRNAs (*miR-21* and *miR-92a*) a difference in expression was observed, however it did not reach a statistical significance. In addition, when ten non-redundant samples were tested to check if miRNAs could be detected in individual samples of culture media, highly specific amplification of mature miRNAs, including *miR-142-3p*, could be noted.

Limitations, reasons for caution: Besides proper embryo development, embryo implantation also depends on the acquisition of a receptive endometrium and appropriate dialogue between the embryo and endometrium. Therefore, the identification of the embryo with the best implantation potential may not guarantee the positive implantation and live birth outcome.

Wider implications of the findings: *MiR-142-3p* may be a biomarker of implantation failure. The identification of specific miRNAs on the culture media offers opportunities for early, fast and cheap diagnosis of implantation, and live birth. This may reduce emotional and financial costs. Moreover, it favors the single embryo transfer, avoiding multiple pregnancies and its consequences.

Trial registration number: None.

P-139 Managing supernumerary embryos at the day of embryo vitrification

A. Sallem[1], P. Santulli[2], V. Barraud-Lange[1], N. Le Foll[1], L. Ferreux[1], C. Chapron[2], D. De Ziegler[2], J.P. Wolf[1], K. Pocate-Cheriet[1]

[1]Cochin University Teaching Hospital, Unit of Reproductive Medicine, Paris, France
[2]Cochin University Teaching Hospital, Department of Gynaecology-Obstetrics II and Reproductive Medicine, Paris, France

Study question: Benefits of culturing day-2 supernumerary embryos whatever their quality and evaluation of predictive factors of ART outcomes in frozen-thawed blastocysts cycles originating from these embryos.

Summary answer: Poor quality embryos (PQE) are able to give healthy babies. Women under 35 years old and day-5 blastocyst expansion are predictive of live birth.

What is known already: The management of supernumerary day-2 PQE is extremely different from an IVF laboratory to another between culturing these embryos until the blastocyst stage and destroying or including them in research programs. The few available data on this topic don't seem to be sufficient to make conclusions concerning the possible benefits of culturing these embryos. Some authors proffer that embryo quality at cleavage stage is correlated with implantation potential, whereas others have stipulated that poor morphological parameters do not preclude successful implantation and that day-2 PQE should be given a second chance by performing extended culture.

Study design, size, duration: Cohort study from November 2012 to February 2015 in the IVF Laboratory Unit of Cochin University Hospital (Paris, France). A total of 3108 supernumerary embryos resulting from 1237 IVF/ICSI cycles were included. Exclusion criteria were cycles with gamete donation and freeze-all and deferred embryo transfer. This study was approved by the National Data Protection Authority.

Participants/materials, setting, methods: At day-2, embryo quality was assessed according to the ESHRE consensus (Istanbul, 2011) distinguishing good-quality embryo (GQE), fair and PQE. After fresh embryo transfer, supernumerary embryos were cultured. Rates of blastulation, good-quality blastocysts, pregnancy,live birth and neonatal outcomes were compared between PQE and GQE. At the blastocyst stage, top, good and fair-quality blastocysts were selected for vitrification. We evaluated factors associated with ART

success when transferring frozen-thawed blastocysts originating from PQE and GQE.

Main results and the role of chance: The blastulation rate was 48.7% in PQE group and 67.2% in GQE group. The percentage of good-quality blastocysts was 47.9% and 60.7% respectively including 7.3% and 14.7% top-quality blastocysts. A total of 150 blastocysts originating from GQE and 729 from PQE were frozen. From the frozen blastocysts, 37 and 161 were thawed and transferred respectively resulting in 19 (51.4%) and 61 (37.9%) clinical pregnancies. These pregnancies gave 13 (35.1%) deliveries in GQE group and 32 (19.9%) in PQE group (p = 0.046). Interestingly, the quality of blastocysts that resulted in live birth was similar in the two groups. We didn't observe any statistically significant difference in neonatal outcomes between the groups. Regarding age and time of blastocyst expansion at day-5 or 6, women under 35 years old and day-5 blastocyst expansion were predictive of ongoing pregnancy and live birth.

Limitations, reasons for caution: The poor predictive value of the morphological approach in embryo selection could constitute a limitation in this study. This aspect is illustrated with the possible contribution of the trophectoderm (TE) to implantation and delivery success but not to the live-birth. More studies on larger series are needed to evaluate it.

Wider implications of the findings: Our study clearly demonstrated the merits of keeping PQE in extended culture, as these gave rise to pregnancies and live births. These data should encourage embryologists to vitrify surplus good and fair-blastocysts quality originating from poor-quality cleavage stage embryos in order to optimize the chances for infertile couples to conceive.

Trial registration number: Not applicable.

P-140 The choice of the best embryo originating from spermatozoa of men with severe male factor infertility: morphokinetics and next-generation sequencing (NGS) results

O. Somova[1], V. Feskov[1], I. Zhylkova[2], O. Tishchenko[1], O. Feskov[1]

[1]Centre of Human Reproduction Sana-Med, IVF Department, Kharkiv, Ukraine
[2]Centre of Human Reproduction Sana-Med, PCR laboratory, Kharkiv, Ukraine

Study question: To examine the influence of poor sperm quality on embryo morphokinetics and aneuploidy rate; to evaluate implantation potential of euploid embryos obtained from poor sperm.

Summary answer: Embryos of men with severe oligoasthenoteratozoospermia have slower morphokinetics and lower implantation potential, however their aneuploidy rate does not differ from embryos of normospermic men.

What is known already: Time-lapse (TL) technology provides more informative evaluation criteria of embryo development that can increase the chance of identifying the embryos with higher implantation potential and improve embryo selection. However, the data concerning the association between morphokinetic parameters and ploidy of embryos after trophectoderm biopsy are controversial. It is known that not all high quality embryos determined according to TL-test, become blastocysts, and among the blastocysts almost 50% embryos with good morphology are aneuploid. Moreover, there are no consistent results regarding possible influence of poor sperm quality on early embryo development and the risk of aneuploidies.

Study design, size, duration: Retrospective study (2015–2016) of morphokinetics and ploidy of 188 blastocysts obtained after ICSI procedure was conducted. 148 blastocysts were formed from spermatozoa of men with severe oligoasthenoteratozoospermia (OAT) and 40 blastocysts were formed from spermatozoa of men with normozoospermia using donor oocytes (female mean age $26 \pm 1,8$ years). Only the good and top quality hatching blastocysts were biopsied and vitrified on 5–7 day followed by NGS PGD.

Participants/materials, setting, methods: Two groups of patients were compared: 36 men with OAT (< 5 million/ml, motility ≤5%, normal sperm morphology ≤2%) and 9 men with normozoospermia (≥20 million/ml, motility > 50%, normal morphology > 35%). Embryo morphokinetic parameters (2pn fading, cell divisions, intervals between divisions, direct and reverse cleavages, blastocyst hatching) and implantation potential based on the TL-test results (TL-high vs.TL-low) were analyzed using TL monitoring system (PrimoVision). The NGS test was performed using low coverage whole-genome sequencing platform (Illumina).

Main results and the role of chance: Among 148 biopsed blastocysts from the group of men with OAT 92 embryos were euploid (62.2%). Almost the same result (65.0%) was obtained in the group of men with normospermia (the control): 26 euploid embryos of 40 biopsied blastocysts. The times of 2pn faiding, division to 2, 3 and 5 cells, duration of t3-t2, t3-2pn faiding, t5-t2 and t5-t3 intervals in the euploid embryos were similar in the both groups, but the times of division to 8 cells, blastocyst hatching beginning and synchrony in division from 3 to 4 cells (s2) were significantly longer in the euploid embryos of OAT men comparing with the control (p < 0.05). Direct and reverse cleavages were observed more often in the embryos of OAT men (respectively, 26.0 and 21.7%) vs. control (10.0 and 10.0%, p < 0.05). The implantation potential of euploid blastocysts was lower in the OAT group vs. control (respectively, 34.8 vs.77.5% of TL-high embryos, p < 0.05). The morphokinetics of abnormal embryos of the both groups were similar to the morphokinetics of euploid embryos in the OAT group and significantly differed from the euploid control. The complex embryo aneuploidy was found in 53.6 and 42.9% of cases in the OAT group and in the control respectively.

Limitations, reasons for caution: The study included only biopsied blastocysts obtained from donor oocytes and the best spermatozoa of men with very poor or high sperm quality. The embryos, which have not become blastocysts, or blastocysts of low morphological quality were not biopsied and not included in the study.

Wider implications of the findings: The complex applying of embryo TL monitoring and comprehensive, cost-effective NGS for PGD of blastocysts aneuploidies allows to select the healthy embryos with high implantation potential. Besides the severe male factor infertility, it is recommended in cases of advanced female age and the high miscarriage rate.

Trial registration number: No registration number.

P-141 Intraindividual embryo morphokinetics are not affected by a switch of the ovarian stimulation protocol between GnRH agonist versus antagonist regimens in consecutive cycles

J.E. Dietrich, A. Freis, F. Beedgen, J. Weigert, T. Strowitzki, A. Germeyer

Heidelberg University Women's Hospital, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany

Study question: Are intraindividual embryo morphokinetics affected by switching the type of GnRH analogue used (agonist versus antagonist) in consecutive treatment cycles of controlled ovarian stimulation (COS)?

Summary answer: Embryo morphokinetics are not affected by a switch in the type of GnRH analogue used for down-regulation in consecutive cycles of COS.

What is known already: Murber et al. (2009) described differences between oocytes/embryos from patients treated with gonadotrophin-releasing hormone (GnRH) agonists versus antagonists and found a higher number of blastomeres in day 2 embryos after antagonist treatment. Muñoz et al. (2013) found that embryos cleaved faster when they were generated in cycles with GnRH antagonist plus GnRH agonist-trigger versus GnRH agonist plus hCG-trigger. However, the group did not detect differences in embryo quality based on morphokinetics. A recent intervention review found no difference between GnRH antagonist and the long protocol of GnRH agonists for COS regarding live birth and miscarriage rates (Al-Inany et al., 2016).

Study design, size, duration: This retrospective cohort study analyzed morphokinetics of embryos from patients (n = 49) undergoing a switch in COS protocols between GnRH agonists (n = 49 cycles, n = 175 embryos) and GnRH antagonists (n = 49 cycles, n = 164 embryos) after culture in a time-lapse incubator (EmbryoScope®, Vitrolife) in our clinic between 06/2011 and 11/2016. Included were all embryos of the two consecutive cycles before and after a switch in the type of COS in the same patient.

Participants/materials, setting, methods: IVF or ICSI was performed on oocytes from agonist cycles (Nafarelin, Triptorelin or Leuprorelin), or antagonist cycles (Cetrorelix or Ganirelix). Embryos were time-lapse imaged up to day 5. Morphokinetics were annotated as described by Ciray et al. (2014) and presented in hours (h) as median (quartiles 25–75). Data were analyzed by pairwise exclusion using Mann-Whitney-test or Fisher's exact test (SPSS Version

22). The significance level is p = 0.05. Patients with preimplantation genetic screening cycles were excluded.

Main results and the role of chance: The mean age (years ± standard deviation) of patients at the time of treatment was 35.65 ± 4.28 (agonist) and 35.84 ± 3.96 (antagonist) (p = 0.94). The number of oocytes collected was 9.03 ± 4.52 (agonist) and 9.53 ± 4.08 (antagonist) (p = 0.54). The fertilization rate was 47.2% (239/506; agonist) and 44.8% (209/467; antagonist) (p = 0.441). We found no statistically significant difference between the analyzed morphokinetic parameters between the study groups. Time to extrusion of polar body 2 (tPB2) was tPB2(agonist) = 3.52 h (2.77–4.22; n = 126) or tPB2 (antagonist) = 3.44 h (2.84–4.16; n = 93) (p = 0.63). The pronuclei had faded (tPNf) at 24.43 h (22.68–27.46; n = 163) (agonist) or 25.13 h (22.89–27.74; n = 152) (antagonist) (p = 0.17). The time to 2-cell stage (t2) was at t2 (agonist) = 27.38 h (25.18–30.60; n = 172) or t2(antagonist) = 27.60 h (25.56–30.68; n = 159) (p = 0.72). There was no significant difference in the times to 3- to 9-cell and morula stage. Early blastocyst stage was reached at tSB (agonist) = 99.74 h (91.37–102.93; n = 65) or tSB(antagonist) = 100.56 h (91.40–104.54; n = 66) (p = 0.41). There was no significant difference in the times to blastocyst, expanding blastocyst, the duration of embryonic cell cycles (ECC) 1 (= t2-tPB2), ECC2 (= t4-t2) and ECC3 (= t8-t4), as well as the synchronicity of cell divisions s2 (=t4-t3) and s3 (=t8-t5). There was no significant difference in the rate of direct cleavage (DC; t3-t2 < 5 h) between the study groups (DC(agonist) = 10/174 (5.75%) vs. DC(antagonist) = 7/158 (4.43%) (p = 0.627)).

Limitations, reasons for caution: We did not test for differences in embryo quality based on standard morphology assessment. Larger confirmation studies need to be performed, as our sample size is small.

Wider implications of the findings: In contrast to another study (Muñoz et al., 2013) we did not find differences in embryo morphokinetics after switching the type of GnRH analogue used for COS. This finding supports the flexible use of GnRH analogues to optimize patient treatment for COS without affecting embryo morphokinetics.

Trial registration number: A trial registration number was not required due to the retrospective study design.

P-142 Extended culture and Day-5 transfer of frozen-thawed cleavage stage embryos is associated with higher implantation rate when compared with embryos frozen-thawed-transferred at the cleavage stage

G. Bozdag[1], M. Polat[2], I. Yarali[3], S. Mumusoglu[1], L. Karakoc Sokmensuer[4], H. Yarali[1]

[3]Anatolia IVF and Woman Health Center, Histology and Embryology, Ankara, Turkey
[4]Hacettepe University- School of Medicine, Histology and Embryology, Ankara, Turkey

Study question: Do implantation rates differ of Day-3 frozen-thawed-transferred cleavage-stage embryos versus Day-3 frozen-thawed-extended cultured and Day-5 transferred blastocysts?

Summary answer: Extended culture of thawed cleavage-stage embryos to Day-5 and transfer enhances implantation and minimizes multiple rates when compared thawing and transferring at the cleavage-stage.

What is known already: When compared to cleavage stage, live birth rate is higher with fresh blastocyst-stage transfer despite lower embryo freezing rate. With improvements in in-vitro culture systems and vitrification techniques, there is, currently, a worldwide trend of more fresh blastocyst-stage transfers with surplus blastocysts frozen on Day 5/6. Progression to blastocyst formation following thawing of a cleavage-stage embryo may reflect competency and viability, and hence may be employed as a selection criterion. There is paucity of data whether thawing cleavage-stage embryos and transferring on Day-5 following extended culture enhances implantation rate when compared with transfer at the cleavage-stage.

Study design, size, duration: Retrospective cohort study of frozen embryo replacement (FER) cycles between April-2013 and November-2016. As a policy, surplus embryos have been frozen exclusively at blastocyst-stage since June-2014; before that date cryopreservation was done at cleavage-stage. At cleavage-state, when number of frozen embryos exceeded planned number of embryos to be transferred (1 or 2), extended culture of two additional days was undertaken. Only, first FER cycle was included per patient. Implantation rate was primary outcome.

Participants/materials, setting, methods: Three groups of patients were generated according to the day of freezing-thawing and embryo transfer. Group A constituted 91 cycles frozen-thawed and transferred at cleavage-stage. Group B constituted 232 cycles frozen (Day 5/6)-thawed and transferred at blastocyst-stage. Group C constituted 41 cycles frozen-thawed at cleavage-stage, extended cultured and transferred at blastocyst-stage (Day 5). Slow freezing was more commonly employed in Groups A (64.8%) and C (65.9%), whereas vitrification was used exclusively in Group B.

Main results and the role of chance: The mean female age, body-mass index, duration of infertility, number of previous in-vitro fertilization attempts was comparable among the three groups. As expected, the number of surplus embryos to be frozen was significantly less in Group B when compared with Groups A and C (2.7 $\pm$ 1.7 vs. 6.7 $\pm$ 2.8 and 6.7 $\pm$ 3.7, respectively, p < 0.001). The survival rates of cleavage-stage and blastocyst-stage embryos were 76.4% and 95.4% (p < 0.001), respectively. The mean number of embryos transferred in Groups A, B and C was all statistically different from each other (1.9 $\pm$ 0.3, 1.4 $\pm$ 0.5 and 1.3 $\pm$ 0.5, respectively, p < 0.001). The respective figures for ongoing pregnancy were 26.4%, 41.8% and 34.2% (Groups A and B, p = 0.01). Implantation rate in Group A was significantly less when compared with Groups B and C (21.6% vs. 49.1% and 40.7%, p < 0.001). Ongoing pregnancy and implantation rates of Groups B and C were comparable. Miscarriage rates were comparable among the three groups. Multiple pregnancy rates were 15.2% and 19.9% in Groups A and B, respectively (p > 0.05); there was no case of multiple gestation in Group C.

Limitations, reasons for caution: Despite comparable baseline demographic features of the three groups, retrospective study design is a drawback. The lack of use of a single freezing method is another drawback despite comparable rates of use of slow-freezing and vitrification methods in Groups A and C.

Wider implications of the findings: If frozen at the cleavage-stage and number of frozen embryos exceeds planned number of embryos to be transferred (1-2 in current series), extended culture of two additional days might enhance selection of the most competent embryo. Such a policy is associated with higher implantation rate and minimizes risk of multiples.

Trial registration number: None.

P-143   Does vitrification of day3 embryos impose methylation errors in in vitro produced human blastocysts?

M. Derakhshan-Horeh[1], A. Moini[2,3], F. Jafarpour[4], F. Abolhassani[1], K. Karbalaie[5], S.M. Hosseini[4], M.H. Nasr-Esfahani[6,7]

[7]Isfahan Fertility & Infertility Center, Isfahan, Iran

Study question: Regarding the possibility of epigenetic risks induced by vitrification, this study assessed the effect of vitrification on DNA methylation pattern of ICR1 in human blastocyst.

Summary answer: Vitrification of Day3 embryo does not appear to alter the DNA methylation pattern of ICR1 in high - quality blastocyst.

What is known already: 'Freeze-all' strategy has been proposed in ART clinics due to prevention of interference between superovulation and endometrial receptivity. Superovulation may decrease endometrial receptivity results in an imbalance synchronized between endometrium and embryo. In addition of benefits of embryo vitrification, there are concerns about possible neonatal complications in children born after freezing ET such as large baby syndrome. Also, vitrification of Day 3 embryo coincides with genome-wide epigenetic reprogramming and zygotic genome activation (ZGA) which may prone embryos to alterations of imprinting control region (ICR). Therefore, we compared methylation status of ICR1 in human blastocyst-derived from vitrified with non-vitrified embryos.

Study design, size, duration: A total 30 embryos were donated from 11 healthy couples with at least two children of same-sex referring for family balancing. Assessment of the embryos was performed in two non-vitrified and vitrified groups. Day3 embryos derived from ICSI were either biopsied or vitrified/warmed and subsequently biopsied. Following biopsy, embryos were cultured to day 5. Day5 blastocysts with sex desired were transferred or vitrified for future use. Un-desired blastocysts were donated for our study.

Participants/materials, setting, methods: The methylation pattern of ICR1, also known IGF2/H19 DMR was determined by bisulfite conversion and sequencing, on 30 blastocysts and one million peripheral blood lymphocytes as quality control to obtain the pattern of imprinted gene methylation in somatic cells. This region involved in imprinting disorders such as BWS and SRS which are linked to ART. We assessed the methylation of 18 CpGs in a 220 bp fragment of ICR1 contains the CTCF binding site.

Main results and the role of chance: To identify whether embryo vitrification could alter the DNA methylation degree of

ICR1 in the blastocyst, the region including 18 CpGs was analysed. In addition, more than 15 clones were sequenced per replicate. The average methylation pattern of CpGs in the non-vitrified and vitrified groups were 38.27 $\pm$ 4.1% and 35.3% $\pm$ 3.6, respectively. Thus, this level of overall methylation between the two groups was not significantly different (P > 0.05). The methylation status of lymphocyte was 49.52 $\pm$ 1.86%. The percentage of hyper-methylated clones of ICR1 in non-vitrified and vitrified groups were 43.75 $\pm$ 5.1% and 38.7% $\pm$ 4.9, respectively. The difference of proportion of hyper- methylated clones between two groups was not significantly (P > 0.05). This value for the lymphocyte was 50%. Therefore, the data revealed that vitrification could not affect DNA methylation pattern of ICR1 in the blastocyst. However, the methylation status of ICR1 in both groups is lower than the expected methylation level of somatic cells. One likely possibility for the observed methylation level in vitrified and non-vitrified embryos would be that methylation level of control regions in imprinting genes are not rigid during pre-implantation development embryo and can be affected at least in part by the genome-wide demethylation.

Limitations, reasons for caution: Possibility the preferential amplification of maternal or paternal allele due to small starting amounts. Also, further studies are needed to make sure that expression of H19 and IGF2 is not changed.

Wider implications of the findings: 1) This finding may confirm the policy of 'freeze all embryo" regarding the adverse effects of superovulation which may perturb endometrial receptivity. 2) Despite a general consensus that imprinted genes are highly protected from genome-wide demethylation during pre-implantation development embryo, but these can be affected at least in part.

Trial registration number: No = 24088.

P-144   The effect of changes in embryo culture environment on the rate of pregnancy and miscarriage

Y. Kida[1], F. Kondo[2], K. Murakami[2], S. Kounogi[1], N. Fukunga[1,2], Y. Asada[1,2]

[1]Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Nagoya-Aichi, Japan
[2]Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Kasugai-Aichi, Japan

Study question: Do changes in embryo culture environment effect the rate of clinical pregnancy and miscarriage?

Summary answer: In this study, changing the culture environment resulted in a significant increase in the rate of Day5 blastocyst transfer whilst the miscarriage rate significantly decreased.

What is known already: Previously, we reported an improvement in blastocyst development and number of good quality embryos by changing from sequential medium to single culture medium (Shimomura et al ESHRE 2014). In addition, we have reported that the blastocyst development rate was improved by changing from standard culture dish to WOW culture dish (consists of 25 microwells and allows group culture under a single drop of medium) (Watanabe et al ASRM 2015).

Study design, size, duration: This retrospective cohort study involved 557 cases (33.5 ± 3.6 years old) of classic culture method (sequential medium & single culture using standard dish: 2010 to 2012) and 550 cases (33.5 ± 3.5 years old) of the current method (single culture medium & group culture using WOW dish: June 2014 to May 2016). The subjects were all undergoing a first cycle of vitrified-warmed single blastocyst transfer with hormone replacement treatment.

Participants/materials, setting, methods: In the classic method, embryos were cultured in 30 μl of sequential Medium(SAGE) with medium changes on Day3/5 using a standard dish. In the current method, embryos were cultured in 60 μl of single culture medium(NakaMedical) using WOW dish(DNP) without medium change. In both methods, embryos were cultured up to Day7. The resulting blastocysts (≥Blast3) were transferred following the vitrified-warmed with Cryotop procedure (KitazatoBiopharma), and the rate of pregnancy and miscarriage was compared by chi-square test.

Main results and the role of chance: There was no significant difference in the pregnancy rate between the two methods (57.2% vs 56.0%). However, the pregnancy rate of the current method was significantly lower in Day6/7 blastocysts compared with the classic method (53.7% vs 36.6%; 42.9% vs 0%). There was no significant difference in the pregnancy rate on Day5/6/7 blastocysts following the classic culture method (59.6% vs 53.7% vs 42.9%). Yet using the current method, the pregnancy rate of Day5 blastocysts was significantly higher (61.0% vs 36.6% vs 0%) between Day5/6/7 blastocysts. C Comparing the miscarriage rates of classic vs current methods, the latter was significantly lower (23.6% vs 13.3%). Also, the miscarriage rate of Day5 blastocysts between the two methods, the current method was significantly lower (20.9% vs 12.6%). There was no significant difference in the miscarriage rate between Day5/6/7 blastocysts of the classic method. Further, there was no significant difference in the miscarriage rate between Day5/6 blastocysts of the current method (20.9% vs 29.3% vs 0%; 12.6% vs 20 .0%). Furthermore, the percentage of Day5 blastocysts was significantly increased (82.9% vs. 61.4%) as compared with the classic method.

Limitations, reasons for caution: This analysis compares methodologies carried out during two time periods.

Wider implications of the findings: The current method resulted in Day5 blastocysts with a significantly higher the pregnancy rate than Day6/7 blastocysts of the same method. Also, the miscarriage rate was significantly lower than in the classic method. Therefore, it is suggested that embryos of current method are improving quality.

Trial registration number: Not applicable.

P-145 Which is the best culture system? Comparison of biological outcomes obtained in single vs group culture performed on 204 sibling zygotesin PGS cycles

M.G. Minasi[1], E. Cursio[1], A. Ruberti[1], F. Scarselli[1], A. Colasante[1], V. Casciani[1], E. Iovine[1], K. Litwicka[1], M.T. Varricchio[1], F. Spinella[2], A. Biricik[2], F. Fiorentino[2], E. Greco[1]

[1]European Hospital, Center for Reproductive Medicine, Rome, Italy
[2]GENOMA, Molecular Genetics Laboratory, Rome, Italy

Study question: It is possible to obtain an improved blastocyst formation rate and/or to increase the number of euploid embryos performing group instead of single culture?

Summary answer: Both culture systems perform similarly; anyway in group culture, increasing the number of embryos cultured simultaneously could be a promising strategy

What is known already: Embryo culture is a critical aspect in IVF. Both single and group cultures are currently applied for human embryos although it is not known which one performs better. Animal studies revealed that culturing embryos in smaller volumes and/or groups significantly increases blastocyst cell number and elevates embryo viability. Several studies highlighted the importance of autocrine and paracrine growth factors influencing embryo development. Culture volume and/or density of co-cultured embryos could be really important in determining the right equilibrium between the final concentration of these embryo beneficial autocrine factors and the embryo-toxic metabolic products which progressively accumulate during embryo culture.

Study design, size, duration: This prospective randomized study started in June 2016 and is still ongoing. Biological outcomes from 204 zygotes obtained in 20 PGS cycles were enrolled. Inclusion criteria were: female age ≤39 years old and at least 6 regularly fertilized oocytes on day-1. Exclusion criteria were: genetic problems, egg donation cycles and severe male factor. Biopsies were performed on 115 blastocysts and analyzed with Next Generation Sequencing. Mean female age was 33.65 ± 3.03 years old.

Participants/materials, setting, methods: All zygotes were split in single (SC) or group (GC) culture (1:1 ratio). Drops of 35 μL and 100 μL of one-step medium at $37°C, 6\%CO_2, 5\%O_2$ was used in SG and GC, respectively. Based on the total 2PN, 3-4-5 zygotes were grouped in the same drop in GC (GC-3, GC-4, GC-5 subgroups). All 2PN, both individually (SG) or collectively (GC), were moved in the final drops after the fertilization check without other medium changeover until the blastocyst stage

Main results and the role of chance: A total of 267 mature oocytes were injected with a fertilization rate of 76.4% (N = 204): 100 and 104 zygotes were allocated in SC and GC, respectively. In SC, 95 embryos were obtained with a blastocyst formation rate of 70.5% (N = 67); 57 of them were biopsied from day-5 to day-7 of culture and 22 resulted euploid (38.6%). In GC, 100 embryos were obtained with a blastocyst formation rate of 60.0% (N = 60); 53 of them were biopsied from day-5 to day-7 of culture and 17 resulted euploid (32.1%) (NS). The top quality blastocysts were 32 (47.8%) and 30 (50.0%) in SC and GC, respectively; 50 blastocysts were obtained on day-5 in both SC (74.6%) and GC (83.3%) groups (NS). In the GC subgroups, 48, 36 and 20 zygotes were allocated in GC-3, GC-4 and GC-5, respectively; 46, 36 and 18 embryos were obtained with a blastocyst formation rate of 58.7% (N = 27), 52.8% (N = 19) and 77.8% (N = 14) in GC-3, GC-4 and GC-5, respectively (NS); 21, 18 and 14 of them were biopsied with an euploidy rate of 28.6% (N = 6), 27.8% (N = 5) and 42.9% (N = 6) in GC-3, GC-4 and GC-5, respectively (NS). The quality and the speed of growth were comparable for all blastocysts.

Limitations, reasons for caution: The number of embryos/blastocysts enrolled need to be enlarged. Probably the volume employed in GC is still too high and/or the number of embryos/blastocysts co-cultured is still too low. We are now reducing the volume of group culture to 35 μL and increasing the number of embryos/blastocysts grouped to 4-5-6.

Wider implications of the findings: Actually the choice of culture system is typically a decision based on the laboratory history and routine and/or on the wish to collect data on a single embryo. Data are lacking regarding the influence of the cultures on the biological outcomes, such as the blastocyst formation and the euploidy rates.

Trial registration number: Not applicable.

P-146 Follicular flushing in patients with poor ovarian response: A systematic review and meta-analysis

K. Neumann, M. Depenbusch, A. Schultze-Mosgau, T. Osterholz-Zaleski, G. Griesinger

University Hospital of Schleswig-Holstein- Campus Lübeck, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany

Study question: Is the use of double lumen needles and follicular flushing in poor response IVF patients associated with the number of oocytes (cumulus-oocyte-complexes; abbr.: COCs) retrieved?

Summary answer: Flushing with double lumen needles does not increase the mean COC yield in patients with poor ovarian response.

What is known already: Flushing ovarian follicles is widely used, especially in natural-cycle IVF patients or poor responders, as a means to increase the

number of COCs per aspiration. At least three recent meta-analyses have concluded that flushing does not increase the mean oocyte yield (Wongtra-Ngan et al., 2010; Levy et al., 2012; Roque et al., 2012). Yet, all RCTs but one included in these reviews were performed in normo-responder patients. Recently, further studies have become available. This review collates the evidence on flushing in poor responders.

Study design, size, duration: Multiple literature databases were searched for randomized, fully published studies comparing the outcome of IVF cycles with single lumen needles/no flushing vs. double lumen needles/flushing in poor response IVF patients. Meta-analyses were performed using standard procedures in the software program RevMan v.5.3. All analyses were done per randomized patient, wherever feasible.

Participants/materials, setting, methods: Three RCTs were identified and included in the meta-analysis. Two trials employed a valid randomization method with concealment of allocation, while one study employed pseudo-randomization. All three studies had the primary objective of testing for a difference in oocyte numbers between flushing and no flushing and in all three trials the necessary sample size was determined a-priori. In the control group of all trials, a single lumen needle was used.

Main results and the role of chance: Flushing using double lumen needles does not increase the mean number of COCs per patient undergoing follicular aspiration, but instead there was a trend towards less COCs with flushing (weighted mean difference [WMD]: -0.61 COCs, 95% confidence interval [CI]: -1.38 to 0.15; $p = 0.11$; $I^2 = 48\%$; three RCTs, n = 158). The proportion of randomized patients having at least one COC retrieved was not different between groups (risk difference: -2%, 95% CI: -13 to 8, $I^2 = 38\%$; $p = 0.64$; two RCTs, n = 127). The proportion of randomized patients undergoing embryo transfer was not different between groups (risk difference: -11%, 95% CI: -26 to 5, $p = 0.17$; $I^2 = 32\%$; two RCTs, n = 127). The clinical pregnancy was not different between groups (relative risk: 0.82, 95% CI: 0.52 to 1.30, $p = 0.4$; $I^2 = 87\%$; three RCTs, n = 158). The procedure duration was significantly increased with flushing (WMD +2.4 minutes, 95% CI: 1.8 to 2.9; $p < 0.001$; $I^2 = 0\%$; three RCTs, n = 158).

Limitations, reasons for caution: The combined sample size is large enough and the individual trials sufficiently homogenous in outcome to conclude with confidence that flushing in poor responders does not increase the COC yield. The combined sample size is still insufficient to allow conclusions on pregnancy likelihood.

Wider implications of the findings: Double lumen needles/flushing should not be employed for follicular aspiration in patients with poor ovarian response, since a positive effect could not be shown for any of the outcomes. Double lumen needles and flushing media are costly, while flushing increase effort for the team, and procedure duration for the patient.

Trial registration number:

P-147 A trial to predict blastocyst development of human embryos by Chip-sensing Embryo Respiratory Monitoring System

T. Kuno[1], M. Tachibana[1], H. Kurosawa[2], N. Shiga[1], A. Takahashi[1], Z. Watanabe[1], M. Ishibashi[1], M. Ihara[1], N. Yaegashi[1]

[1]Tohoku University Hospital, OB/GY, Sendai, Japan
[2]Tohoku Medical and Pharmaceutical University Wakabayashi Hospital, OB/GY, Sendai, Japan

Study question: Does the Chip-sensing Embryo Respiration Monitoring system (CERMs) enable prediction of frozen-thawed embryo development to blastocyst stage and safely applicable to clinical IVF?

Summary answer: Oxygen consumption rate correlated to developmental capability of embryos to the blastocyst stage, and CERMs can be safely applied to clinical IVF program.

What is known already: Recently, we developed a non-invasive chip-sensing embryo oxygen consumption measurement device, CERMs, in which circumvent the differences in inter-observer subjective view. CERMs enabled measure the oxygen gradient formed by its respiration as sensitive as the scanning electrochemical microscopy (SECM) technique. Oxygen consumption rates measured by CERMs correlated with in vitro embryo development to blastocyst stage, albeit with the limited numbers of samples.

Study design, size, duration: This is a prospective original research study. The oxygen consumption rate of redundant frozen-thawed human embryos was assessed using CERMs. An impact of its measurement by CERM on in vivo development was assessed by the mouse embryo transfer. The endpoints for the study were to assess feasibility of prediction of embryo development to blastocyst stage by CERMs, as well as recovering mouse fetuses.

Participants/materials, setting, methods: The oxygen consumption rates of 30 and 51 human embryos that were frozen-thawed on 2nd and 3rd day after fertilization, were measured by CERMs at 6, 24, 48, 72 and 96 hours after thawing with standard morphological evaluation. Embryos that have reached blastocyst stage and those of arrested were divided into two groups (blastocyst and arrested, respectively) and were analyzed. Mouse blastocyst obtained by IVF was transferred to synchronized surrogate and fetuses were recovered.

Main results and the role of chance: The characteristics of the patients (age distribution, infertility factor and type of assisted conception) were comparable in both groups. Oxygen consumption rates of both D2 and D3 human embryos that have reached the blastocyst stage were significantly higher than those of arrested embryos at 48, 72 and 96 hours after thawing ($p < 0.05$). Thus, irrespective to frozen stage of embryos, in vitro development of frozen-thawed human embryos to the blastocyst stage would have higher respiratory activity at 48 h after thawing. However, some portion of 48 h hours after thawing of D3 embryos would have reached to blastocyst stage. Therefore, we focused on D2 frozen-thawed embryos and the probability of reaching blastocyst stage increased significantly with every 1 fmol/s increase of oxygen consumption rate (odds ratio (OR) = 1.978; 95% CI, 1.020–4.577; $p = 0.04$) albeit with the limitation that this theory is applicable at 48 h after thawing. Based on the ROC curve, the cut-off oxygen consumption rate value was 5.0 fmol/s (sensitivity = 0.89; specificity = 0.55; AUC = 0.74). We recovered mouse foetuses that were measured oxygen consumption rates by CERMs. Thus, measurement procedure is not harm for subsequent embryonic development in vivo.

Limitations, reasons for caution: A correlation between oxygen consumption and the in vivo viability of embryos remains unknown. Individual respiratory activity of mouse embryos might be too small to evaluate this. Thus, clinical trials would be desirable to address this question. The effect of frozen-thaw manipulations on the respiratory activity is also unknown.

Wider implications of the findings: Selection of quality embryos by CERMs may have an impact on obtaining better clinical outcomes, albeit with clinical trials being required. CERMs may be useful for further optimization of culture condition or enable the omission of long-term in vitro embryo culture by early determination of quality embryo.

Trial registration number: not applicable.

P-148 Gonadotropin releasing hormone agonist (GnRH-ag) triggering in in-vitro maturation (IVM) cycles: new insights into physiology

A. Hershko Klement[1], D. Navve[2], Y. Ghetler[2], A. Wiser[2], O. Gonen[2], T. Shavit[2], A. Shulman[2]

[1]Kiryat Ono, Israel,
[2]Meir medical center, Obstetrics and Gynecology, Kfar Saba, Israel

Study question: What is the outcome of GnRH-ag triggering in IVM cycles?

Summary answer: In IVM cycles, GnRH-ag triggering shows a significantly higher rate of metaphase II eggs on the day of retrieval and a significantly higher fertilization rate.

What is known already: hCG has been the traditional triggering of ovulation mode in both IVF and IVM cycles. Recently, hCG triggering is challenged and is often replaced by GnRH-ag triggering. In IVM even small follicles respond to hCG priming and reach the MII stage at recovery with no need for in vitro maturation. Furthermore, these in vivo matured eggs retrieved in an IVM cycle are developmentally superior compared with those which are matured in vitro. Since there is a lack of information regarding the use of GnRH agonist in these circumstances we report our unit's experience in the IVM practice.

Study design, size, duration: a retrospective cohort analysis of 60 IVM cycles between 2015–2017 comparing cycle outcome by mode of triggering.

Participants/materials, setting, methods: 44 patients going through IVM cycle in a tertiary university affiliated hospital. Indications for treatment were a

pure ovulatory disorder, a mixed indication including an ovulatory component and oncology patients performing fertility preservation. Our IVM protocol includes gonadotropin (rFSH) exposure for 3 days in cases were endometrial lining is thinner than 6 mm after day 6 and only if the cycle is planned for an embryo transfer.

Main results and the role of chance: A total of 60 IVM cycles were included, 20 of them triggered by GnRH agonist (S.C decapeptyl 0.3 mg) and 40 triggered by recombinant hCG (S.C. 250 micrograms). Means and P values are presented hereby for the GnRH-ag triggering group and HCG group performance, respectively: total number of eggs retrieved 9.7, 10.4 (P value 0.6), MII egg ratio on the day of retrieval 0.25,0.14 (P value 0.02), final MII egg ratio 0.53, 0.59 (P value 0.4) and fertilization rate of injected ova :0.8, 0.6 (P value 0.01). In a sub-analysis comparing only patients who were not exposed to gonadotropins (14 patients in the GnRH-ag group, 9 in the hCG group), both retrieval day MII ratio and fertilization rate showed a significant benefit to the GnRH-ag triggering. Only 5 embryo transfers were performed so far for the GnRH-ag group, reflecting the common cancer indication and not the embryological performance; out of those we report one live-birth, one 1st trimester miscarriage and a pending pregnancy test. Despite the small sample size, the day of retrieval maturation rates and fertilization rates reflect a highly significant advantage for the GnRH-ag triggering.

Limitations, reasons for caution: patient allocation was not random and treatment variations were affected by indication. In spite of the low exposure to rFSH of the GnRH-ag group, they presented a better embryological performance.

Wider implications of the findings: These results reflect a possible advantage for GnRH-ag in IVM cycles, especially those performed for fertility preservation. The fact that immature follicles can perform better after exposure to a GnRH-ag triggering is suggestive of the importance of FSH surge in follicular maturation.

Trial registration number: This is not a clinical trial. REB approval number MMC0031-17.

P-149 Impact of conscious sedation during oocyte retrieval on clinical pregnancy rate in assisted reproductive technology? An equivalence study in France

N. Bourgon[1], A. Berdin[1], A. Bailly[2], A.L. Parmentier[3], P. Koeberle[4], D. Riethmuller[5], P. Lagre[1]

[1]Besançon University Hospital, Assisted Reproductive Technology Unit- Obstetric and Gynecology, BESANCON, France
[2]Besançon University Hospital, Assisted Reproductive Technology Unit- Reproductive Biology, BESANCON, France
[3]Besançon University Hospital, Clinical Methodology center, BESANCON, France
[4]Besançon University Hospital, Anesthesia and Intensive Care Unit, BESANCON, France
[5]Besançon University Hospital, Obstetric and Gynecology, BESANCON, France

Study question: Does using conscious sedation during oocyte retrieval change clinical pregnancy rate per aspiration cycle.

Summary answer: There is no reduction of clinical pregnancy rate per aspiration cycle with conscious sedation during oocyte retrieval.

What is known already: Oocyte retrieval is an important step of assisted reproductive technology (ART). In France, general anesthesia is most commonly used for transvaginal oocyte aspiration. Conscious sedation is the most popular method of analgesia used in ART in many countries. Cochrane systematic review didn't recommend a technique compared to another. Although conscious sedation is associated with better patient satisfaction score. However, few studies have evaluated this technology at centers with french practices.

Study design, size, duration: We performed a retrospective cohort study in our ART center. We compared two periods: period 1 from 01/01/09 to 12/31/11 and period 2 from 01/01/13 to 12/31/16. Primary outcome was clinical pregnancy rate per aspiration cycle. Clinical pregnancy was defined as the presence of a heart beat in US-scan. We performed a non-inferiority study. Equivalence between two rates was established if they differed by less than 25% with reference rate (period 1).

Participants/materials, setting, methods: We included consecutively all patients who underwent transvaginal oocyte aspiration in our ART center. During period 1, general anesthesia protocol associates midazolam 1-2 mg I.V. and alfentanil 1 mg I.V. During period 2, conscious sedation associates pre-medication (prazepam 10 mg P.O. and ketoprofène 100 mg P.O.) and an association during procedure with midazolam 1 mg I.V., nalbuphine 0,2 mg/kg I.V., ondansetron 4 mg IV and medical nitrous oxide and oxygen mixture. Different steps were carried out according to french or international guidlines.

Main results and the role of chance: We performed 1371 aspirations during period 1 and 1495 aspirations during period 2. After exclusions, we analyzed respectively 1338 and 1452 procedures. There was no difference about cause of infertility. We have gradually changed our practices over the years with an increasing use of antagonistic protocol (6.80% vs 25.12%, p < 0.001) but there was no difference in oocytes collected count (9 VS. 10, p = 0.008). They were no difference in semen parameters even if we changed technic for semen preparation. Although fertilized oocytes count was greater in period 2 (4.9 vs. 5.1, p = 0,008), there was no difference in numbers of oocytes 2PN and embryos obtained. There were more transferred embryos and frozen embryos in period 2 (1.6 vs. 1.7, p < 0.001 and 1.1 vs. 1.3, p = 0,002). Overall, clinical pregnancy rate per aspiration cycle was 37% in Period 1 and 35% in Period 2.

Limitations, reasons for caution: We chose to study two three-year periods in order to limit selection bias and mandatory variations in ART performance. This leads to variations in practices. However, there is no current scientific evidence of a difference in efficacy for these variant parameters from one period to another.

Wider implications of the findings: Firstly, absence of significant differences between the two groups allows us to validate our protocol. Then we will be able to distribute it to other centers. Finally we will try to improve it.

Trial registration number:

P-150 Different GnRH analogs effects on the level of apoptotic and developmental cumulus cells gene expression in ART cycle

S. Azizollahi[1], B. Hossein Rashidi[2,3], E. Shahrokh-Tehraninejad[4], S. Amanpour[1], M. Bagheri[3], F. Haghollahi[3]

[1]Tehran University of Medical Sciences, Vali-e-Asr Reproductive Health Research Center, Tehran, Iran
[2]Tehran University of Medical Sciences, gynecology, Tehran, Iran
[3]Tehran University of Medical Sciences-, vali-e-Asr Reproductive Health Research Center, Tehran, Iran
[4]Vali-e-Asr Reproductive Health Research Center- Tehran University of Medical Sciences- Tehran- Iran, gynecology, Tehran, Iran

Study question: Whether different GnRH analogs(agonist or antagonist) prescription can affect cumulus cells gene expression?

Summary answer: Cumulus cells gene expression is significantly different following different type of GnRH analogs administration

What is known already: GnRH (gonadotropin realizing hormone) agonist (GnRH-A) and antagonist (GnRH-ANT) are widely used in ovarian stimulation cycle in order to suppress the endogenous luteinizing hormone (LH) surge. Different characterization and mechanism of action between GnRH analogues in IVF (in vitro maturation) cycle have been well defined. The presence of GnRH receptors on the surface of ovarian epithelial cells and granulosa (GC) and cumulus cells (CC) was detected. Cumulus cells play an important role in follicular development, Based on this background present study proposed to investigate GnRH agonist and antagonist effects on cumulus cell gene expression and IVF outcome.

Study design, size, duration: Sixty 60 infertile patient were enrolled in the study based on our exclusion and inclusion criteria. The patient were divided in two groups randomly, 28 of them allocated to the GnRH agonist group by 0.1 mg/day S.C. triptorelin and 150–225 IU S.C rFSH Gonal-F, administrating based on standardized long protocol. The patient 32 women allocated in GnRH antagonist and treated by (0.25 mg/day) Cetrotide and 150–225 IU S.C rFSH Gonal-F, according to the fixed protocol.

Participants/materials, setting, methods: Defined Clinical and embryological parameters were compared. Percentage of Metaphase II (MII) oocytes,

fertilization rate, grade A and AB embryo percentage on Day3 post-insemination were assessed as embryological parameter in each groups. Pregnancy rate, and the number of ovarian follicles before OPU were investigated as clinical aspect of our study. In order to molecular assessment BAX, BCL-2, survivn, ALCAM and VCAN were evaluated in Cumulus cells by performed Real time PCR.

Main results and the role of chance: Molecular evaluation: relative gene expression of Bax gene expression was significantly higher in CCs of patient received GnRH agonist (39.1 ± 2) in compare with GnRH antagonist (27.01 ± 4.2) group. ($P < 0.001$). Higher Bcl-2 mRNA expression in CCs of GnRH antagonist group (61.4 ± 2.2) versus GnRH agonist (44.3 ± 4.2) were observed significantly ($P < 0.001$). The ALCAM expression (16.8 ± 0.6 vs 22.2 ± 1.3) was observed significantly different in GnRH agonist and antagonist groups respectively. Significant difference in VCAN (40.5 ± 7.9 vs 41.8 ± 6.7) and survivine (64.8 ± 6 vs 66.9 ± 7.6) between GnRH agonist and antagonist was not determined respectively.

Clinical parameters evaluation: Although the number of dominant ovarian follicle, pregnancy rate are more in GnRH antagonist group but differences was not statistically significant

Embryological evaluation: The mean number of obtained COC percentage of MII oocyte, PN and grad A embryo did not significantly differ between GnRH agonist and antagonist

Limitations, reasons for caution: To accurately the moral issues The protocol of present randomized study was approved by the Ethics Committee of Tehran University of Medical Sciences, informed consents was fulfilled and signed by all of the participants.

Wider implications of the findings: there is an article that indicat GCS apoptosis rate was not correlated to oocyte maturity, quality and pregnancy outcome. But strong correlation of CCS apoptosis and poor oocyte quality was concluded by several studies.

Trial registration number: 29126.

P-151 A single cell analysis of cumulus cells from cumulus-oocyte complexes by flow cytometry

M. Tsuneto, K. Yumoto, M. Sugishima, C. Mizoguchi, J. Yamauchi, A. Tanaka, N. Okada, S. Miyazaki, M. Nakaoka, Y. Kai, K. Iwata, Y. Mio

Mio Fertility Clinic, Reproductive centre, Yonago, Japan

Study question: Are cumulus cells from cumulus-oocyte complexes (COCs) a heterogeneous population of cells?

Summary answer: Cumulus cell samples prepared from COCs included heterogeneous cell populations. Flow cytometric analyses revealed differential antigen expressions on the surface of cumulus cells.

What is known already: Previous research has tried to predict oocyte quality by analysing the oocyte-surrounding cumulus cells using a non-invasive assay. Transcriptomic analyses of the cumulus cells found candidate genes that could predict oocyte quality. However, these results are still controversial. Previously, single cell analysis of cumulus cells has not been performed. Flow cytometric analysis could provide biological information from cumulus cells and enable the purification of cumulus cells for a precise transcriptomic assay to predict oocyte quality.

Study design, size, duration: From June to December 2016, cumulus cells were collected from intracytoplasmic sperm injection-treated patients who provided informed consent. The age of patients ranged from 30 to 46 years.

Participants/materials, setting, methods: Flow cytometric analysis was performed on cumulus cells from 22 patients. In cases where patients gave more than 2 COCs, the cumulus cells derived from the COCs were pooled. After hyaluronidase treatment of the COC, cumulus cell samples were collected for staining with antibodies and analyzed by flow cytometry (Gallios, Becton-Dickinson, USA).

Main results and the role of chance: The cell suspension collected from the COCs included $63.1\% \pm 15.95\%$ dying/dead cells stained with propidium iodide. In the propidium iodide-negative living cells, CD45-positive blood cells and CD235a-positive erythrocytes were detected, suggesting that blood cells contaminated the suspension during oocyte retrieval. After screening out blood cells, non-hematopoietic living cells were detected to be two or three times larger than hematopoietic cells. These non-hematopoietic cells expressed CD49a

($95.9\% \pm 5.43\%$), activated leukocyte cell adhesion molecule (ALCAM, $75.5\% \pm 17.96\%$ of non-blood living cells), and CD56 ($40.8\% \pm 17.75\%$) on the cell surface. The non-hematopoietic cells also expressed follicular stimulating hormone receptor (FSHR) which has been reported to be expressed in cumulus cells, although hematopoietic cells had no expression of FSHR. These data indicate that CD49a and ALCAM are good markers of cumulus cells and that cell purification by cell sorting to eliminate dead cells and blood cells would be helpful for performing precise gene expression analyses of cumulus cells, in order to search for oocyte quality-relevant genes.

Limitations, reasons for caution: The current work is a pilot study of a small number of samples and a larger analysis of cumulus cells from individual COCs should be done in the future.

Wider implications of the findings: Flow cytometry would be useful, not only for precise transcriptomic analyses, but also for a quick investigation of cumulus cell status, e.g. percentage of apoptotic cells or status of mitochondrial activation could predict oocyte quality.

Trial registration number: Not applicable.

P-152 Treatment with GM-CSF improves pregnancy rates in poor responders

S.H. Min, K. Ja-Seong, L. Hyeyoung, M. Hwa-Sook

Good Moonhwa Hospital, Center of Reproductive Medicine, Busan, Korea- South

Study question: Is the inclusion of GM-CSF in embryo transfer media associated with increased clinical outcomes rates in patients with poor responders IVF attempts?

Summary answer: Better results in terms of clinical pregnancy and ongoing implantation rate were observed after treatment of GM-CSF in embryo transfer media.

What is known already: Cytokines drive the dialogue between the embryo and endometrium and are increasingly expressed throughout embryo development. GM-CSF is known for its importance in the development of blastocysts and in normal fetal and placental development. It is reported that inclusion of GM-CSF in embryo culture media significantly increases ongoing implantation rates in women who have previously experienced miscarriage. However, it is still unclear whether poor responders IVF attempts should be another indication for the use of GM-CSF.

Study design, size, duration: This prospective study was performed between January 2016 and September 2016 at a reproductive center. All patients involved gave written consent, and institutional review board approval was granted. This study includes 55 non-treatment and 60 treatment couples.

Participants/materials, setting, methods: A prospective study was conducted including patients with a poor responders following conventional ICSI in our center. In the treatment cycles, embryos were exposed to a commercially available ready-to-use 2 ng/ml GM-CSF for 10 min immediately before ET. ET was performed either on Day 2 or Day 3. Clinical pregnancy and ongoing implantation rates were compared, p-value of < 0.05 was considered statistically significant.

Main results and the role of chance: The average female age, number of oocytes retrieved, embryo developmental stage and number of embryos transferred did not vary significantly among the groups. Fertilization and cleavage rates did not differ. However, Clinical pregnancy rates (22/60 (38.3%) vs 17/55 (30.9%), and ongoing implantation rates (18.9 ± 5.3 vs 14.2 ± 4.8) were higher in GM-CSF treatment group compared to control, but these differences did not reach statistical significance.

Limitations, reasons for caution: This is an observational study with limited number of patients, offering preliminary evidence for the efficiency of GM-CSF in embryo transfer media in patients with poor responder IVF attempts. This study is still not powered to exclude possible associations between take home baby rate and perinatal outcomes on babies born.

Wider implications of the findings: The findings of this study indicate that GM-CSF treatment improves the rates of pregnancy and ongoing implantation rates in poor responders. However, this treatment does not seem to completely resolve the poor responders. Further investigations are necessary to determine the effects of GM-CSF treatment of the culture conditions.

Trial registration number: NA.

P-153 Defining a novel method to describe giant oocytes by cytoplasmic diameter -Comparison of the mitotic spindle diameter by fluorescence immunostaining-

Y. Konuma[1,2], H. Kitasaka[1,2], M. Tokoro[3], M. Kojima[1,2], N. Fukunaga[1,2,3], Y. Asada[1,2,3]

[1]Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Kasugai, Japan
[2]Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Nagoya, Japan
[3]Asada Ladies Clinic Medical Corporation, Asada Institute for Reproductive Medicine, Kasugai, Japan

Study question: Is an oocyte cytoplasmic diameter $\geq 130\mu m$ useful as a means of defining Giant Oocytes (GO)?

Summary answer: Using a cytoplasmic diameter $\geq 130\mu m$ is a useful criterion for defining a GO.

What is known already: The diameter of a human oocyte is approximately $110\mu m$, but larger diameter oocytes have been documented in ART treatment cycles and referred to as Giant Oocytes (GO). GO appear to be a product of the cytoplasmic fusion of two primary oocytes, and there are examples of both ova in which some mitotic spindles which are fused or not fused. Accordingly they have a higher risk of aneuploidy than normal oocytes. However, the criterion for identification of GO are not clear, and the classification is often dependent on the experience of the embryologist.

Study design, size, duration: We examined 37,315 oocytes collected from 4,160 ART cycles which underwent controlled ovarian stimulation between January 2014 and March 2015. The cytoplasmic diameter of oocytes that were judged to be larger than normal was measured. 56 MII phase oocytes analyzed had a diameter of $\geq 130\mu m$ and were classified as GO. MII oocytes from conventional IVF cycles in which fertilization did not occur were used as a control group.

Participants/materials, setting, methods: Oocytes defined as GO had further measurements taken (overall diameter- cytoplasmic diameter and including the zona pellucida). Furthermore, these oocytes were fixed and immunofluorescence staining was carried out. They were stained with an α-Tubulin antibody and DAPI. Spindles were classified into three groups GO1 (1 spindle present), GO2 (2 spindles present) and control oocytes. The size of the spindle was measured by the distance between the two spindle poles, and chromosomes align distance equatorial plane.

Main results and the role of chance: GO had a cytoplasmic diameter of $144.3 \pm 10.7\mu m$ and a total diameter including the zona pellucida of $205.5 \pm 22.2\mu m$. After staining of the 56 GO, it was possible to analyze 47. Of these 25 were classified as GO1 and 22 oocytes were GO2. The average equatorial plane diameter of the spindle was $18.0 \pm 3.3\mu m$ in GO1, $11.7 \pm 2.2\mu m$ in GO2 and $12.3 \pm 1.3\mu m$ in control oocytes. The average diameter between the two spindle poles was $19.1 \pm 2.2\mu m$ in GO1, $14.5 \pm 3.2\mu m$ in GO2 and $13.2 \pm 2.0\mu m$ in control oocytes. GO1 were significantly different in these parameters compared to the other groups ($p < 0.05$).

Limitations, reasons for caution: In this study, we compared only the size of the mitotic spindle. Future studies should consider tests, such as Next Generation Sequencing to identify chromosome content.

Wider implications of the findings: Based on the results there were two types of GO, one of which had one large spindle and the other had two normal size spindles. From these findings, it is anticipated that the chromosomal content of GO would be up to 2 times higher than normal ova.

Trial registration number: None.

P-154 Automatic vitrification and warming of ovarian and testicular tissues

A. Arav[1], S. Ledda[2], Y. Natan[1], P. Levi Setti[3], M. Leong[4], P. Patrizio[5]

[1]Fertilesafe Ltd., R&D, Nes-Ziona, Israel
[2]University of Sassari, Department of Veterinary Medicine, Sassari, Italy
[3]Humanitas Research Hospital, Fertility Center, Milan, Italy
[4]The Women's Clinic, The Women's Clinic, Hong Kong, Hong Kong
[5]Yale University, Fertility Center, New Haven, U.S.A.

Study question: Previously we reported automated vitrification of oocytes/embryos. Here we address whether automated vitrification and warming can be used for ovarian cortical strips and testicular extracts.

Summary answer: This study is the first report describing a device allowing successful automation of both vitrification and warming procedures for gonadal tissue.

What is known already: Vitrification is the method of choice for preserving oocytes and embryos and is slowly gaining acceptance also for gonadal tissue. However, the procedure is cumbersome, requires highly skilled personal and is not standardized thus producing variable results. Having an automated device allowing the precise exposure of the tissue to cooling and warming solutions is desirable, particularly for preserving fertility for cancer patients. We have developed a fully automated device (Sarah, Fertilesafe Ltd., Israel) for both vitrification and warming for gonadal tissue slices in addition to oocytes and embryos.

Study design, size, duration: Ovarian strips cut into $400\,\mu m$ slices were prepared from 6 weeks old BL C57 female mice ovaries (n = 4). Testicular tissue extracts were prepared from testis of slaughtered lambs (n = 2), using an 18 g needle. Slices were either grown in culture or underwent vitrification and warming with a new automated robotic device (Sarah). The gonadal tissue was inserted into 0.3 ml straws (CBS, IMV, France) comprising a special capsule with $50\,\mu m$ pores and loaded in the robotic device.

Participants/materials, setting, methods: Straws loaded in the Sarah device were exposed to increasing concentration of equilibrium and vitrification solutions followed by plunging into LN slush at the last stop. Automated warming started by exposing the straws for 1 minute to reducing concentrations of warming solutions at $37°C$ until completion into holding medium. Ovarian slices were in-vitro cultured for 14 days and evaluated by L/D fluorescent staining, fixation and H&E histology. Testicular tissue was evaluated by Hoechst vital staining.

Main results and the role of chance: Cooling and warming rates measured using $50\,\mu m$ T-type thermocouple were over $4500°C/min$ using LN and over $10,000°C/min$ when straws were plunged into LN slush ($-208°C$). After warming, spermatogonial cells recovered from the seminal tubules showed high viability rates (23/25 (92%), 44/50 (88%), 23/30 (83.33%) compared to fresh controls (100% viable). After warming, the vitrified ovarian cortical strips showed over 90% survival of antral follicles (79/89) after 2 weeks of in vitro culture. Slides of ovarian strips after 14 weeks in culture stained with H&E showed the following number of antral follicles per $1\,mm^2$ – Fresh controls (n = 5): 2.6 ± 1.5; 1.6 ± 0.5; 1.3 ± 0.5; 2.6 ± 0.5; 1.6 ± 0.5. Vitrified/warmed (n = 5): 2 ± 1; 3 ± 1; 3 ± 1; 3.6 ± 0.5; 3 ± 1. These results show that in the vitrified/warmed slides there were slightly more antral follicles compared to the slides of the fresh controls. Since these results were not statistically different that the vitrification/warming process did not damage the ovarian slices.

Limitations, reasons for caution: These preliminary successful results with a newly automated device for both vitrification and warming were obtained on animal gonadal tissue and should be corroborated in human tissues.

Wider implications of the findings: Here we report for the first time a method that can successfully vitrify and warm ovarian and testicular slices by a fully automated, operator-independent process. The standardization and simplification of the vitrification/warming procedures of gonadal tissue can be of immense benefit for cancer patients worldwide.

Trial registration number: N/A.

P-155 Improvement of final oocyte maturation with combination of a gonadotrophin releasing hormone (GnRH) agonist with a human chorionic gonadotrophin (hCG) trigger in in vitro fertilization

E. Abi Rached[1], M.A. Metten[2], O. Pirrello[3], I. Lichtblau[4], J. Ohl[3], K. Bettahar[3], C. Rongieres[3]

[1]Service de Gynécologie Obstétrique- CHRU de Hautepierre, Bas Rhin, STRASBOURG, France
[2]Service de Recherche Clinique- Fondation Ophtalmologique Adolphe de Rothschild, Ile de France, Paris, France
[3]Service d'Assistance Médicale à la Procréation- Centre Médico-Chirurgical Obstétrique CMCO, Bas Rhin, Schiltigheim, France

[4]*Laboratoire de Biologie de la Reproduction- Centre Médico-Chirugical Obstétrique CMCO, Bas Rhin, Schiltigheim, France*

Study question: Do mature oocytes have a better rate of associating a double ovulation triggered in patients with a history of low proportion of mature oocytes?

Summary answer: The double trigger in comparison to the release by hCG only obtains 1,46 times more mature oocytes IC 95% (1,18-1,80) p < 0,001

What is known already: The fertilizable oocytes in in vitro fertilization (IVF) or in intracytoplasmic sperm injection (ICSI) have to be at the stage of metaphase II. In case of repeated immature oocyte retrieved, it was assumed that by prolonging the time between ovulation triggering and oocyte pick up (OPU) and the GnRH agonist trigger, with the consequent simultaneous induction of an FSH surge, the "double trigger" could overcome oocyte meiotic maturation resulting in successful aspiration of mature oocytes, pregnancy, and delivery (*Beck Fluchter* 2012).

Study design, size, duration: It is a retrospective monocentric study between May 2014 and September 2016, which compares the same patient, an attempt with a classic trigger (hCG alone) with a double trigger in the following attempt. In total, 56 patients were included consecutively. That's why the patients in pre-implantation genetic diagnosis (PGD) were included, although the rates of pregnancies are not taken account due to the risk of lacking in healthy embryo transfer.

Participants/materials, setting, methods: Patients had at least one attempt of IVF-ICSI under antagonists or agonist with a rate of immature oocytes $\geq$ to 40 % and had a double trigger for the following attempt. The ovarian stimulation was realized under antagonist and the double trigger associated hCG (hCG 5000 or 10000 UI or hCG recombinante *Ovitrelle* 250 UI) and agonist of the GnRH (*Decapeptyl* 0,2 mL). The main criteria was the percentage of mature oocytes retrieved.

Main results and the role of chance: The number of mature oocytes obtained by double trigger was 7,4 on average versus 5,1 in the classic group trigger with a relative risk (RR) of 1,46 IC 95 % (1,18-1,80) p < 0,001. There was no difference between both groups concerning the duration of the stimulation, the total dose of gonadotrophin received and the hormonal dosages before the triggering (LH, estradiol progesterone). The number of zygotes obtained in the first day (2PN) was 5,2 in the double trigger group versus 3,4 in the classic release group RR [1,54 (1,18-2,01] p0,002. Also for the number of embryos obtained in the second day: 5,5 versus 3,4 RR [1,66 (1,29-2,13]] p < 0,001 and the number of frozen embryos: 1,6 versus 0,6 RR [4,89 (2,32-10,30)] p < 0,001, there was not a significant improvement of pregnancy rates OR [11,1 (2,45–50,44)] p0.003.

Limitations, reasons for caution: It is a retrospective study which compares the results of the same patient. There is an inherent bias. The rates of the pregnancy rate are biased because of patients' inclusion in PGD. All the frozen embryos were not transferred, which does not report on cumulative pregnancy rates.

Wider implications of the findings: The double trigger allows for obtaining a larger number of mature oocytes and embryos to be transferred. However, our study could not show if there was also an improvement of the cumulative rates of pregnancies. Due to the encouraging results, a randomized prospective study must be established.

Trial registration number: Not applicable.

P-156 The prediction of sperm fertility potential from infertile men in real-time during intracytoplasmic sperm injection

F. Ghasemian[1], S.A. Mirroshandel[2]

[1]*University of Guilan, Biology, Rasht, Iran*
[2]*University of Guilan, Computer Engineering, Rasht, Iran*

Study question: Which male features have a predictive value for fertility potential and the occurrence of a pregnancy in infertile men undergoing intracytoplasmic sperm injection (ICSI)?

Summary answer: Follicle stimulating hormone (FSH), age, male infertility factor (e.g. oligozoospermia,asthenozoospermia,teratozoospermia,normozoospermia, and oligoasthenoteratozoospermia), testosterone and luteinizing hormone (LH), head size, and vacuole were relevant predicting parameters.

What is known already: The most prediction models of reproductive medicine are focused on female parameters and treatment success, and there are a few studies about the effect of male factors, and sperm parameters on treatment success from infertile couples with male factor infertility. Currently, there is also no prediction model for sperm fertility potential and the occurrence of pregnancy in real-time during ICSI.

Study design, size, duration: During 2012 to 2014, 209 patients with male factor infertility at the infertility therapy center of Alzahra (Iran, Rasht) were included in this study. To assay of male features, female factor infertility was excluded in this study.

Participants/materials, setting, methods: Selected sperms for intracytoplasmic injection were analyzed using sperm morphology analysis (SMA) algorithm in real-time during ICSI. Therefore, the characteristics of sperm parts (e.g. head and acrosome size, vacuole, neck, cytoplasmic droplet, and tail shape) were determined. According to selected sperm dataset and patient information, the fertility potential of each sperm and pregnancy chance of embryo resulted of that sperm were predicted. Measuring was done by CorrelationAttributeEval and Ranker of WEKA software.

Main results and the role of chance: The effect of male features such as FSH (0.074), age (0.07), male infertility factor (0.04), testosterone (0.04), LH (0.038), and head size (0.034) were weighted more than the other parameters for formation of a zygote, respectively. Also, the occurrence of a pregnancy from embryos resulted of injected sperm was associated with male BMI (0.17), testosterone (0.1), age (0.04), FSH (0.04), the head size (0.02), and vacuole (0.013) of spermatozoa for ICSI.

Limitations, reasons for caution: This study is focused on men's demographic and motile sperm morphologies in real-time during ICSI. The genetic information has not been considered because the selection of sperm during ICSI is performed based on morphology parameters.

Wider implications of the findings: This model enables researchers to evaluate the impact of morphological sperm features and men's demographic on fertility potential in infertile men in real-time during ICSI. Therefore, it can help to embryologist for selection of the best sperm in real-time during ICSI and could promote the outcomes of assisted reproductive techniques.

Trial registration number: Not applicable.

P-157 Distinctive characteristics of extracellular vesicles derived from spent medium from day 3 and day 5 embryos

E. Giacomini[1], R. Vago[2,3], A.M. Sanchez[1], S. Makieva[1], P. Podini[4], N. Zarovni[5], V. Murdica[2], R. Rizzo[6], D. Bortolotti[6], E. Papaleo[1], P. Viganò[1]

[5]*Exosomics Siena S.p.A, Siena, Italy*
[6]*University of Ferrara, Department of Medical Sciences- Section of Microbiology and Medical Genetics, Ferrara, Italy*

Study question: Are human embryo extracellular vesicles (EVs) carriers of information mediating maternal-embryonic communication?

Summary answer: Molecular characterization of human embryo-derived EVs reveals a number of biomolecules (proteins, mRNA) that may suggest an emerging way of embryo-maternal cross-talk.

What is known already: Successful embryo implantation and consequent pregnancy is critically dependent on a two-way communication between the maternal uterus and the blastocyst. However, given the ethical restrictions and the lack of mechanistic studies, the identification of key embryonic signals remains so far elusive. There are plenty of evidence indicating that EVs shuttle biomolecules that can profoundly affect the phenotype and activity of their target cells. EV secretion has been reported for most cell types including embryonic stem cells and in vitro produced embryos derived from some mammalian species. However, to date no comprehensive data have been reported regarding human embryo-derived EVs.

Study design, size, duration: Embryo spent culture medium samples employed in this study were obtained from patients referring to the Centro Scienze Natalità of the San Raffaele Hospital in Milano, Italy, with an indication to ART. Spent culture medium was collected from embryos at the cleavage stage or from expanded blastocysts without signs of degenerating cells.

Participants/materials, setting, methods: Conditioned medium was collected from embryos cultured to day 3 and day 5 after fertilization, pre-cleared of debris and subjected to a series of ultracentrifugations in order to isolate EVs. The characterization of EVs was performed by Nanoparticle Tracking Analysis and transmission electron microscopy. The presence of specific EVs proteins and RNAs was investigated by western blot and RT-PCR. The uptake of fluorescent labeled EVs by primary endometrial cells was monitored by using Vybrant™ DiO.

Main results and the role of chance: Conditioned media from non-manipulated human embryos cultured *in vitro* for 3 or 5 days contain EVs with a diameter ranging from 50 to 200 nm with most of them smaller than 100 nm. Western blotting demonstrated the presence of CD9 and CD63 markers in embryo-derived EVs. The exosome marker protein ALIX was detected in both Day 3- and Day 5-EVs confirming the presence of bona fide exosomes in the EV preparations from embryo secretome. *POU5F1* and *NANOG* mRNAs were detected in both Day 3-EVs and Day 5-EVs, indicating the presence of both transcripts in EVs from embryos at different developmental stages. The embryonic origin of these EVs was confirmed by the presence and their enrichment in the non-classical HLA-G protein at appropriate stages of development. In order to examine whether EVs derived from embryos could be uptaken by primary endometrial cells and thus potentially establish a communication with the maternal side, EVs labeled with a fluorescent dye were co-cultured with primary endometrial cells. Uptake of dye-labeled embryo-derived EVs by primary endometrial cells was also demonstrated with a fluorescence intensity signal greater for cells treated with vesicles derived from blastocysts.

Limitations, reasons for caution: Some data were obtained from the analysis of pooled human embryo culture media instead from medium from a single embryo culture. Lower amount of starting material can impact the quality of the result and therefore we are confident that using pooled medium may, at this stage, be more informative.

Wider implications of the findings: Our finding showing that *in vitro* cultured human embryos can secrete EVs that can be uptaken by the maternal side raises some exciting possibilities regarding their potential therapeutic use as a co-factor for promoting the establishment of a successful pregnancy.

P-158 A prospective randomised trial comparing embryo development in the MINC incubator versus the EmbryoScope incubator

P.K. Lowen[1], A.J. Kermack[2,3,4], S.J. Wellstead[5], P.C. Calder[2,4], F.D. Houghton[4], N.S. Macklon[1,2,3,4]

[1]University Hospital Southampton NHS Foundation Trust, Complete Fertility Centre, Southampton, United Kingdom
[2]University Hospital Southampton NHS Foundation Trust and University of Southampton, National Institute for Health Research Southampton Biomedical Research Centre, Southampton, United Kingdom
[3]University Hospital Southampton NHS Foundation Trust, Department of Obstetrics and Gynaecology, Southampton, United Kingdom
[4]University of Southampton, Human Development and Health Academic Unit-Faculty of Medicine, Southampton, United Kingdom
[5]University Hospital Southampton NHS Foundation Trust, PAH Reproductive Health Research Team, Southampton, United Kingdom

Study question: Does culturing embryos in the EmbryoScope versus the MINC benchtop incubator increase the number and quality of blastocysts formed on Day 5?

Summary answer: Culturing embryos in the EmbryoScope rather than the MINC incubator significantly increased the number and quality of blastocysts formed on Day 5.

What is known already: It is unknown whether culturing embryos in the EmbryoScope or the MINC incubator provides a better environment for the developing embryo and hence an improved outcome for patients. There is a popular view that the EmbryoScope is superior with some clinics reporting 60–70% success rates using this device compared to 30–40% using the MINC incubator. These increased success rates are thought to be due to embryos remaining in a constant environment and more information being available for embryo selection.

Study design, size, duration: Between January 2015 to November 2016, 81 couples undergoing IVF or IVF with ICSI were recruited and consented to participate in the study prior to oocyte recovery. Of these 81 couples, 51 continued to meet criteria and their 585 embryos were randomly allocated to the EmbryoScope or the MINC, with 289 cultured in the EmbryoScope and 296 in the MINCs.

Participants/materials, setting, methods: Participants were aged 42 years or under, had an antral follicle count of ≥12 and ≥6 2PN zygotes. Zygotes were cultured individually in 25 μl of G1+ (Vitrolife) followed by 25 μl of G2+ (Vitrolife) in either slides (EmbryoScope) or culture dishes (MINC). Embryos were graded by an embryologist on days 3 and 5. Differences in outcomes were analysed using Chi squared test.

Main results and the role of chance: The proportion of embryos cultured in the EmbryoScope that developed into blastocysts on day 5 was significantly higher than those allocated to the MINC incubator (159/289 (55%) EmbryoScope versus 133/296 (45%) MINC; P = 0.015). The same applied to the total number of blastocysts (192/289 (66%) EmbryoScope versus 170/296 (57%) MINC; P = 0.025). Furthermore, significantly more embryos formed blastocysts suitable for cryopreservation on D5 following culture in the Embryoscope (90/289 (31%)) versus MINC (69/296 (23%), p = 0.033), however, this difference did not remain significant when blastocysts grades were further subdivided. Culturing embryos within EmbryoScope did not significantly increase the blastocyst utilisation rate (117/192 (61%) EmbryoScope versus 100/170 (59%) MINC, P = 0.231), the number of blastocysts frozen (99/192 (51%) EmbryoScope versus 80/170 (47%) MINC; P = 0.392) or transferred (18/192 (9%) EmbryoScope versus 13/170 (8%) MINC, P = 0.558). Furthermore there was no significant difference in pregnancy rate per embryo transfer (71% EmbryoScope versus 73% MINC, P = 1.00) or clinical pregnancy rate (59% EmbryoScope versus 53% MINC, P = 1.00).

Limitations, reasons for caution: Embryo culture in the EmbryoScope was disturbed when slides were removed to change the medium and whilst medium was refreshed in the EmbryoScope, embryos in the MINC were transferred to new dishes. The study was also not powered to determine a difference in clinical outcome parameters.

Wider implications of the findings: Although incubation of embryos in the EmbryoScope increased the number and quality of blastocysts formed, this was not reflected in an impact on pregnancy rates. While this may be due to insufficient statistical power, both incubators provided good outcomes.

Trial registration number: ISRCTN73037149.

P-159 Blastocoel expansion as a morphokinetic marker of genetic quality in embryos from donor eggs

T. Huang[1], S. Kiehm[2], C. Yin[3], M. Leung[3], H.J. Ahn[4], T. Kosasa[5], B. Kessel[6]

[6]Pacific In Vitro Fertilization Institute, Department of Obstetrics and Gynecology and Women's Health- John A. Burns School of Medicine, Honolulu- Hawaii, U.S.A.

Study question: How does blastocyst formation time and the rate of subsequent blastocoel expansion correlate with euploidy in donor embryos having genetic screening

Summary answer: Euploid embryos tend to form blastocysts sooner and expand more rapid than aneuploids, enabling a morphokinetic analysis identifying subgroups enriched for euploidy

What is known already: Egg donation is an important option for infertile couples. Embryo ranking for single embryo transfer remains a central challenge to minimize risks from multiple pregnancy. Without preimplantation genetic screening (PGS), the laboratory must rank embryos based on morphology. Time-lapse imaging offers one new approach, but its value in embryo selection remains controversial. Blastocoel expansion rate has recently been described in donor egg embryos forming sustained pregnancies (Huang et al., 2016), but there is no information correlating expansion rates with karyotype in wider embryo cohorts. Results here support the hypothesis that expansion rate assessments can improve euploid embryo selection.

Study design, size, duration: This was a retrospective observational study utilizing 91 blastocysts from 15 consecutive egg donation cycles performed in 2016.

Participants/materials, setting, methods: The median age of donors was 24.3 yrs. Retrievals averaged 16.3 mature and 14.2 fertilized eggs. After ICSI, embryos were cultured in an Embryoscope (Vitrolife, USA) with laser zona drilling on D3 and biopsy on D5-D6. Blastocoel expansion was measured as the cross-sectional area (CSA, in u^2) of trophectoderm-enclosed space both within and herniated outside of the ZP. It was measured hourly for 10 hours beginning at blastocyst formation (tB).

Main results and the role of chance: Of 91 embryos biopsied, there were 51 (56.0%) euploid, 30 (33.0%) aneuploid, and 10 (11.0%) mosaic calls. Euploid blastocysts exhibited a statistically greater expansion curve regression slope over the first 10 hours than either aneuploids or mosaics (560 vs. 347 vs. 420, respectively; p < 0.04). Euploids also formed blastocysts (tB) earlier (102.4 vs. 111.2 vs. 117.9 hrs, respectively; p < 0.001). There were no statistical differences between mosaics and aneuploids in tSB or tB (p > 0.05). Based on expansion curve results, a scatter analysis was performed correlating Tb with expansion CSA at 8 hours from Tb, where 86.7% of all euploids formed blastocysts < 112 hours from fertilization. Euploidy was increasingly enriched in subgroups showing increasingly expanded blastocoels. This ranged from 63.6% (at cutoff CSA > 14,000u^2) to 79.3% (CSA > 16000u^2) to 85.8% euploid (CSA > 18000u^2). Although few total euploid embryos (13.3%) formed blastocysts at > 112 hours, they showed remarkably productive expansion with CSA's > 16,000 u^2 8 hours into the expansion period; in contrast, aneuploid/mosaics embryos expanded comparatively more slowly and were distributed more broadly across tB times and CSA range (11,000–23,000u^2).

Limitations, reasons for caution: This was retrospective observational study and further limited by the sample size of both patients and blastocysts. In addition, this is the first application of a new metric of blastocyst expansion to biopsied embryos which limits comparison of results and power analysis.

Wider implications of the findings: The value added by morphokinetic analysis for ranking of embryos for transfer remains challenging and controversial. The results reported here in egg donor PGS cases suggest that both the time of blastocyst formation and a new metric describing blastocoel expansion may be useful for objective, non-invasive embryo selection algorithms.

Trial registration number: No Registered Trial Performed.

P-160 Effects of increasing paternal age on clinical outcomes in vitrified egg donation cycles

E. Iovine, V. Casciani, M.G. Minasi, A. Ruberti, E. Cursio, F. Scarselli, A. Colasante, R. Polese, A. Greco, P. Greco, A. Caragia, M.T. Varricchio, E. Greco

European Hospital, Medicina della Riproduzione, Roma, Italy

Study question: Does increasing paternal age negatively influence embryo development and assisted reproduction technique (ART) clinical outcomes in egg donation cycles with vitrified oocytes?

Summary answer: In vitrified egg donation cycles there is a significant reduction in clinical pregnancy and implantation rates with increasing paternal age.

What is known already: Literature reports that increasing paternal age is correlated with decrease in ejaculate volume, sperm morphology and motility. Furthermore, increasing paternal age is associated with epigenetics aberrations and DNA mutations/damage along with chromosomal aneuploidies in spermatozoa. Advanced paternal age could also influence embryo ploidy and incidence of different types of disorders like autism, schizophrenia and bipolar disorders. All this factors negatively affect ART success rates. On the other hand it would seem that embryo quality is not related with embryo ploidy. In egg donation cycles, the effect of oocytes ploidy on embryo chromosomal assessment is reduced due to lower maternal age.

Study design, size, duration: From October 2014 to December 2016, 213 egg donation cycles with vitrified oocytes (average 6.62 ± 1.33 per cycle) were retrospectively analyzed. Couples were divided in two groups according to paternal age: group A (100 cycles) and group B (113 cycles). No statistical difference was found in donors' age. Inclusion criteria were: a) more than 4 oocytes surviving thawing and b) use of ejaculate sperm. Data were analyzed with Fisher's exact test.

Participants/materials, setting, methods: Paternal age was 30–44 (40.09 ± 3.14) and 45–72 (49.42 ± 4.21) years old in group A and B respectively (p < 0,05). Semen parameters were equivalent according to WHO 2010 in both groups; donors' age was 27.31 ± 3.57 and 26.3 ± 3.80 years old in group A and B respectively (NS). Oocytes were delivered from Spain by dry-shipper and injected after 2-hour post-thawing incubation. All oocytes were cultured in 6.0%CO_2 and 5.0%O_2 until cleavage stage and transferred. Supernumerary embryos were frozen.

Main results and the role of chance: Thawing survival rates were 92.5% (N = 612/661) and 93.7% (N = 704/751) in groups A and B respectively (NS). In group A and B fertilization rate was 75.2% (N = 460/612) and 78.4% (N = 522/704), respectively (NS). Top quality embryos on day 2 were 50.6% (N = 402) and 52.1% (N = 448) in group A and B, respectively (NS) and top quality embryos on day 3 were 54.2% (N = 364) and 52.1% (N = 385), respectively (NS). On day 3, 97 and 108 fresh embryo-transfers were performed in group A and B respectively. In group A 1,81 ± 0.44 embryos/cycle and in group B 1.79 ± 0.52 embryos/cycle were transferred. Clinical pregnancy rates were 49.4% (N = 48/97) and 36.1% (N = 39/108) in group A and B, respectively (p < 0.05). Implantation rates were 35.5% (N = 64/180) and 22.6% (N = 45/199) in group A and B, respectively (p < 0.05). Use of donor oocytes minimize maternal aneuploidy contribution and this data show that advancing paternal age could influence sperm quality and ploidy rate of obtained embryos and therefore their competence according to clinical pregnancy and implantation rates and the whole performance of ART.

Limitations, reasons for caution: Due to cleavage stage embryo-transfer program, blastocysts development wasn't analyzed and the relationship between increasing paternal age and blastocyst formation rate and morphology wasn't investigated. With advancing paternal age also maternal age of the recipient increases therefore a maternal effect could be implicated in the clinical outcomes.

Wider implications of the findings: Egg-donation success rate could decrease with advancing paternal age. Final aim will be defining a universal cut-off for advanced paternal age and investigating correlations between oocyte vitrification, increasing paternal age and their effect on ploidy. Future plans are to analyze semen samples fragmentation and sperm maturity for sperm nuclear assessment.

Trial registration number: Not applicable.

P-161 can transfer of a poor quality embryo along with a top quality embryo influence outcome during fresh and frozen IVF cycles

M.T. Lao[1], K. Jayaprakasan[2], E. Michael[3], A. Varghese[4]

[1]Milton, Canada,
[2]Derby Fertility Unit- Royal Derby Hospital, Medical, Nottingham, United Kingdom
[3]Astra Fertility Group, Medical, Mississauga- Ontario, Canada
[4]Astra Fertility Group, Embryologist, Mississauga- Ontario, Canada

Study question: To evaluate the effect of double embryo transfer (DET) with a poor quality embryo (PQE) along with a top quality embryo (TQE) on IVF outcome.

Summary answer: DET with PQE plus TQE does not increase the live birth rate but increases multiple births when compared to single embryo transfer (SET) with TQE.

What is known already: While SET is the recommended approach to achieve single live births during IVF, DET is considered, especially when there are only PQEs available in addition to one or no TQE on the day of transfer to maximize the treatment success. It is not clear whether transferring a PQE along with a TQE can influence the outcome during fIVF and FET cycles.

Study design, size, duration: A review of prospectively collected data of all the blastocyst transfers as part of fIVF (n = 939) and FET (n = 1009) cycles performed between 2010 and 2016 was undertaken. A total of 1948 cycles were analysed.

Participants/materials, setting, methods: Only one cycle per participant was included. SET with TQE (group1) was set as control and outcome for SET with PQE (group2) and DET with 2 TQEs (group3), PQE plus TQE (group4) and 2 PQEs (group5) were compared. Odds ratios were calculated after controlling for age using logistic regression analysis.

Main results and the role of chance: The live birth rates for group4 (DET with PQE plus TQE) were statistically similar to group1 (SET with TQE) during fIVF (26.5% Vs 33.7%; OR: 0.95(0.53–1.7)) and FET (24.2% vs 32.7%; OR: 0.75(0.48–1.2)), although there was a trend for lower success. Conversely, multiple births were higher in group4 for fIVF (19% vs 4.7%; OR: 2.9(1.3–6.6)) and FET (10.3% vs 2.6%; OR: 2.4(1.2–4.9)). The live birth rates for group2 (12.2% for fIVF and 14.6% for FET) and group5 (21.2% for fIVF and 14% for FET) were lower and for group3 were higher (40.8% for fIVF and 40.3% for FET) when compared to group1. Multiple births were significantly higher with DET regardless of the embryo quality compared to SET with TQE.

Limitations, reasons for caution: The study was limited by the observational design and a randomized controlled trial is warranted to confirm the findings. However, we made effort to limit the bias by including consecutive cycles, only one cycle per participant and by performing the statistical analysis by controlling for confounders like age.

Wider implications of the findings: The data from the study do not support the idea of DET with one PQE along with a TQE, when there is a dilemma where there is only one TQE and one or more PQE remaining available for transfer during fIVF and FET cycles.

Trial registration number: 0.

P-162   Oocyte meiotic spindle structure gradation and its effect to the quality characteristic of the embryos

I. Ilyin[1], J. Gontar[1], N. Buderatskaya[1], O. Fedota[2], O. Parnitskaya[1], K. Ilyina[1], E. Kapustin[1], S. Lavrynenko[1], Y. Lakhno[1]

[1]Medical center IGR, Medical center IGR, Kyiv, Ukraine
[2]V. N. Karazin Kharkiv National University, Medical department, Kharkiv, Ukraine

Study question: Does the oocyte meiotic spindle structure possibly serve as prognostic marker in blastocyst formation?

Summary answer: Various types of spindle organizations predict the morphological quality of the blastocysts.

What is known already: Well known that oocyte meiotic spindle visualisation is very useful for a safer performance of intracytoplasmic sperm injection (ICSI). Due to polarized light microscopy it was found that correctly shaped oocyte's spindle is related to better outcomes of assisted reproductive technologies (ART) (Matsunaga R., 2015; Korkmaz C., 2011). But there is no clear assessment criterion for evaluating the oocyte's spindle structure with respect to the development of blastocyst.

Study design, size, duration: This study involved 389 oocytes obtained from 40 women who were treated with IVF/ICSI cycles at our medical center from October to December 2016. The mean age ($\pm$ SD) of the included women was $33{,}7 \pm 7{,}6$. Due to spindle structure, we evaluated the number of zygotes, embryos on cleavage stage and AA category blastocyst.

Participants/materials, setting, methods: Oosight imaging systems™ (USA) was used for obtaining polarized light. The structure was evaluate and classified as the following spindle's grade characteristics: A - compact rhomboid spindle with defined edges, B - modifiedspindle form with blurred edges, C - weak spindle visualization, D - spindle on the 1st polar body border and cytoplasm (telophase I), E - spindle not visualized. Statistical analysis was carried out

using Shapiro-Wilk test for normality, Chi-square test, Criterion φ-angular Fisher transformation.

Main results and the role of chance: In accordance with structure spindle criteria evaluation suggested by us, the number of oocytes distributed in the following way: A graded spindle had 156 oocytes, B graded – 96, C graded – 92, D graded – 12, E graded – 33 oocytes. Thus oocyte distribution into grades was uneven and complies as 0,4:0,25:0,23:0,03:0,09 (p = 0,001). The mean age ($\pm$ SD) of the included women had no statistically significant difference (SSD) between the groups with different oocyte grades and was $30{,}70 \pm 3{,}8$, $30{,}05 \pm 4{,}3$, $31{,}27 \pm 3{,}6$, $32{,}0 \pm 3{,}1$, $31{,}9 \pm 4{,}7$ years respectively. The number of fertilized oocytes in grades A, B, C were comparable (87,5%, 87,5%, 89,1%) and had SSD relative to the indicators of the oocyte spindle grades D and E (50,0%, 9,7%) (p = 0,004). Same regularity was observed for the three-day developing embryos - A:B:C (82,1%:87,5%:85,9%) versus D:E (33,3%:63,6%), (p = 0,001). Estimation of the blastocysts number by morphology on the fifth day after fertilization showed that the proportion of AA category blastocysts obtained from A graded oocytes consisted 51,0% from the tota AAl blastocysts amount (n = 110) and significantly higher than the blastocysts number of AA category that was forming from B (25,5%) and C (21,7%) graded oocytes (p = 0,01).

Limitations, reasons for caution: It was found that the dividing spindle is sensitive to the changes in environmental conditions, particularly to temperature. The spindle depolymerization begins due to decreasing temperature of below 37˚C, which impairs the visualization quality. So the duration of the spindle structure evaluation should be very short.

Wider implications of the findings: The visualization of the oocyte meiotic spindle and prediction of the blastocysts obtained according to spindle structure grade could help to understand the effectiveness of the ART using cytoplasmic donation techniques in the group of patient carriers of the mitochondrial diseases above 40 years of age.

Trial registration number: None.

P-163   The effects after intracytoplasmic morphologically selected sperm injection (IMSI) on euploidy rate of embryo

S.Y. Kim[1], J.H. Eum[1], W.Y. Choi[1], S. Kwon[1], J. Lee[1], T.H. Kim[1], D.R. Lee[2], J.J. Ko[2], E.M. Chang[1], W.S. Lee[1]

[1]Fertility Center of CHA Gangnam Medical Center, CHA University- College of Medicine, SEOUL, Korea- South
[2]CHA University, Biomedical Science, Seoul, Korea- South

Study question: Can intracytoplasmic morphologically selected sperm injection (IMSI) technique improve the euploidy rate of embryo in preimplantation embryos?

Summary answer: We observed that sibling embryos performed IMSI showed significant higher euploidy and good quality rate compared to control embryos.

What is known already: It is well known that the sperm vacuoles were marked as zones without chromatin in the sperm nucleus which may prove chromosomal or DNA defects. Also, such morphological defects of sperm nuclei could correlate with higher aneuploidy rate in sperm.

IMSI allows the selection of motile spermatozoa without DNA fragmentation and head vacuoles at high magnification. Although some studies have been reported the advantages of IMSI, the correlation of IMSI and euploidy rate of embryo remains unclear.

Study design, size, duration: This study performed in 208 sibling oocytes of 20 ICSI cycles from March 2016 to April 2016 in the Fertility center of CHA Gangnam Medical Center. The oocytes were randomly assigned to IMSI and conventional ICSI.

Participants/materials, setting, methods: IMSI was carried out at high magnification (6000X); whereas, conventional ICSI was performed at 400X magnification. Only good quality spermatozoa (normal head shape and one or two small vacuole) were selected for injection. Embryo development was checked on day 3 and embryo biopsy for PGS were performed on day 3 - day 5. And then, biopsied embryos were cultured individually in continuous single culture medium (CSC medium, Irvine scientific, CA).

Main results and the role of chance: No difference was observed in the rates of fertilization (77.08% vs. 81.25%) and biopsied embryo (71.6% vs.

65.9%). But IMSI showed a higher incidence of the rates of embryo quality (48.7% vs. 40.7%) and euploidy (30.2% vs. 15.0%) as compared with conventional ICSI.

Limitations, reasons for caution: Further studies with larger sample are needed. In addition, this study was restricted to sibling embryos, so further studies with implantation rate and pregnancy rate are needed.

Wider implications of the findings: Our results represent that microinjection of selected spermatozoa with morphologically normal nuclei improves the incidence of normal embryos. This study highlights IMSI-PGS strategy could be one of the favorable options for the patients having a higher risk of aneuploidy such as aged women, severe male factor and repeated implantation failure.

Trial registration number: Not applicable.

P-164 Polyunsaturated fatty acid concentration in the human follicular fluid may affect fertilisation

K. Mekaru, M. Miyagi, K. Akamine, C. Heshiki, Y. Aoki

University of the Ryukyus, Obstetrics and Gynaecology, Okinawa, Japan

Study question: Does the concentration of polyunsaturated fatty acids in the follicular fluid affect fertilisation and the quality of embryos?

Summary answer: The concentration of polyunsaturated fatty acids in the follicular fluid plays an important role in fertilisation.

What is known already: The metabolite composition of the follicular fluid, which represents the intrafollicular environment, may be an important factor affecting fertilisation and subsequent early embryo development. Polyunsaturated fatty acids are essential fatty acids that are not synthesised in the body, but are utilised as an energy source for processes from oocyte nuclear maturation to embryonic development. There is a study stating that linoleic acid and arachidonic acid in the follicular fluid are correlated with the fertility percentage. However, published data to support claims relating to effects on reproductive health are lacking.

Study design, size, duration: A prospective study was conducted on 10 women eligible for in-vitro fertilisation and embryo transfer between August 2015 and December 2015. Ten serum and 52 follicle fluid samples were collected and analysed. This study was approved by the clinical research ethics investigation committee at university of the Ryukyus.

Participants/materials, setting, methods: Two millilitres of follicular fluid was collected from six consecutive follicles of each patient. Each individual follicle was aspirated independently and matched to an oocyte growing in this particular follicular milieu.The fatty acid concentration in each follicle was analysed using gas chromatography, and its association with fertilisation and embryonic quality was studied.

Main results and the role of chance: The concentration of 22 polyunsaturated fatty acids was significantly lower in the follicles, at approximately one-third their concentration in the serum. The concentrations of linoleic acid and arachidonic acid, both of which are n-6 type polyunsaturated fatty acids, in the follicular fluid of fertilised oocytes were 228.7 µg/ml and 73.8 µg/ml, respectively, and were significantly lower than those in the follicular fluid of unfertilised eggs [247.6 µg/ml (p = 0.03) and 80.9 µg/ml (p = 0.03), respectively]. Similarly, the concentrations of eicosapentaenoic acid, and docosahexaenoic acid which are n-3 type polyunsaturated fatty acids, were significantly lower in the follicular fluid of fertilised oocytes than in the follicular fluid of unfertilised oocytes. The concentration of polyunsaturated fatty acids in the follicular fluid played no significant role in determining the embryo quality.

Limitations, reasons for caution: The sample size was small, and the number of good quality embryos was less. These might be some reasons why the relationship between the embryo quality and polyunsaturated fatty acid concentration in the follicular fluid could not be established.

Wider implications of the findings: The results suggest that specific fatty acids are utilised more during fertilisation and play an important role in fertilisation. The intake of these fatty acids, particularly essential fatty acids, may improve fertilisation.

Trial registration number: 498.

P-165 The autologous mitochondrial transfer into mature oocytes is an attractive option in patients who produce poor quality embryos

Y. Miyamoto[1], A. Koike[1], S. Hashimoto[2], T. Inoue[3], Y. Morimoto[3]

[1]*HORAC Grand Front Osaka Clinic, Division of Reproductive Technology, Osaka, Japan*
[2]*IVF Namba Clinic, Division of Research, Osaka, Japan*
[3]*HORAC Grand Front Osaka Clinic, Doctor, Osaka, Japan*

Study question: The aim of this study is to investigate the effect of autologous mitochondrial transfer into mature oocytes on human embryonic development.

Summary answer: The present study suggested that autologous mitochondrial transfer into mature oocytes improved embryonic development from the women with previously poor quality eggs.

What is known already: It has been shown that mitochondrial function in mature oocytes plays an important role for the development after fertilization in mammals. Autologous germ line mitochondrial transfer into mature oocytes is a method to inject mitochondria retrieved from own egg precursor cells into oocytes. However, there are not enough reports on the effects of this treatment regarding embryonic development.

Study design, size, duration: A total of 85 oocytes retrieved from 13 patients (29 cycles) who underwent IVF treatment with mitochondria transfer into mature oocytes were included in the analysis. The study period was between February and November 2016.

Participants/materials, setting, methods: All participants had history of failed IVF. Their previous IVF data showed the problems of poor quality in their oocytes and/or embryos. The developmental competences of the Day3 embryos were compared between the group A (IVF treatment with mitochondria transfer into mature oocytes) and group B (their previous IVF data). Embryos were evaluated as eligible when they reached to at least 5 cells cleavage stage and being grade 1 to 3 on Veeck's classification.

Main results and the role of chance: The average age of the patients was 37.8 ± 5.4 years old, ranging from 31 to 46 years old. Seven patients were in the 30 s, and 6 patients were in the 40 s.

The rate of all eligible embryos was 64.5 ± 20.9% in group A and 42.5 ± 29.9% in group B, and the difference was significant (p < 0.05). The rate of eligible embryos in patients in their thirties was 66.5 ± 22.0% in group A and 31.9 ± 24.5% in group B, and the difference was significant (p < 0.05). However, the rate of eligible embryos in patients in their forties was 62.2 ± 21.3% in group A and 54.8 ± 33.1% in group B, and the difference was no significant.

Limitations, reasons for caution: This is a descriptive study with limited number of patients. It possibly includes the difference in the patients' background.

Wider implications of the findings: The study indicated that autologous mitochondrial transfer into mature oocytes could be an effective treatment to improve the quality of the embryos derived from the women with poor quality oocytes or embryos in their previous IVF cycles. This treatment would be more effectively indicated for younger age patients.

Trial registration number: None.

P-166 Embryonic survival, development and cryoinjury of repeatedly vitrified mouse preimplantation embryos

D. Lee[1], J. Youm[1], S.K. Kim[1], J.Y. Lee[3], B.C. Jee[1], S.H. Kim[2]

[1]*Seoul National University Bundang Hospital, Obstetrics and Gynecology, Seongnam, Korea- South*
[2]*Seoul National University Hospital, Obstetrics and Gynecology, Seoul, Korea- South*
[3]*Hamchoon Women's Clinic, Obstetrics and Gynecology, Seoul, Korea- South*

Study question: Do three times vitrified mouse 8-cell embryos have great cryoinjury, low survival, and subsequent poor pregnancy success?

Summary answer: Repeated vitrification of 8-cell mouse embryos even up to three times appears to be efficient to preserve their survival and developmental potential.

What is known already: Survival rate and developmental potential are similar between once frozen and twice frozen mouse embryos.

Study design, size, duration: Prospective study using six hundred 8-cell stage embryos obtained from 60 female mice. Study duration was several weeks as the interval between vitrification and warming was one week and the interval between warming and re-vitrification was one hour.

Participants/materials, setting, methods: Six hundred 8-cell stage embryos were obtained from 60 female mice and randomly assigned to control and three experimental groups. Embryos were vitrified by indirect methods. The developmental outcomes such as survival rate, blastocyst-forming rate, and the percentage of hatching/hatched blastocyst were assessed. The cell numbers of hatching/hatched blastocyst were counted after nuclear staining. From hatching/hatched blastocysts, the mRNA expressions for Cirbp, Casp3, Sod1, Gpx3, and Cat were quantified by real-time quantitative RT-PCR.

Main results and the role of chance: In once, twice, or three-time vitrified mouse 8-cell stage embryos, survival rates, blastocyst-forming rates, the percentages of hatching/hatched blastocyst, and the cell counts were all similar when compared with non-vitrified control group. The mRNA expression levels of Cirbp, Casp3, Sod1, Gpx3 and Cat were not affected.

Limitations, reasons for caution: Only survival rate and developmental potential were evaluated in vitrified mouse 8-cell embryos. Further studies are necessary to evaluate live birth rates using three times vitrified 8-cell embryos in humans and to assess long-term safety outcomes.

Wider implications of the findings: If corresponding results in humans, clinicians confidently will decide to thaw more embryos than intended for transfer in order to increase the pregnancy rate by the selection of the morphologically highest quality embryo. Extra embryos may be refrozen up to three times without compromising own survival rate and developmental potential.

Trial registration number: This study is not a clinical trial.

P-167 Conventional IVF revisited: Is ICSI really better for non-male factor infertility? Randomized controlled double blind study

A. Urfan[1], M. Isikoglu[2], A. Kendinci Ceviren[3], B. Aydinuraz[2], A. Urshanova[2]

[1]Gelecek The Centre For Human Reproduction, Embryology lab, Antalya, Turkey
[2]Gelecek The Centre For Human Reproduction, IVF Department, Antalya, Turkey
[3]Gelecek The Centre For Human Reproduction, Embryology, Antalya, Turkey

Study question: Is ICSI really better than conventional IVF for non-male factor infertility?

Summary answer: IVF should be the choice of assisted reproductive technique in properly selected non-male factor infertility cases.

What is known already: Although total fertilization failure is the major drawback for the embryologists and the IVF practitioners, based on the existing literature, the overall risk/benefit analysis still favors conventional IVF in non-male factor infertility cases. But according to the ESHRE EIM database pertaining to 1997–2012, the percentage of IVF use has been continuing to decrease steadily which is under massive scuritinization.

Study design, size, duration: In this double blind RCT, 1133 patients started an ART program from March 2015 were evaluated and 138 non-male factor patients with women age ≤42 were included in the study. Exclusion criteria: history of total fertilization failure, number of retrieved cumulus-oophorus-complex (COCs) < 6 and patients who would undergo total cryo-preservation for any reason. We present the preliminary data and the study is ongoing at the moment.

Participants/materials, setting, methods: Sibling COCs were randomly allocated to IVF or ICSI. The decision to transfer IVF or ICSI embryo(s) was made depending on the quality of the embryos. In case of transferring two embryos, pure IVF or pure ICSI embryos were chosen. Neither the clinician nor the patients were aware of the group the embryos belong to.

Main results and the role of chance: Demographic variables, ovarian reserve and infertility etiologies were similar for IVF-ET (#64) and ICSI-ET (#74) groups. Duration of stimulation, total gonadotropin dosage, peak estradiol levels were also similar. Mean number of COCs (18,95 vs 19,24 p = 0,856) and number of embryos transferred (1,81 vs 1,81 p = 0,980) were similar, the ratio of good quality embryos/total embryos (56,89% and 55,97%) were similar (p > 0,05). Clinical pregnancy (63% vs 49% p = 0,103) and implantation rates (31% vs 28% p > 0,05) similar. Abortion rates (12,5% vs 8,1% p = 0,394) were also similar.

A total of 1306 COCs were allocated for IVF while 1331 COCs were denuded for ICSI. Fertilization rate was significantly higher in ICSI group (56,20% vs 63,78% p < 0,05). There were ten total fertilization failure, all in IVF group. Although the fertilization rate was higher for ICSI, excluding the cases with total fertilization failure revealed similar fertilization rates.

Limitations, reasons for caution: Higher sample size for both groups would provide more accurate comparison of the two techniques.

Wider implications of the findings: We provide the first data comparing the outcome of IVF and ICSI techniques from Turkey a country with a very high proportion (98%) of ICSI cycles. Cost advantage, feasibility and the similar clinical outcome makes IVF the choice of technique in properly selected non-male factor infertility cases.

Trial registration number: GTB20150304.

P-168 Transfer of a single vitrified-thawed blastocyst does not increase twinning rate

M. Kharitonova[1], V. Apryshko[1,2], I. Zorina[3], S. Yakovenko[4]

[1]Altravita IVF clinic, Laboratory of Embryology, Moscow, Russia C.I.S.
[2]Lomonosov Moscow State University, Faculty of Biology, Moscow, Russia C.I.S.
[3]Altravita IVF clinic, Altravita IVF clinic, Moscow, Russia C.I.S.
[4]Lomonosov Moscow state University, Biophisics Department, Moscow, Russia C.I.S.

Study question: Does transfer of a single vitrified-thawed blastocyst cause an increase of the twinning rate compares to a fresh blastocyst transfer?

Summary answer: Twinning rate does not increase after a vitrified-thawed blastocyst transfer compared to a fresh blastocyst transfer

What is known already: Transferring a single blastocyst has been shown to significantly reduce multiple pregnancy rates, but there is a probability of twinning even in this case. There are conflicting reports regarding treatment methods in ART and their involvement in increasing the twinning rate and especially very little data concerning the influence of vitrification of blastocyst on the twinning rate.

Study design, size, duration: This study is a retrospective cohort study assessing twin pregnancies following fresh or vitrified-thawed single blastocyst transfer. Data from 2010 till 2016 was analysed.

Participants/materials, setting, methods: A total of 22668 patients in Altravita IVF clinic who following ICSI and transfer with a fresh or vitrified-thawed single blastocyst. 70 of them demonstrated twin pregnancy at the 7-week ultrasound. Vitrification (Kitazato, Japan or Cryotech, Japan) was used as the method of cryopreservation. For statistical analysis, z-score was used to determine correlation between type of transfer and twinning rate.

Main results and the role of chance: The twinning rate after single blastocyst transfer is 0,3% and does not exceed the twinning rate after natural conception. Multiple pregnancies were registered in 25 of 9507 patients after a single fresh blastocyst transfer (0,26%). After single vitrified-thawed blastocyst multiple pregnancy was registered in 45 cases (0,34%) of 13161 and the difference between two groups of patients was not significant. There was also no elevated percentage of multiple monochorionic pregnancy rate between the two groups of patients (0,2%).

Limitations, reasons for caution: A few multiple pregnancies can be dizygotic because of spontaneous pregnancy during the embryo transfer cycle

Wider implications of the findings: Estimation of risks of twinning after single embryo transfer gives the possibility of planning the optimal number of embryos for a transfer.

Trial registration number: no.

P-169 Tocotrienol-rich fraction supplementation improves oocytes quality in aging mice and upregulates the expression of anti-aging genes in mouse ovary

A.S. Nuraliza, A. Saidatul, H. Norerlyda, A. Nasibah, M. Muhamad

Faculty of Medicine- UiTM- Sg Buloh Campus, Sg Buloh, Malaysia

Study question: Does tocotrienol-rich fraction (TRF) supplementation improves oocytes quality and delaying the consequences of aging by upregulating the expression of anti-aging genes in mouse ovary?

Summary answer: Tocotrienol-rich fraction supplementation improves oocytes quality in aging mice and delaying the consequences of aging by up-regulating the expression of anti-aging genes in mouse ovary.

What is known already: Female reproductive aging resulted from oxidative stress will lead to a decline in biological function of ovaries, produce low quality of oocytes which eventually contributes to infertility. Low expression of anti-aging genes is directly related to the poor development of embryos retrieved from aging mice. Tocotrienol-rich fraction, a reputable antioxidant prevents the retardation of embryogenesis and pregnancy failure following various oxidative stress conditions. The proposed mechanisms of action of TRF is by lowering the plasma levels of malondialdehyde (MDA) (an oxidative stress biomarker) as well as cause a decrease in embryo fragmentation due to DNA damage.

Study design, size, duration: Thirty-two female mice (*Mus musculus*) were equally divided into four groups. In Experiment 1: six-week- old young mice were used as a negative control and eight-month-old aging mice were used as a positive control. While in Experiment 2: six-month-old aging mice were used; i.e. control group and group supplemented with TRF at the dose of 150 mg/kg. Supplementation of TRF was given orally for two months.

Participants/materials, setting, methods: At the end of the supplementation period, mice were superovulated and euthanized. The ovaries and oocytes were collected for the gene expression analysis (SIRT1, CDKN2A and E2F1 genes) as well as assessment of oocyte quality.

Main results and the role of chance: The percentage of normal morphology of oocytes were significantly reduced and the fragmented oocytes were significantly increased in the aging group when compared to the young group respectively. No significant difference were noted in the percentage of normal and fragmented oocytes between control and TRF-supplemented group. The percentage of DNA damage in oocytes were significantly higher in the aging when compared to the young group. Interestingly, the percentage of DNA damage in oocytes from TRF-supplemented group was significantly lower as compared to control group. Viable ovarian tissues were used for the gene expression analysis. Aging caused down regulation of anti-aging gene, SIRT1 and upregulation of CDKN2A and E2F1 genes, the two genes that that downregulate the expression of SIRT1 gene. Conversely, TRF supplementation upregulates the expression of SIRT1 gene while the expression levels of CDKN2A and E2F1 were decreased.

Limitations, reasons for caution: Gene expression analysis can only be done using ovarian tissue and not using oocytes as large quantity of oocytes is required for gene expression analysis.

Wider implications of the findings: Tocotrienol-rich fraction supplementation improves the quality of oocytes in aging mice by lowering the percentage of DNA damage. TRF exerts anti-aging effect on the ovary by up-regulates the expression of anti-aging genes in the ovary. The preservation of the production of good quality oocytes by TRF will potentially improve fertility.

Trial registration number: Not applicable.

P-170   In vitro culture in the presence of amorphous calcium carbonate improves mice embryos compaction and hatching rates

Y. Ben[2], Y. Natan[1], Y. Pliensky[2], A. Arav[1]

[1]Fertilesafe Ltd., R&D, Nes-Ziona, Israel
[2]Amorphical Ltd., R&D, Nes-Ziona, Israel

Study question: In the present study, we wanted to find out whether adding amorphous calcium carbonate (ACC) to the culture media affects mice embryos growth rates.

Summary answer: We have found that adding ACC to commercial media culture have improved mice embryos compaction and hatching rates compared to culture media without ACC.

What is known already: Culturing embryos for 1 week has become a standard in assisted reproduction technology (ART). One condition that is well known to affect the in-vitro culture (IVC) of embryos is the pH It is known that low pH may activate a lysosome proteases such as cathepsin family and it was shown that high cathepsin levels is inversely correlated to embryonic quality, most likely due to the cleaving E-Cadherin thus impairing the embryos ability to compact. ACC is more soluble than crystalline calcium carbonate (CCC) and adding it to the media minimize pH fluctuations.

Study design, size, duration: Experimental research was done of 6–8 weeks old mice (CBA x BL C57) superovulated (n = 10) with PMSG and hCG. Male mice proven to be fertile were then put together with the superovulated females. Females were euthanized after 24 hours (approximately 36 hours post-coitus) and embryos at 2 cell stage were retrieved from the oviducts. The embryos were assessed for compaction, blastocyst and hatching rates.

Participants/materials, setting, methods: Embryos from 5 females were divided into 3 groups: (1) 40 embryos were transferred to 20 µL drops with Quinn's Advantage cleavage media (SAGE, Origio, Denmark), overlaid with mineral oil, cultured at 37.0°C under 5% CO_2 and atmospheric oxygen. (2) 122 embryos, same as group 1 with the addition of 1.7 mM of ACC (3) 42 embryos, same as group 1 with the addition of 1.7 mM of crystalline calcium carbonate (CCC). Embryos were cultures until blastocyst/hatching stage.

Main results and the role of chance: Embryos development in cleavage media was compared to embryos development in cleavage media supplemented with 1.7 mM of ACC or with 1.7 mM CCC. The number of embryos at each stage and their portion from the initial number was calculated. The data was statistically analyzed using JMP software. We observed enhanced embryonic growth in the media comprising ACC and CCC at all stages compared to embryos grown with cleavage media only, with an advantage to ACC which was especially enhanced at the hatching rate. CCC showed visible particles in the media whereas ACC is transparent due to its amorphous structure.

Embryonic Stage	Cleavage Media (CM)	CM & 1.7 mM ACC	CM & 1.7 mM CCC
Compaction	30.2% ± 7.9% **B**	81.2% ± 11.9% **A**	85% ± 3.0% **A**
Blastocysts	87.7% ± 6.2% **A**	96.4% ± 3.6% **A**	100% ± 0% **A**
Hatched	57.8% ± 14.25% **AB**	88.7% ± 7.4% **A**	83% ± 1% **AB**

Table 1: IVC of mice embryos grown either in Quinn's Advantage cleavage media (CM) or embryos grown with CM supplemented with amorphous calcium carbonate (ACC) or CM supplemented with crystalline calcium carbonate (CCC). The data is presented as mean ± St. Error mean. Different letters represent statistical differences (P<0.05).

Limitations, reasons for caution: The main limitation of this study is that the cleavage medium used (SAGE Quinn Cleavage) is designed for human IVC and not for mice embryos. A human embryo study should be done as well.

Wider implications of the findings: The results of this study suggest that adding amorphous calcium carbonate (ACC) to commercial media improves embryos in-vitro growth and development with an enhanced advantage at the hatching rate which can lead to higher implantations and pregnancies rates.

Trial registration number: The experiments were approved by the Israeli ethics committee for animal experiments and the authorization number is IL-15-04-119.

P-171   Embryo morphokinetics are affected by culture media type: an interim analysis of a sibling oocyte study

A. Barrie, K. Schnauffer, C. Kingsland, S. Troup

Liverpool Women's Hospital, The Hewitt Fertility Centre, Liverpool, United Kingdom

Study question: Are the morphokinetic profiles of preimplantation embryos altered when cultured in three different, commercially available culture media using a sibling oocyte study design?

Summary answer: Morphokinetic parameters are significantly influenced by culture media type including time to six-cell (t6), seven-cell (t7), morula (tM) and time between nine-cell and morula (t9-tM).

What is known already: With the advent of time-lapse systems, many are seeking to determine more effective mechanisms for embryo selection by using an embryo's morphokinetic profile to predict viability. However, data presented thus far suggests that treatment, environment and patient parameters

can affect an embryo's early morphokinetic profile indicating that the use of standardised morphokinetic embryo selection algorithms (ESAs) may not be clinically effective.

Study design, size, duration: An ongoing sibling oocyte study commencing August 2016 where oocytes/embryos following ICSI/IVF fertilisation check were randomised to three culture media; G-TL™, SAGE-1-Step™ and Continuous Single Culture®(CSC). Nineteen absolute and interval morphokinetic parameters were assessed for differences in medians using the related-samples Friedman's two-way analysis of variance by ranks. Blastocyst formation rate (BFR), utilisation rate (UR) and incidence of abnormal cleavage events were analysed using Chi-square tests for homogeneity. All results were considered significant at p < 0.05.

Participants/materials, setting, methods: Patients (n = 28) undergoing their first treatment cycle of conventional IVF or ICSI where both patients were < 37 years, fresh, autologous gametes were used and six oocytes injected (ICSI) or three embryos created (IVF) contributed 307 oocytes resulting in 259 embryos. Absolute (t2, t3, t4, t5, t6, t7, t8, t9, tM, tSB, tB) and interval parameters (s2, s3, cc2, cc3, cc4, t9-tM, tM-tSB, tSB-tB) were assessed. Time zero was defined as pronuclear-fading.

Main results and the role of chance: Of 259 embryos, 36% were cultured in G-TL, 32% in SAGE-1-Step and 32% in CSC. Of the nineteen morphokinetic parameters assessed four were found to vary significantly between media types (respective means (h), p-value); t6 (24.37, 24.05, 28.35, p < 0.001), t7 (31.43, 29.20, 30.09, p = 0.047), tM (58.80, 56.77, 53.35, p = 0.002) and t9-tM (11.43, 9.51, 6.34, p = 0.001). All other morphokinetic parameters were not significantly different between the three culture media (p > 0.05). Nine of the 28 treatments were ICSI, contributing 90 oocytes and 85 embryos, with all others contributed from IVF. Eight treatment cycles resulted in no embryo transfer (ET) due to a clinical contraindication. One day 3 and 19 day 5 ETs were performed. The BFR was not different between any culture media at 67.4%, 78.5% and 72.9%, respectively (p = 0.281). The UR (embryos transferred and cryo-preserved) were significantly different; 38.3%, 65.1% and 58.3%, respectively (p < 0.001). A total of 73 embryos underwent an abnormal division event (cell lysis, direct cleavage, chaotic cleavage, absent cleavage and reverse cleavage); 43.8%, 23.3% and 32.9%, respectively (p = 0.130).

Limitations, reasons for caution: The data examined is limited in terms of sample size. Although significance has been shown in a number of morphokinetic parameters, significance may be found in other parameters where a larger sample size is examined.

Wider implications of the findings: This investigation allows for the control of confounding factors of patient or treatment origin therefore, it is surmised; any observed effect is a true reflection of the culture media. This implies that the development and validation of ESAs must be specific, robust and prospective before being introduced for clinical use.

Trial registration number: NA.

P-172   Risk factors analysis for Early Embryonic Arrest

Z. WEI[1], C. Lu[2], F. Gong[2], G. Lu[2], G. Lin[2]

[1]Citic-Xiangya Reproductive& Genetic Hospital, Reproductive Center, Changsha, China
[2]Reproductive and Genetic Hospital of Citic-Xiangya, IVF center, Changsha, China

Study question: What are the risk factors for early embryonic arrest (EA) in a population receiving fertility treatment?

Summary answer: Maternal Age, number of retrieved oocytes, basal AMH level, fertilization rate, treatment of infertility and Semen manipulation were associated with increased risk of EA.

What is known already: Normal embryonic development is the key step to establish a successful pregnancy. It is estimated that about 30%–60% of the human embryos arrest at different early stages of development. Although some gene mutation could explain a fraction of EA occurrence. However, there was lack of systematic analysis on the risk factors.

Study design, size, duration: We performed a retrospective cohort study on patients with primary infertility in CITIC-Xiangya Reproductive and Genetic Hospital from 2013 to 2015, involving a total of 20,364 cycles.

Participants/materials, setting, methods: The patients with all Day3 embryos arrest at/before the second cleavage were regard as EA Patient. Logistic regression analysis was performed adjusting for Maternal Age, Maternal Body Mass Index (BMI), Maternal Hormone Level of basal condition/the day of HCG administration, treatment of infertility(IVF-ET/ICSI/Half ICSI/IVM/PGD/PGS), Semen manipulation, number of retrieved oocytes, fertilization rate and cleavage rate.

Main results and the role of chance: 713 of 20,364 (3.5%) patients were positive for EA. Univariate analysis shows all the above risk factors have significance (p<0.05) except basal Estradiol/prolactin and Progesterone level and cleavage rate. In a logistic regression analysis, adjusting for confounding factors, demonstrated that IVM (OR 0.31, 95%CI 0.16–0.58), Swim-up for semen manipulation (OR 0.30, 95%CI 0.13–0.63), higher Maternal Age (OR 1.50, 95% CI 1.40–1.61), higher LH level after HCG administration(OR 1.03, 95%CI 1.02–1.03), lower number of retrieved oocytes (OR 0.41, 95%CI 0.37–0.46), lower basal AMH level (OR 0.96, 95%CI 0.94–0.99) and lower fertilization rate (OR 0.96, 95%CI 0.95–0.96) were positively associated with EA.

Limitations, reasons for caution: This dataset for the risk factor analysis just from one center. It should validated using the dataset from the other center.

Wider implications of the findings: This analysis will help to predict the probability of EA occurrence, and may help to develop some clinical intervention treatment, such as reasonable selection of treatment of infertility and Semen manipulation according to the maternal age, AMH level and number of retrieved oocytes.

Trial registration number: Not applicable.

P-173   Mitochondria membrane potential and developmental ability of mouse oocytes were enhanced by high hydrostatic pressure treatment

M. Kobayashi, K. Ohata, A. Yoshida

Kiba Park Clinic, Research center, Tokyo, Japan

Study question: Does high hydrostatic pressure (HHP) treatment affect to the function of organelles and embryonic development of mouse oocytes?

Summary answer: HHP treatment induced increase of mitochondrial membrane potential (MMP) in mouse unfertilized oocytes and enhancement of the developmental ability to blastocyst stage.

What is known already: A novel technique termed high hydrostatic pressure (HHP) treatment has been reported to improve the survival rate after cryo-preservation of several mammalian gametes and embryos. However, the mechanism of the improvement by HHP treatment and the effect on the function of organelles such as nuclear, mitochondria, and cytoskeleton have not yet been cleared. In addition, available information about the effect of HHP to unfertilized oocytes is very limited.

Study design, size, duration: Unfertilized oocytes obtained from female C57BL/6J mice were treated with different pressures (10, 20, 30, and 40 MPa for 30 min at room temperature), and non-treated oocytes were used as control (n = 50–60 oocytes/group). The metaphase-II (M-II) spindle morphology, MMP, and developmental ability were compared between each group.

Participants/materials, setting, methods: Morphology of MII spindle was examined immunohistochemical staining with tubulin specific antibody. For evaluation of MMP, oocytes were stained wit JC-1 dye (5 µg/mL, 15 min) and the ratio of red to green fluorescence of JC-1 was calculated and compared between each group. In addition, oocytes were fertilized by ICSI with spermatozoa derived from C57BL/6J male mice and cultured in KSOM medium for 4 days to estimate the developmental ability.

Main results and the role of chance: After HHP treatment, all oocytes survived and any morphological change did not observe in each HHP condition. Immunostaining analysis revealed that HHP treated oocytes had normal barrel shape M-II spindle with aligned chromosomes in the equatorial plane. MMP of oocytes treated with HHP at 30 MPa showed significantly higher than that of control and other conditions. There was no significant difference in fertilization rate between each HHP group and control. The blastocyst rate of oocyte treated with HPP at 30 MPa was significantly higher than other HHP conditions and

control (10 MPa: 58.3%, 20 MPa: 56.1%, 30Mpa: 67.9%, 40Mpa: 61.1%, control: 56.9%, p < 0.05).

Limitations, reasons for caution: This study was conducted using a mouse model with artificially induced the high hydrostatic pressure condition. This finding does not directly represent human infertility.

Wider implications of the findings: This study may provide one of reason for the improvement of survival rate after cryopreservation of gametes and embryos by HHP treatment. Further, HHP treatment could be a new approach for improvement of the developmental ability of oocytes compromised by some defects such as aging and oxidative stress.

Trial registration number: Not applicable.

P-174 Nrf2, a downstream molecule of Sirt1, regulates Cyclin B1 for spindle organization during mouse oocyte meiosis

R. Ma[1], W. Liang[2], L. Chen[1], Y. Lin[1], X. Qiu[1], M. Xie[1], J. Zhou[1], Q. Wang[3], B. Yao[1]

[1]Nanjing Jinling Hospital, Center for Reproductive Medicine, Nanjing, China
[2]Nanjing No.454 Hospital, traditional Chinese medicine department, Nanjing, China
[3]Nanjing Medical University, State Key Laboratory of Reproductive Medicine, Nanjing, China

Study question: The role of Nrf2 in oocyte meiosis and oocyte aging.

Summary answer: Our data indicate a role for Nrf2 during oocyte meiosis and uncover a striking beneficial effect of increased Nrf2 expression on aged oocytes.

What is known already: Good oocyte quality is a central component of female fertility. Advanced reproductive biotechnologies depend on a sufficient source of oocytes. Nuclear factor-E2 related factor 2 (Nrf2) is an important transcription factor. Lines of studies showed that Nrf2 plays a critical role in the regulation of oxidative stress, aging-associated diseases and inflammation.

Study design, size, duration: We investigated the effects of Nrf2 on oocyte maturation and its possible mechanism using a mouse oocyte model.

Participants/materials, setting, methods: Granular cells of 62 women (age from 22 to 49) were collected for studying the relationship of Nrf2 and woman age. Oocytes from 6–8 weeks and 8–10 months old mouse were used in this study. A series of biological methods was applyed, including oocyte collection and culture, micro injection, RNA interference, western blotting, immunofluorescence and Confocal microscopy, quantitative real-time PCR.

Main results and the role of chance: We show that the expression of Nrf2 is related to female age in ovarian granular cells. Our data demonstrated that Nrf2 depletion disrupted oocyte maturation and spindle/chromosome organization ($36.5 \pm 6.2\%$ vs. $9.4 \pm 5.4\%$ control, p < 0.05) by regulating the expression of Cyclin B1. Depleting sirt1 resulted in reduced Nrf2 expression, which indicated that there was a Sirt1-Nrf2-Cyclin B1 signaling pathway in mouse oocytes. Additionally, we find lower Nrf2 protein level in oocytes from aged mice by immunoblotting and that maternal age-associated meiotic defects can be ameliorated through overexpression of Nrf2 ($52.3 \pm 6.8\%$ old vs.$30.2 \pm 4.0\%$ old+Nrf2; P < 0.05), providing support for the hypothesis that decreased Nrf2 is one of a number of factors contributing to oocyte age-dependent deficits.

Limitations, reasons for caution: Using animal model and in vitro experiments.

Wider implications of the findings: The present results will help us to improve oocyte quality of aged women to provide new theoretical basis and ideas.

Trial registration number: None.

P-175 Assisted oocyte activation is beneficial for patients with total fertilization failure in IVF cycle caused by developmental arrest in sperm condensation/pronuclear formation stage

J. Dai[1], S.P. Zhang[2,3], F. Gong[3,4], C.F. Lu[2,3], G.X. Lu[4,5,6], G. Lin[3,4,6,7]

[1]Reproductive and Genetic Hospital of CITIC-XIANGYA, IVF laboratory, Changsha-Hunan, China
[2]Reproductive and Genetic Hospital of CITIC-XIANGYA, IVF laboratory, ChangSha, China

[4]Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive Center, ChangSha, China
[5]Key Laboratory of Reproductive and Stem Cell Engineering, Ministry of Health, ChangSha, China
[6]National Engineering and Research Center of Human Stem Cell, ChangSha, China
[7]Key Laboratory of Reproductive and Stem Cell Engineering, Ministry of Health-, ChangSha, China

Study question: To investigate candidate patient population with total fertilization failure (TFF) in IVF cycle who might be beneficial from assisted oocyte activation (AOA) in the next cycle.

Summary answer: By Total Fertilization Failure Arrest Test (TFFAT), AOA is beneficial for the TFF patients with all oocytes arrested in sperm condensation or pronuclear formation stage.

What is known already: TFF occurs in 2-3% of IVF cycles. The majority of the patients could benefit from ICSI in the next cycle and had normal fertilization rate. Despite the success of ICSI, TFF still occurs in 1–3% of next ICSI cycles with enough oocyte number and these patients may seek for a third treatment attempt. ICSI-TFF mainly caused by deficiency in sperm activation factors or lack of oocyte calcium oscillation. ICSI followed by AOA can restore fertilization in many sperm-related deficiency cases. But, currently there is no accurate analysis available to predict the TFF risk for second ICSI attempt.

Study design, size, duration: A prospective study was conducted in TFF patients (n = 83) underwent IVF cycle at the Reproductive and Genetic Hospital of CITIC Xiangya from August 2015 to March 2016.

Participants/materials, setting, methods: 661 unfertilized oocytes from IVF-TFF patients were donated for TFFAT. The stage of fertilization arrested in was judged by Immunofluorescent staining using anti-H3K27me3 and anti-Protamine antibodies. Patients with sperm penetration barrier were suggested to use ICSI in the next cycle. Others with sperm discondensation or pronuclear formation problem were suggested to perform ICSI-AOA. The main outcome parameter was fertilization rate. The minor outcome parameters were cleavage rate, good-quality embryo rate, TFF rate and low-fertilization rate.

Main results and the role of chance: By TFFAT, 77% of TFF patients were arrested in the stage of sperm penetration. 4.6% of TFF patients were arrested in the stage of sperm condensation and other 12.4% were arrested in the stage of pronuclear formation. Some of TFF patients (n = 27) had already finished the next cycle when the TFFAT was diagnosed. In conventional ICSI group (fertilization arrest in sperm penetration, n = 21) with 158 oocytes, the normal fertilization rate was 95.5%, cleavage rate was 98.5% and good quality embryo rate was 57.6%. In ICSI-AOA group (fertilization arrest in sperm condensation or pronuclear formation, n = 6) with 70 oocytes, the normal fertilization rate was 90.7%, cleavage rate was 95.3% and good quality embryo rate was 68.3%. All patients in two groups didn't meet TFF cycle or low fertilization cycle again.

Limitations, reasons for caution: The current work is a prospective study of a small number of ICSI-AOA patients. Larger trials with an increased number of patients are needed to confirm our findings.

Wider implications of the findings: TFF in previous IVF cycle can be largely avoid in subsequent ICSI cycles by TFFAT. Moreover, our findings uncovered the different causes of TFF patients in IVF cycle.

Trial registration number: None.

P-176 Influence of culture length on blastocysts implantation potential: analysis of 781 euploid blastocysts obtained in 629 PGS cycles

R. Polese[1], M.G. Minasi[2], A. Ruberti[2], A. Colasante[2], V. Casciani[2], E. Iovine[2], G. Nastri[2], P. Greco[2], K. Lytwycka[2], C. Arrivi[2], F. Spinella[3], A. Biricik[3], F. Fiorentino[3], E. Greco[2]

[1]European Hospital, reproductive medicine, Roma, Italy
[2]European Hospital, reproductive medicine, Rome, Italy
[3]Genoma, Molecular Genetics Laboratory, Rome, Italy

Study question: Does the time required to reach blastocyst stage influence the implantation potential?

Summary answer: It seems that the time needed to reach the blastocyst stage is deeply linked to the embryo implantation potential in an inversely proportional trend.

What is known already: Embryo morphology has always been considered an important predictor of successful implantation and pregnancy. However, the Preimplantation Genetic Screening (PGS) technology proved that this parameter seems to have quite low predictive value on implantation potential. Few studies focused on the comparison of pregnancy rates obtained with blastocysts vitrified on day 5 or day 6, demonstrating that the latter have a statistically significant lower value. Until now little is known if the clinical outcomes could be different transferring an euploid embryo obtained after 5, 6 or 7 days of culture.

Study design, size, duration: In this retrospective study, 781 cryopreserved euploid blastocysts obtained in 629 PGS cycles were transferred in single frozen-mbryo transfers performed from April 2011 to October 2016. All blastocysts were biopsied and vitrified on day-5,-6 or -7 of culture (BD5, BD6, BD7 groups); blastocysts were further divided on the basis of their quality in A, B and C grades. Clinical pregnancy (CP), advanced pregnancy (over 3 months) (AP) and abortion rates were compared between the groups.

Participants/materials, setting, methods: Mean female age was 35.7 ± 3.96 years. In order to classify the blastocysts on the basis of their morphology, the expansion grade, the inner cell mass (ICM) and the trophoectoderm (TE) quality were analyzed. Grade-A included expandend blastocysy and good or very good ICM and TE quality; grade-B included not expanded blastocysy and good or very good ICM and TE quality; grade-C included all expansion grades and poor or very poor ICM and TE quality.

Main results and the role of chance: Out of the 746 analyzed blastocysts, 463, 287 and 31 were in BD5, BD6 and BD7 groups, respectively. In BD5, 122 (26.3%) grade-A, 259 (55.9%) grade-B and 82 (17.7%) grade-C blastocysts were obtained. In BD6 78 (27.2%) grade-A, 88 (30.7%) grade-B and 121 (42.2%) grade-C blastocysts were obtained. In BD7, 7 (22.6%) grade-A, 1 (3.2%) grade-B and 23 (74.2%) grade-C blastocysts were obtained. In BD5 grade-A, grade-B and grade-C, 66 (54.1%) 154 (59.5%) and 36 (43.9%) CP, 61 (50%), 139 (53.7%) and 29 (35.4%) AP and 5 (4.1%), 15 (5.8%) and 7 (8.5%) miscarriages were obtained, respectively. In BD6 grade-A, grade-B and grade-C, 37 (47.4%), 49 (55.7%) and 50 (41.3%) CP, 33 (42.3%), 42 (47.7%) and 42 (34.7%) AP and 4 (5.1%), 7 (7.9%) and 8 (6.6%) miscarriages were obtained, respectively. In BD7 grade-A, grade-B and grade-C, 2 (28.6%), 1 (100%) and 6 (28.6%) CP, 2 (28.6%), 1 (100%) and 3 (13.0%) AP and 0 (0%), 0 (0%) and 4 (17.4%) miscarriages were obtained, respectively. Both CP and AP resulted higher in BD5 compared to BD6 (p = 0.03 and p = 0.02, respectively) and to BD7 (p = 0.005 and p = 0.001, respectively);CP and AP resulted higher in BD6 compared to BD7 (p = 0.05 and p = 0.02, respectively).

Limitations, reasons for caution: The main limitation of morphology assessment is that it is an operator-dependent static system. Furthermore, some blastocysts were already formed on the day antecedent the biopsy without reach enough expansion to perform safely the technique, therefore being cultured one day more and consequently counted in the subsequent group.

Wider implications of the findings: Our data show a strong correlation between the day needed to reach blastocyst stage and implantation potential. Trasferring an early (day-5) euploid blastocyst is most clinically advantageous than a blastocyst obtained later (day-6 or day-7) and it should be considered when more blastocysts are available for the transfer.

Trial registration number: not applicable.

P-177   Blastocoele re-expansion speed is correlated with pregnancy outcome in frozen embryo transfer cycles

D. Shaonan[1], P. Nana[2], Z. Suopin[2], L. Changfu[3], G. Fei[4], L. Guangxiu[5], L. Ge[5]

[1]CITIC-Xiangya Reproductive and Genetic Hospital, IVF lab, changsha Hunan, China
[2]CITIC-Xiangya Reproductive and Genetic Hospital, IVF lab, changsha, China
[3]CITIC-Xiangya Reproductive and Genetic Hospital, LVF lab, changsha, China
[4]CITIC-Xiangya Reproductive and Genetic Hospital, reproductive center, changsha, China
[5]CITIC-Xiangya Reproductive and Genetic Hospital, CITIC-Xiangya Reproductive and Genetic Hospital, changsha, China

Study question: Is the blastocoele re-expansion speed after warming correlated with clinical outcomes in frozen embryo transfer (FET) cycles?

Summary answer: For blastocyst with poor morphological score, blastocoele re-expansion speed is positively correlated with clinical pregnancy rate in FET cycles.

What is known already: Previous studies suggested that the blastocysts with incomplete blastocoele re-expansion had poor clinical outcomes compared with the fully expanded blastocysts in FET cycles, however, the blastocoele re-expansion speed was not involved in most studies.

Study design, size, duration: This is a retrospective study including all FET cycles with single blastocyst transfer from Jan, 2015 to Apr, 2016. Only the fully expanded blastocysts (grade 4 according to Gardner's scoring system) before vitrification are selected. Photographic images of all warmed embryos have been taken at 1 hour after warming. A total of 553 warmed blastocysts are recruited in this study.

Participants/materials, setting, methods: Blastocysts were divided into three groups according to blastocoele re-expansion level (BRL) 1 hour after warming: 75%–100% blastocoelic re-expansion, 50%–75% blastocoelic re-expansion and 0–50% blastocoelic re-expansion. The BRL was calculated as the ratio of the expanded blastocoelic cavity diameter to the whole blastocyst diameter. Classified by blastocyst morphological score, clinical pregnancy rates were compared among the three groups

Main results and the role of chance: The age, BMI and infertility period of patients had no differences in three groups. For blastocysts with good morphology score (≥ 4BB), the clinical pregnancy rates were 57.1% (28 / 49), 56.3% (36 / 64) and 33.3% (3 / 9) for blastocysts with 75%–100%, 50%–75% and 0–50% blastocoelic re-expansion, and no difference was found. For blastocysts with poor morphology score (< 4BB), the clinical pregnancy rates were 46.2% (55 / 119), 37.3% (91 / 244), 23.5% (16 / 68) for blastocysts with 75%–100%, 50%–75% and 0–50% blastocoelic re-expansion, blastocysts with faster-speed blastocoele re-expansion had a higher clinical pregnancy rate (P < 0.05).

Limitations, reasons for caution: This study is limited to its retrospective design and small sample size.

Wider implications of the findings: This study suggested that the speed of blastocoele re-expansion had a predictive value for developmental potential of blastocysts with poor morphological score in FET cycles.

Trial registration number: Not applicable.

P-178   Long-term vapor storage in liquid nitrogen for human vitrified embryos

E.A. Park[1], Y.J. Cho[1], J.Y. Lee[1], S.Y. Moon[1], B.Y. Kim[1], K.Y. Kang[1], E.B. Joe[1], K.H. Choi[1], Y.S. Kim[2], M.K. Koong[2], I.S. Kang[2], T.K. Yoon[2], J.H. Lee[3]

[1]CHA Fertility Center Seoul Station, Embryology, Seoul, Korea- South
[2]CHA fertility center Seoul Station, Ob/Gyn- College of medicine- CHA University, Seoul, Korea- South
[3]College of life science- CHA University, biomedical Science, Seoul, Korea- South

Study question: Is vapor cryopreserved LN2 storage beneficial for vitrified human embryos that are frozen compared to vitrified human embryos having direct contact with LN2

Summary answer: There are no significant differences compared to human embryos being cryopreserved in LN2 vapor storage and having direct contact with LN2.

What is known already: Embryos having direct contact within the LN2 storage has a chance of cross contamination and biohazard issues during long term storage. Embryos in the LN2 vapor storage will have an indirect contact with the LN2 phase and will have no cross-contamination or biohazard.

Study design, size, duration: There was a set-up for investigated vapor with vitrification protocols for safe and stable frozen processing for in vitro fertilized embryo storage. This study was done over six months with 740 embryos.

Participants/materials, setting, methods: This study is a retrospective study and has been approved by the IRB at the CHA Fertility Center Seoul. The embryo has underwent vitrification for long term storage with vapor or direct contact in LN2. After the thawing of the embryo, we checked on the survival

ratio. Then we kept maintaining the embryo transfer of the surviving embryo. We transferred only one or two embryos per patient and kept analyzing the implantation and pregnancy ratio.

Main results and the role of chance: A total of 740 fertilized human embryos are then vitrified frozen, then are stored by vapor (n = 151 cycles) or direct contact (n = 160 cycles) for 6 months in LN2. The presented study shows that the human blastocyst stored in LN2 vapor storage is able to retain full well development. Survival was 97.8% (in LN2 vapor storage) and 97.6% (LN2 storage with direct contact), and the vapor storage of human embryos had no significantly different survival rates after long term storage. For one blastocyst transfer, clinical pregnancy was 50.0% in vapor, 54.0% of direct contact (p = 0.72). Therefore, two blastocyst transfers show that clinical pregnancy was 66.3% by vapor and 63.8% by direct contact storage in LN2 (p = 0.76). There also were no significant differences between the LN2 vapor storage and the storage that allowed the embryos to have direct contact with LN2 in regards to the implantation and the clinical pregnancy of embryo transfer. Especially, age dependent pregnancy ratio also had no significantly different patterns between vapor and direct contact storage methods. Vapor storage systems thus represent a useful alternative for safe and effective long-term storage of vitrified human embryos that can avoid cross contamination chances from having direct contact with LN2.

Limitations, reasons for caution: This study is retrospective analysis.

Wider implications of the findings: Embryo development is not usable for being a predictor of the aneuploidy embryo.

Trial registration number: This is not a critical trial.

P-179   Clinical validation of a noninvasive biomarker for embryo selection based on thermochemiluminescence analysis of the embryo spent culture medium

L. Alegre[1], S. Arrones[1], S. Shnizer[2], C. Tzali[2], D. Beltrán[1], M.J. De los Santos[1], A. Pellicer[3], M. Meseguer[1]

[1]Instituto Universitario IVI, IVF Laboratory, Valencia, Spain
[2]Carmel Diagnostics, Technology, Kiryat Tivon, Israel
[3]Instituto Universitario IVI, Reproductive Medicine, Valencia, Spain

Study question: To determine if the oxidative stress and oxidisability of each embryo's spent culture media can be considered a good biomarker of implantation potential

Summary answer: The transferred embryos which have a lower oxidative stress (higher oxidation potential) in their culture medium show a higher implantation potential

What is known already: Since the development of Time-lapse technology, we have achieved more accurate information about embryo morphology and additional morphokinetic events. One major achievement is to transfer the embryo with highest implantation probability. However, it can be improved by the use of supplementary tools based on embryo spent culture media analysis. New noninvasive analysis strategies such as the oxidation potential of the culture medium may provide valuable data of the embryo quality without disturbing culture conditions

Study design, size, duration: TCL (thermochemiluminescence) is an oxidative stress (OS) determination technique of biological samples. It is based on heat oxidation induction, which generates the formation of electronically Excited Species (EES). A Retrospective study focused on the search for novel indicators of embryo quality was performed based on that OS analysis concept. The study included a total of 400 embryo spent culture media samples. All the embryo transfers were at blastocysts stage

Participants/materials, setting, methods: Embryos were cultured in independent wells in Embryoscope Incubator (Vitrolife,Denmark). TCL-device was able to analyzed 368 of 400 samples obtained. A minimum of 15 μl/embryo CCM-medium (Vitrolife) were necessary for measurements. Two groups were formed according to embryo destiny: transferred+vitrified (T+V group) and discarded (D group), 159 vs. 83 embryos, respectively. Photons emitted per second (cps) were measured during oxidation. Parameters recorded were: TCL-amplitude after 50 seconds (H1), 100 seconds (H2) and 280 seconds (H3).

Main results and the role of chance: Differences were found when the oxidation parameters results were related with implantation rate. These values were obtained from 76 transferred embryos, retrospectively analyzed. From a total of 49 implanted embryos, the 69% of them showed H1 > 77 cps, H2 > 90 cps values were collected from the 70% of the implanted embryos and H3 > 88 cps was registered in 76% of them. A consistent difference was also found when the average of TCL's settings between T+V and D group were compared. The results were distributed as follows: H1: 95.17 cps vs. 90.51 cps; H2: 94.05 vs. 88.82 cps; H3: 112.64 vs. 88.06 cps, belonging to T+V and D group, respectively. The Embryos growing-up in less oxidized environment (those that present highest oxidation potential) have higher implantation than the rest of cohort's embryos

Limitations, reasons for caution: The retrospective nature of the analysis and the limited sample size, although more data will be collected in future prospective studies

Wider implications of the findings: TCL assay is a fast and reliable method of oxidative stress measurement. It could be used, together with morphokinetic data to select the highest implantation potential embryo of the cohort right before the transfer. Consequently, TCL profile is a good candidate to become a noninvasive biomarker of embryo quality

Trial registration number: N/A.

P-180   Correlation between mitochondrial DNA content, morphokinetic parameters and embryo ploidy status

A. Bayram[1], I. Elkhatib[1], A. Linan[1], A. Arnanz[1], N. Garrido[2], I. Villar[2], B. Lawrenz[3], H. Fatemi[3]

[1]IVI Middle East Fertility Clinic LLC, IVF Lab, Abu Dhabi, United Arab Emirates
[2]IVI Foundation, Research, Valencia, Spain
[3]IVI Middle East Fertility Clinic LLC, Clinic, Abu Dhabi, United Arab Emirates

Study question: Is mitochondrial DNA (mtDNA) content related with the early embryo development and embryo ploidy status?

Summary answer: Embryos with higher number of mitochondria showed slowed division pattern, however, no relationship was found between mtDNA content and ploidy status of the embryos analyzed.

What is known already: Previous studies indicated that the mtDNA copy number (the value is called as MitoScore) in the embryos could be used to predict their implantation capacity.

According to these studies, an increase in the mtDNA in the embryo is suggestive of an insufficient level of energy and a low implantation potential. Recently, several studies demonstrated that mtDNA quantity might also be associated with embryo ploidy status.

However, to the best of our knowledge, there are no published data on possible effects of the insufficient energy on the early embryo developmental parameters.

Study design, size, duration: Observational study, including 408 embryos of 66 patients, undergoing PGS and mtDNA copy number from April to December 2016.

Embryo development was monitored by a tri-gas time lapse incubator. The analyzed parameters(times in hours)were t_{Pnf} to t_{SB},cc2(t_3-t_2),S2(t_4-t_3) and S3 (t_8-t_5).Mitoscore values were categorized using the median, partitioning the studied population in two groups (group A with the lower mitoscore values and group B with the higher) and compared with ploidy status of the embryos.

Participants/materials, setting, methods: PGS was done with NGS technology on day 3 of embryo development on embryos with ≥5 nucleated blastomers and ‹ 25 % fragmentation. Biopsied blastomers were sent for high resolution NGS and quantification of mitochondrial DNA/nuclearDNA. Morphokinetic parameters and PGS results were annotated and analyzed according to mitoscore values.

Mann-Whitney and Kruskal-Wallis tests were used for comparison of median timings, mitoscores and PGS results.P-value < 0.05 was considered statistically significant.

Main results and the role of chance: The mean age of the female partner was 34.6 years (range 18 – 44 years). Out of the analyzed embryos, 140 (34.3%) were chromosomally normal, 211(51.7%) abnormal and 57(14%) complex abnormal.

We found that several parameters were significantly correlated with mitoscore values. Timings (median [IQR]) increased with increasing mtDNAcounts: 22.58 h[3.55] in group A compared with 23.58 h[5.23] in group B (p-value = 0.005), 25.14 h[3.78] in group A compared with 26.38 h[5.17] in group B (p-value = 0.003), 35.59 h[5.38] in group A compared with 37.72 h [6.22] in group B (p-value < 0.001), 37.22 h[5.38] in group A compared with 39.34 h[6.42] in group B (p-value < 0.001), 48.25 h[8.86] in group A compared with 50.28 h[11.08] in group B (p-value = 0.002), 51.06 h[8.03] in group A compared with 53.21 h[11.20] in group B (p-value = 0.007), 53.64 h[10.36] in group A compared with 55.58 h[11.90] in group B (p-value = 0.008), 57.38 h[13.56] in group A compared with 60.52 h[17.66] in group B (p-value = 0.004) and 73.03 h[15.61] in group A compared with 75.78 h[17.01] in group B (p-value = 0.009) for t_{Pnf}, t_2, t_3, t_4, t_5, t_6, t_7, t_8 and t_9 respectively.

However, no statistically significant differences were found for the morphokinetics parameters CC2, S3, S2, t_M, t_{SB} and t_{HB}. Additional, no significant differences were observed for mtDNA values according to the groups determined by the variable PGS (p-value = 0.206).

Limitations, reasons for caution: Associations between mitoscore, morphokinetics and ploidy require careful interpretation due to lack of consensus for definitions, variable PGS methodologies, embryo mosaicism, day of biopsy, the sample sizes and time lapse devices used. Larger studies are required to reconfirm the current findings.

Wider implications of the findings: According to these results, euploid and aneuploid embryos have equal mitoscore distributions and therefore altered mitochondrial number and ploidy are independent. However, embryos with higher count of mitochondria take longer time to divide themselves. Out of those results it can be concluded that slow division might cause accumulation of mtDNA.

Trial registration number: Research Ethics Committee Reference No: REFA008.

P-181   Markers of the first lineage separations in human blastocysts

A. Reignier[1], D. Meistermann[2], D. Moreno[2], S. Kilens[2], J. Lammers[1], P. Barriere[1], L. David[2], T. Freour[1]

[1]CHU Nantes, Biologie et médecine de la reproduction, Nantes, France
[2]inserm, Center for Research in Transplantation and Immunology, Nantes, France

Study question: Is it possible to identify specific markers of expression of early lineage-specific genes in human blastocyst by immunofluorescence (IF)?

Summary answer: KLF17, SOX17 and GATA2 are respective specific markers of epiblast cells, primitive endoderm and trophectoderm, which can be observed in IF in human blastocysts.

What is known already: Human embryo development begins in transcriptional silence with an oocyte to zygotic transition, followed by a major molecular event named Zygotic Genome activation (ZGA) occurring between the 4- and 8-cell stage for humans. After ZGA, and especially at the morula stage, some differences emerge among embryonic cells, ultimately leading to the formation of 3 cell lineages at the blastocyst stage: pluripotent epiblast cells, primitive endoderm cells and extraembryonic trophectoderm cells, respectively contributing to fetal tissues, yolk sac and placenta.

Study design, size, duration: This study was performed in frozen-thawed human blastocysts donated for research according to French regulation (authorization AG11-0126AMP)

Participants/materials, setting, methods: Frozen-thawed embryos donated for research were fixed in PFA 4% at the morula, early (B2) or expanded (B4) blastocyst stages. The expression of three proteins: GATA2, SOX17 and KLF17 was assayed by immunofluorescence for three embryos of each stage. The following antibodies were used: goat anti Sox17 (1:200, R&D AF1924), rabbit anti Klf17 (1:500, Sigma HPA024629), mouse anti Gata2 (1:50, Sigma WH0002624M1). Images were acquired on an inverted Nikon A1 confocal microscope by confocal microscopy

Main results and the role of chance: KLF17 is strongly expressed in all cells at the morula and B2 stages, and rapidly becomes restricted to the epiblast cells at the B4 blastocyst stage. In contrast, GATA2 is expressed in trophectoderm after B2 stage, and SOX17 is expressed in ICM at the B4 stage. The results were the same for each of the three embryos analyzed for each stage. These

results are is in line with single-cell RNA-seq data performed on human embryos (Petropoulos et al., 2016)

Limitations, reasons for caution: This study needs to be continued in a larger number of embryos in order to confirm the specificity and dynamics of expression of each marker. The corresponding gene expression should also be studied with an RNA-Fish approach.

Wider implications of the findings: Understanding cell lineage molecular mechanisms is important to improve embryo quality evaluation and culture in ART. Improving the characterization of human epiblast cell markers is also mandatory to bring new insights into the field of human naïve pluripotent stem cells.

Trial registration number: none.

P-182   Trophectoderm biopsy does not impact embryo viability after vitrification: results from a multicentre prospective study

G. Orlando[1], R. Maggiulli[1], D. Cimadomo[1], V. Parini[2], I. Parisi[2], A. Capalbo[3], E. Albani[2], E. Levi Setti[2], F.M. Ubaldi[1], L. Rienzi[1]

[1]GENERA, Reproductive Medicine Center, Rome, Italy
[2]Humanitas, Clinical and Research Center, Milan, Italy
[3]GENETYX, Molecular Genetics Laboratory, Marostica- Vicenza, Italy

Study question: Does trophectoderm biopsy technique increase blastocysts' vulnerability to vitrification/warming injuries?

Summary answer: Trophectoderm biopsy does not impact post-thawing behaviour of vitrified blastocysts. Only blastocyst re-expansion and degeneration grade after warming are predictive of blastocysts' implantation potential.

What is known already: The optimization of preimplantation genetic diagnosis for aneuploidies (PGD-A) cycles requires cryopreservation to obtain a reliable diagnosis, and the employment of an efficient vitrification program to preserve blastocyst developmental competence. Previous studies have shown that trophectoderm biopsy has no impact on embryo viability in fresh cycles, however, there is still a lack of knowledge about the impact of this procedure on blastocyst viability after warming. The developmental potential of warmed blastocysts has been previously evaluated in terms of re-expansion grade that has been reported as a predictive factor of clinical outcomes.

Study design, size, duration: A multicenter prospective cohort study was performed between June 2016 and December 2016, including all the patients who underwent warming cycle with single blastocyst transfer (SET). A total of 383 warmed blastocysts were included in the study (258 from PGD-A cycles and 125 from standard ICSI cycles). 285 SETs had a conclusive clinical outcome when writing this abstract (197 and 88 in PGD-A and standard cycles, respectively).

Participants/materials, setting, methods: The female age was 37.7 ± 3.5 and 34.6 ± 3.9 in PGD-A and standard group, respectively. As primary outcome, the post-warming blastocyst behaviour was evaluated 1.5hr after warming. Blastocysts were graded according to degeneration (absent/partial/full), re-expansion (1 = 80–100%/2 = 20–80%/3 = 0–20%) and morphology grades (excellent/good/average/poor). Secondary outcome was the ongoing implantation (> 14 weeks of gestation). Logistic regression analysis corrected for confounding factors (female age,PGD-A/standard care group,BMI,stimulation protocol,total FSH dosage,main infertility factor,sperm factor,PGD-A indication,incubator,culture media,biopsy/vitrification/warming operator,blastocyst quality) was performed.

Main results and the role of chance: The rate of degeneration after warming was similar in the PGD-A and in the standard groups (n = 2/258, 0.8% versus n = 3/125, 2.4%). Partial (n = 42/258, 16.3% versus n = 24/125, 19.2%) and absent degeneration (n = 214/258, 83.0% versus n = 98/125, 78.4%) rates were also similar.

No difference was found also in the rate of no re-expansion (n = 24/258, 9.3% versus 9/125, 7.2%), partial expansion (n = 78/258, 30.2% versus n = 37/125, 29.6%) and full expansion (n = 156/258, 60.5% versus n = 79/125, 63.2%).

The rates of blastocysts whose morphological quality worsened after warming was similar between PGD-A and standard cycles (n = 65/256, 25.4% versus n = 23/122, 18.9%). Even if either only ICM's quality (n = 37/256, 14.4% versus n = 11/122, 9.0%) or the TE's one was considered (n = 36/256, 14.1% versus n = 16/122, 13.1%).

The overall clinical outcomes highlighted that not re-expanded blastocysts have a significantly lower ongoing implantation rate than fully expanded ones (n = 3/23, 13.0% versus n = 74/168, 44.0%; p = 0.006). Similarly, also partially-degenerated blastocysts have a significantly lower ongoing implantation rate than fully-viable ones (n = 13/58, 22.4% versus n = 94/227, 41.4%; p = 0.009).

Logistic regression analysis identified the re-expansion grade 1.5hr after warming as the strongest predictor of ongoing implantation. Specifically, not re-expanded blastocysts showed an OR of 0.25 (P = 0.04).

Limitations, reasons for caution: These findings are relative to the trophectoderm biopsy protocol that involves simultaneous zona opening and trophectoderm cells retrieval on fully-expanded blastocysts (no day3 hatching step involved). A higher sample size is advisable to confirm the current results.

Wider implications of the findings: This study provides further evidences that trophectoderm biopsy does not impact embryo developmental and reproductive potential. Furthermore, interesting clues to increase predictive power upon implantation may arise from post-warming blastocysts evaluation which could influence the clinical practice (e.g. warming of an additional blastocyst).

Trial registration number: none.

P-183 Modification of late embryo development after blastomere removal on day 3 for preimplantation genetic diagnosis

T. Freour[1,2], J. Lammers[2,3], A. Reignier[2,3], C. Splingart[3], P. Barrière[2,3]

[1]CHU de Nantes, Médecine de la Reproduction, Nantes Cedex 01, France
[2]INSERM UMR1064, ITUN, Nantes, France
[3]CHU de Nantes, Médecine de la reproduction, Nantes, France

Study question: Is there a difference in late morphokinetic parameters between biopsied embryos on day 3 for PGD and non-biopsied embryos in control group?

Summary answer: Late morphokinetic events at the morula and blastocyst stages occurred significantly earlier in biopsied embryos than in control non-biopsied embryos.

What is known already: Preimplantation genetic diagnosis (PGD) implies embryo biopsy, either on day 3 or at the blastocyst stage. Although trophectoderm biopsy has been shown to yield some advantages over day 3 biopsy, many teams still perform embryo biopsy on day 3, followed by embryo transfer on day 4 or at the blastocyst stage. Although some studies reported delayed compaction and blastulation after Day 3 biopsy, this remains controversial. Time-lapse systems (TLS) bring new insights into embryo development and can be used to revisit the eventual impact of embryo biopsy on subsequent late cellular events.

Study design, size, duration: This case-control monocentric retrospective study was conducted in couples referred for PGD with biopsied embryos (cases) and in ICSI patients with normal caryotype (controls). We analyzed the clinical and biological data of all consecutive patients who had undergone ICSI or PGD cycle with own oocyte and embryo culture performed with the Embryoscope® between May 2013 and April 2016.

Participants/materials, setting, methods: Each embryo was investigated by detailed time-lapse analysis measuring the exact timing of the developmental events up to blastulation in hours after ICSI procedure. All embryos in both groups were cultured in sequential media in the Embryoscope® under low oxygen pressure (6% CO_2, 5% O_2). Embryo biopsy was performed in decompaction medium, with 1 or 2 blastomeres removed according to developmental stage (< 8 or ≥8 cells).

Main results and the role of chance: Among the 2903 mature oocytes that were microinjected in the PGD group, 1792 were fertilized (61.4%) and 977 were biopsied on day 3 (55%). In the ICSI control group, 3838 oocytes were microinjected, 2241 were fertilized (58.4%) and 1115 had a quality on day 3 compatible with biopsy criteria (50.5%). Both groups were comparable in terms of patients' characteristics and early morphokinetic parameters. Concerning post day 3 development, tM (morula) and tSB (early blastocyst) and tB (full blastocyst) occured significantly earlier in biopsy group than in control group (95.32 ± 0.37 vs 97.17 ± 0.34, 103.1 ± 0.49 vs 106.1 ± 0.39 and 111.2 ± 0.60 vs 113.3 ± 0.43 respectively, p < .05 for all comparisons).

Limitations, reasons for caution: We did not analyze the respective impact of removing 1 or 2 cells on late embryo development. Our control group consisted in a large but not matched group of ICSI cycles. PGS is not authorized in our country.

Wider implications of the findings: Further studies conducted on embryos donated for research could help deciphering the cellular and molecular mechanisms potentially involved in the modification of post-biopsy embryo development. In this respect, the comparison of transcriptomic data obtained in biopsied and non-biopsied embryos from a same cohort could be of interest.

Trial registration number: not applicable.

P-184 Can morphokinetic parameters help in identifying balanced embryos in chromosomal translocation carriers undergoing PGD when PGS is forbidden by regulation?

J. Lammers, A. Reignier, C. Splingart, P. Barriere, T. Freour

Biologie et Médecine de la Reproduction - CHU Nantes, CHU Nantes 44000, Nantes, France

Study question: Are there any morphokinetic differences between balanced and unbalanced embryos in chromosomal translocations carriers referred for PGD which could be included in a prediction model?

Summary answer: We found some morphokinetic differences between balanced and unbalanced embryos, but previously published algorithms for aneuploidy screening did not perform well in our PGD population.

What is known already: Preimplantation genetic diagnosis (PGD) is a procedure developed for couples at high risk of transmitting a specific genetic abnormality or of pregnancy loss because of a specific chromosomal translocation, whereas Preimplantation genetic screening (PGS) consists in the selection of euploid embryos for transfer, this last technic being forbidden in some countries. Recently, several ART laboratories implemented time-lapse in order to improve embryo culture conditions and embryo quality evaluation. As PGS is an expensive and relatively invasive procedure, some studies evaluated the predictive interest of time-lapse for embryo ploidy, with promising but still partial results needing confirmation.

Study design, size, duration: This case-control monocentric retrospective study was conducted in couples referred for PGD because of chromosomal rearrangement, either reciprocal or robertsonian. Clinical and biological data of all consecutive patients who had undergone ICSI-PGD cycle with own oocyte and embryo culture performed with the Embryoscope® between May 2013 and April 2016 were analyzed.

Participants/materials, setting, methods: All mature oocytes were injected and cultured in the Embryoscope® (6% CO_2, 5% O_2) until day 3 where all embryos with at least 6 blastomeres and little fragmentation underwent biopsy of 1 or 2 cells for further genetic analysis of both chromosomes implicated in the translocation by FISH. Each embryo was investigated by detailed time-lapse analysis measuring the exact timing of the developmental events in hours after ICSI procedure.

Main results and the role of chance: Mean female age was 32.0 ± 3.6 years, mean female BMI was 24.3 ± 4.2 kg/m^2. The mean number of oocytes aspirated was 13.7 ± 5.6. A total of 1176 oocytes were microinjected and cultured in the Embryoscope®, among which 749 were fertilized (63.7%) and 427 were biopsied (57%). Among them, 177 displayed a balanced chromosomal status (41.5%).

Some cleavage timings were significantly different between balanced and unbalanced. t3, t5 and t9+ occurred significantly earlier in unbalanced than in balanced embryos. Concerning cell cycle and synchrony, cc2 and interval t5 − t2 were significantly longer in balanced than in unbalanced embryos. However, there was considerable overlap between groups, preventing from building a statistically relevant prediction model.

In a second phase, we tested the performance of a recently published morphokinetic predictive model for embryo aneuploidy (Basile et al., 2014) in our PGD population of couples with chromosomal rearrangement. The respective proportion of balanced embryos was not significantly different in the 4 groups (p > .05 for all comparisons).

Limitations, reasons for caution: The principal limitation of our study is that we only compared balanced and unbalanced embryos for one specific

chromosomal rearrangement, and not for all chromosomes, as aneuploidy screening (PGS) is not allowed in our country.

Wider implications of the findings: Although promising studies reported a predictive interest of morphokinetic parameters for embryo aneuploidy screening, this strategy needs to be further validated and does not seem to be relevant for the identification of balanced embryos in chromosomal translocation carriers when PGS is forbidden.

Trial registration number: NA.

P-185   Clinical validation of a new automated analysis for embryo selection based on time-lapse technology

L. Alegre[1], B. Aparicio-Ruíz[1], K. Loewke[2], S. Arrones[1], C. Albert[1], J. Remohí[3], M. Meseguer[1]

[1]Instituto Universitario IVI, IVF Laboratory, Valencia, Spain
[2]Cellogy- Inc, Biotechnology, California, U.S.A.
[3]Instituto Universitario IVI, Reproductive Medicine, Valencia, Spain

Study question: Can an automated embryo assessment, based on similarity algorithm, classify embryos in regards to their implantation potential as compared to manual annotations or standard morphology?

Summary answer: Utilising two dimensional morphokinetic analysis, blastocysts with a UAD value > 1.03 (a defined arbitrary unit of distance) have significantly lower implantation rate than blastocysts with UAD < 1.03

What is known already: Selecting the best embryo for transfer is needed to achieve the first goal for IVF treatments, implantation. Time-lapse technology has helped to elucidate key events of embryo development but nevertheless, not all apparently good quality blastocysts manage to implant. The development of novel tools that will assist in even better selection of embryos with most implantation potential enable IVF clinics to get closer to that goal

Study design, size, duration: The study was done in two stages. First, a retrospective analysis of embryos from 799 couples belonging to an oocyte donation program was conducted. In the second phase, embryo analysis was performed before embryo transfer in fresh cycles for 108 patients. In all cases, the embryos were assessed by an automated embryo analysis software

Participants/materials, setting, methods: In the first stage, cleavage timings and cell cycle lengths of 3,781 embryos were registered automatically. Morphokinetic parameters were positioned in 2D-plots and the average distances from the data cloud of KID (known-implantation-data) embryos were calculated, followed by the generation of quality ranking system based on implantation outcomes. The same procedure was followed in the second stage, where 147 embryos were transferred according to their ranking position based on their expected implantation potential

Main results and the role of chance: In the first stage, a retrospective quality ranking of embryo implantation potential was generated based on UAD values obtained from 1,021 analyzed KID embryos. The implantation rates obtained in five chosen grades were: A 34%, B 25%, C 24% and D 19% (**A:** UAD < 0.5, **B:** UAD = 0.5 − 1.0, **C:** UAD = 1.0− 3.0 and **D:** UAD ≥ 3.0). These results were comparable with Basile et al. 2015 algorithm and ASEBIR morphologic classification in day 3 of embryo development. When embryos in the second stage were analyzed, a more accurate hierarchy data was generated: **A:** UAD ≤ 0.50, **B:** UAD = 0.50–0.66 **C:** UAD = 0.66–1.03 **D:** UAD > 1.03. KID embryos were distributed in these 4 groups as follows: 50% in Group A, 48% in Group B, 41% in Group C and only 25% in Group D. Most implanted embryos were found in Groups A, B and C (UAD < 1.03), whereas the implantation rate in Group D (UAD > 1.03) was significantly lower, 46% vs. 25% respectively

Limitations, reasons for caution: The retrospective nature of the analysis, although validated throughout an independent dataset, may limit its universal application

Wider implications of the findings: The automated assessment system provided by time-lapse culture and associated software utilizing an automatic two dimensions grading avoids inter-observer biases and achieves more accurate selection of embryos with the highest implantation potential. This in turn can lead to improved clinical outcomes

Trial registration number: N/A.

P-186   Does Kisspeptin/ Kisspeptin Reseptor system has an local direct effect on oocyte maturation and fertilization?

B. Avci[1], G. Kuspinar[1], I. Kasapoglu[2], S. Saribal[1], G. Uncu[2]

[1]Uludag University School of Medicine, Histology and Embryology, Bursa, Turkey
[2]Uludag University School of Medicine, Obstetrics and Gynecology, Bursa, Turkey

Study question: Does Kiss1/Kiss1Receptor mRNA expression in oocytes or surrounding cumulus cells (CCs) and follicular fluid or serum concentrations have an direct effect on oocyte maturation or qualitative functions for further steps?

Summary answer: Positive correlation between mean follicular diameters of mature-fertilized oocytes and follicular kisspeptin concentrations, suggests a direct action on oocyte maturation and fertilization.

What is known already: Kisspeptin signalling system is the main regulator of the reproductive axis and is considered to be the most potent modulator molecule for gonadotrophin releasing hormone (GnRH). Although well known Kiss1 reproductive functions at the level of central nervous system, its direct role on ovarian control has not yet been fully elucidated yet. İmmediate gonadal effect for the presence of kisspeptin locally remains unknown.

Study design, size, duration: This was a prospective cohort study of a total of 26 oocytes and 52 cumulus cells, and 52 samples of folliculer fluid retrieved from infertile patients underwent intracytoplasmic sperm injection (ICSI) cylcles.

Participants/materials, setting, methods: Samples provided from infertile women who underwent ovarian stimulation, divided into three groups according to the stage of oocyte maturity and fertilization. Group 1 included 16 immature oocytes with their micro-enviroments, Group 2 included 10 mature-unfertilised oocytes with their micro-enviroments and Group 3 consisted from 26 micro-enviroments of mature fertilized oocytes as a control group. Kiss1/Kiss1R mRNA in oocytes, CCs, serum and follicular fluid levels were measured. The quantitative results were compared within each group.

Main results and the role of chance: The mean follicular diameter was measured as 18 mm ± 1.84 in Group 1, 20.6 mm ± 1.96 in Group 2 and 19.65 mm ± 1.46 in Group 3. A statistically significant difference was determined between Group 1 and 2 (p < 0.001) and between Group 1 and 3 (p < 0.001). The follicular and serum concentration of Kiss1/Kiss1R showed positive correlation between each other (p = 0,007; p < 0,001 respectivly). Serum and follicular fluid Kiss1 concentrations were found to be correlated in line with each other, with lowest level in group 3 and the highest in group 1, and there was no significant difference between the groups (p = 0,301; p = 0,862). Although, follicular concentrations of Kiss1 and Kiss1R and between mean follicle diameter showed significant positive correlation only in Group 3 (mature and fertilized oocytes) (respectively p = 0,003; p = 0,026). CCs and oocyte Kiss 1 concentrations were also parallel to each other, but they both failed to induce any change on oocyte maturation (p = 0,568; p = 0,181 respectivly) or fertilization (p = 0,181).

Limitations, reasons for caution: The cumulus cells and oocytes were obtained from patient who underwent ovarian stimulation, which in comparison with natural cycles, may have affected gene and protein expression. Also due to the ethical restriction and patient rights, fertilized oocytes regarded as potential embryos and were not analyzed.

Wider implications of the findings: Our data demonstrate that, in addition to crucial effects at the central nervous, kisspeptin/KISS1R systems are co-expressed and are functionally active in follicular development.

Trial registration number: We do not have a clinical trial registration number.

P-187   In vitro exposure to environmental relevant dose of bisphenol A does not influence the rabbit blastocyst transcriptome

J. Moreau[1], M. Tymen[1], C. Archilla[2], N. Gatimel[1], L. Jouneau[2], E. Balmisse[3], J. Parinaud[1], V. Duranthon[2], R.D. Léandri[1]

[1]Université de Toulouse, Research Group in Human Fertility- EA3694, TOULOUSE, France
[2]INRA, UMR 1198 Reproductive and Developmental Biology, Jouy-en-Josas, France
[3]INRA, Toulouse Experimentation Platform on Rabbit Species PECTOUL, Auzeville, France

Study question: Does in vitro exposure of preimplantation rabbit embryos to environmental doses of bisphenol A (BPA) affect its gene expression?

Summary answer: Exposure to a concentration of BPA relevant to the human situation does not affect rabbit embryo gene expression.

What is known already: In mice, in vitro studies have shown that a single addition of BPA at the nanomolar range at the start of 2 cell-embryos culture can speed up embryo development while it slows it down at high doses (100 μM) without affecting blastocyst cell numbers. Because mice preimplantation embryo development presents important differences with the human one, our goal was to evaluate the transcriptomic effects of an in vitro exposure to a concentration of BPA relevant to the human situation (2 ng/ml = 8.76 nM) on another mammalian species, the rabbit, assumed as a more relevant model for reproductive and developmental toxicology.

Study design, size, duration: In vivo fertilized one cell embryos recovered from different stimulated females were pooled, randomly distributed by groups of 25 to 35 in 50 μl drops of culture medium G1+/G2+ (Vitrolife, Goteborg, Sweden) containing 2 ng/ml Bisphenol A or not (vehicle only) and cultured until 97 hours post coitum. Then, 4 pools of 9 expanded blastocysts in the control and BPA exposed conditions were constituted and frozen.

Participants/materials, setting, methods: Total RNA was extracted from each pool of exposed and control blastocysts, amplified and labelled using the One Color Microarray-based Gene Expression Analysis low input Quick AMP labeling kit (Agilent®). After purification, cRNAs were hybridized on a customized Agilent Rabbit array (24 K). Transcriptomic analysis was explored using Hierarchical Clustering, Principal Component Analysis and Independent Component Analysis. Standard statistical analyses (Limma R-package) was then performed to identify genes whose expression has been modified between exposures.

Main results and the role of chance: Embryo development and blastocyst rates were unaffected by BPA. Exploratory analysis using Hierarchical clustering or principal component analysis failed to evidence any difference in global gene expression explained by the culture conditions of the blastocysts. Furthermore, applying the False Discovery Rate (FDR) multiple analysis correction method, no gene was evidenced as differentially expressed between exposed and control embryos at the $p < 0.05$ level using the LimmaR-package. If FDR was not applied and the raw p-value was set at < 0.01, only 9 genes with a two-fold ratio (> 2 or < 0.5) of expression between BPA exposed and control embryos were retrieved. RT-qPCR analysis failed to confirm any difference in gene expression for those genes between culture conditions. Therefore, in our hands, BPA at concentration relevant to the human situation had no effect on gene expression of the rabbit blastocyst.

Limitations, reasons for caution: BPA addition was performed at the start of the embryo culture. We cannot rule out a degradation of the toxicant along the 4 days culture period. Furthermore, epigenetic evaluation was not performed in this study so that epigenetic alterations cannot be eliminated.

Wider implications of the findings: This study highlights the necessity to study other mammalian species than mouse when assessing the effect of any potential embryotoxic molecule. The previous results on mice came from BPA exposure beginning at the 2 cell embryo stage i.e at the time of the major phase of embryo genome activation.

Trial registration number: not applicable.

P-188 Possible influence of the different shipment types on the viability of vitrified oocytes

B. López, E. Criado, C. González, B. Renilla, J.A. Sánchez

Ovobank, Laboratory, Marbella, Spain

Study question: During the oocytes shipment, is there any influence related to the different shipment types and oocytes viability when they are thawed?

Summary answer: There is a significant difference between shipment types; we can state the possible influence of the different shipment types on the viability of vitrified oocytes.

What is known already: Oocyte donation has become a fundamental part of ART. The demand for oocyte donation has increased lately, as it has become a treatment option. The introduction of oocyte cryopreservation into donation programmes overcomes many challenges. It simplifies the logistics of ART cycles as there is no need for menstrual cycle synchronization between donor and recipient and it has also led to the development of ova banks. In many European countries, gametes donation 'has recently been approved by law", so the incipient need for egg donors makes many of them turn into cryobanks, often located outside their borders.

Study design, size, duration: 5336 vitrified oocytes have been shipped during the research, from November 2014 until September 2016, in two types of shipments: Standard air delivery by plane via a conventional cargo company; and Lab to Lab, in which a member of Ovobank staff is personally in charge of the door-to-door delivery. The survival data from every centre have been analysed and they have been classified by their shipment type in an Excel table for subsequent analysis.

Participants/materials, setting, methods: Oocytes at methaphase II from donors aged 18–31 were used. They were collected via follicular puncture 36 hours after trigger, then vitrified following Kitazato protocol (Cryotop) and stored in tanks with liquid nitrogen afterwards at Ovobank laboratory (FIV Marbella, Spain). Dry Shipper Dewars containers were used for their delivery. The shipment types were the above mentioned: Standard air delivery and Lab to Lab.

Main results and the role of chance: In the research we have only analyzed the survival rate, since in the other rates there are many factors that may affect the result and not only the shipment.

Out of the 5336 shipped oocytes from November 2014 to September 2016, 5262 thawed have been reported: 2278 thawed oocytes were sent via conventional cargo companies (DHL, TNT or Feddex) and 2984 thawed oocytes were sent via Lab to Lab (by Ovobank staff).

Overall, when the survival rate is analysed according to the type of shipment, it is significantly higher in Lab to Lab deliveries than in standard air delivery (74,9% vs 70,5%).

These data show that oocytes may be damaged if they are shipped via standard carrier. This is probably due to the container handling, the possible exposure to X-rays, the use of commercial airlines, etc.

The safest shipment type according to this data is Lab to Lab, as a member of Ovobank staff is continuously looking after the container during the delivery, from Ovobank laboratory to the recipient clinic laboratory.

Limitations, reasons for caution: The sent oocytes batches come from different donors and stimulations, in addition they have been thawed by different centres and professionals who, even thought they have followed the established protocol, may have limited the obtained results.

Wider implications of the findings: Due to the constant flux of oocytes shipments by Ovobank, we are continuously receiving results from their thawing, so we will have to continue researching, analyzing and going in depth on the influence of the different shipment types on the viability of vitrified oocytes.

Trial registration number: Not applicable.

P-189 GnRH agonist triggering affects early-stage embryo morphokinetic parameters

G. Oron[1], A. Ben-Haroush[2], R. Garor[3], D. Asher[3], M. Tuttnauer-Hamburger[4], Y. Shufaro[3], B. Fisch[3], O. Sapir[3]

[1]*Rabin Medical Center- Beilinson Hospital, Infertility and IVF Unit- Helen Schneider Hospital for Women, Petach - Tikva, Israel*
[2]*Rabin Medical Center- Beilinson Hospital-, Infertility and IVF Unit- Helen Schneider Hospital for Women, Petach Tikva, Israel*
[3]*Rabin Medical Center- Beilinson Hospital, Infertility and IVF Unit- Helen Schneider Hospital for Women, Petach Tikva, Israel*
[4]*Rabin Medical Center- Beilinson Hospital- Petach Tikva, Infertility and IVF Unit- Helen Schneider Hospital for Women, Petach Tikva, Israel*

Study question: Our objective was to compare embryo morphokinetic of embryos derived from GnRH antagonist cycles triggered with either GnRH agonist hCG, using the time lapse monitoring system (TMS).

Summary answer: hCG triggering was associated with a higher proportion of optimal day-1 embryo morphokinetic parameters compared with GnRH agonist triggering even after adjustment for confounding variables.

What is known already: GnRh agonist triggering elicits an endogenous surge of LH and FSH that remain elevated for 24–36 hours, opposed to the hCG-

mediated LH activity that persists for several days. Oocyte and embryo kinetics are affected by treatment protocol and ovulation triggering medications.

Study design, size, duration: A retrospective cohort study evaluating all TMS [EmbryoScope, Unisense Fertilitech, Aarhus, Denmark] data of fresh antagonist cycles in women ≤42, between April 2013 and December 2016. Timing of PB-extrusion, PN-fading, cleavage timings (t2-t8), second cell cycle (CC2 = T3-T2) and second synchrony (S2 = T4-T3) durations were compared. Optimal CC2 was defined as > 5 hours and optimal S2 was defined as < 1 hour. KID score was used for assessing embryo quality.

Participants/materials, setting, methods: Embryo morphokinetic parameters and cycle outcome were compared between embryos derived from GnRH antagonist with final oocyte maturation triggered by GnRH agonist (Decapeptyl 0.2 mg) or hCG (Ovitrelle 250 mcg). Multivariate logistic analysis was performed for confounding factors including maternal age, BMI, type of gonadotropin used and estradiol levels.

Main results and the role of chance: We analyzed 8,422 embryos deriving from 727 cycles; 2,406 embryos in the GnRH agonist triggering and 6,016 embryos in the hCG triggering group. The percentage of embryos with optimal s2 duration, symmetric blastomeres and no multinucleation was higher with hCG triggering group. These early kinetic parameters occurring during the first 24 hours from fertilization were the only ones found to be affected by type of medication triggering. Later stage embryo kinetic parameters of cleavage t2-t8 were similar. Differences remained significant in a multivariate model after adjusting for confounding variables that might have an effect on embryo morphokinetics. The proportion of high (4/5) KID score embryos and pregnancy rates per transfer were similar in cycles with final oocyte maturation triggered by GnRH agonist or hCG.

Limitations, reasons for caution: It is yet to be determined if these differences in embryo kinetic parameters are of any clinical significance considering embryo grading (KID score) and pregnancy rates were similar. Furthermore, despite statistical adjustment for confounding variables, the physician's choice of triggering was affected by patient characteristics and response to treatment.

Wider implications of the findings: The TMS allows embryo quality assessment by documenting timing of events and length of intervals in embryo development, providing a more objective scoring of the embryos, for embryo selection. Type of oocyte maturation triggering might influence embryo morphokinetics parameters and should be considered in embryo selection models.

Trial registration number: none.

P-190   Artificial oocyte activation improves morphokinetic parameters and number of quality blastocysts: a sibling oocyte study

V. Nagornyy[1], V. Veselovsky[2], P. Mazur[1], V. Zukin[2]

[1]Clinic of reproductive medicine 'Nadiya', Embryology department, Kiev, Ukraine
[2]Clinic of reproductive medicine 'Nadiya', IVF department, Kiev, Ukraine

Study question: How the artificial oocyte activation (AOA) with calcium ionophore affects the embryo development and aneuploidy rate?

Summary answer: The AOA embryos developed faster, but morphokinetics were similar to control after arrested embryos exclusion. Euploidy rate was similar, but with AOA blastocysts yield increased.

What is known already: The most of failed ICSI fertilization cases can be explained by the lack of oocyte activation by spermatozoa. The AOA by short exposure of freshly fertilized oocytes to medium containing calcium ionophore can overcome recurrent low or failed fertilization and give successful pregnancy. However the impact of AOA on embryo development is mostly unknown. This study compares morphokinetic, quantitative and aCGH data for embryos obtained after AOA to same patient's embryos fertilized by standard ICSI.

Study design, size, duration: This retrospective study includes total of 62 patients with AOA cycles performed between April 2015 and December 2016. For 39 of them the time-lapse culture data was available for both AOA and standard ICSI embryos. Additionally, for 37 patients the embryo ploidy was established by aCGH after trophectoderm biopsy in both AOA and non-AOA cycles. Data from development of same patient's "sibling" embryos from conventional ICSI were used as a control.

Participants/materials, setting, methods: The indications for AOA were the previous ICSI cycles with poor fertilization, cleavage stage arrest or severe teratozoospermia. Ovarian stimulation, ICSI and embryo culture followed standard protocols. The AOA was done after ICSI by placing oocytes for 15 minutes in the medium containing 10μmol/l calcimycin (A23187). Conventional ICSI was performed in control group. Time-lapse imaging culture was carried out in EmbryoScope™ or MIRI-TL™ until day 5 and trophectoderm biopsy for aCGH was done if required.

Main results and the role of chance: The fertilization rate was significantly higher in AOA group compared to control (71.2% vs 63.1%). After 43 embryo transfers 21 clinical pregnancies were achieved in AOA group, with average of 1.3 embryos per transfer.

According to time-lapse data the AOA embryos were significantly faster than the sibling controls in timing of pronuclear fading, first and second round of mitotic divisions. Interestingly, after the embryos not reaching blastocysts were excluded the both groups showed equal morphokinetic behaviour.

The euploid rate in the AOA group was 36.1% compared to 32.5% in control group, with no statistically significant difference. However, the yield of blastocysts with good morphology that hatched enough for trophectoderm biopsy was higher after AOA (3.6 blastocysts per cycle compared to 2.7 in control group).

Limitations, reasons for caution: While AOA can help in case of reduced or failed ICSI fertilization, at this moment this procedure is considered as an experimental technique. This study is a retrospective analysis and thus can be a subject to bias.

Wider implications of the findings: The AOA can help patients with previous low or failed fertilisations and infertile couples with severe male factor. The early development dynamics and ploidy of embryos that were obtained with AOA seems to be unaltered by procedure. These data are an additional step towards wider application of this technique.

Trial registration number: Not a RCT trial.

P-191   Relative humidity of outside air influences ongoing pregnancy rates if outside air is not conditioned for humidity before passing through the carbon/potassium permanganate filters

I. Van Der Auwera, K. Vandenborne, R. Campo, W. Ombelet

Ziekenhuis Oost-Limburg, Genks Institute for Fertility Technologie, Genk, Belgium

Study question: What could be the reason for inexplicable fluctuating IVF results in a high tech clean-air ART laboratory with experienced lab technicians and standard operating procedures?

Summary answer: The relative humidity of unconditioned outside air influences efficiency of activated carbon/potassium permanganate filters which can result in significantly impaired ongoing pregnancy rates.

What is known already: It is generally known that air quality and the presence of VOC's can have detrimental effects on embryonic growth and ongoing pregnancy rates. Therefore cleanroom technology, including a high efficiency particulate air filter (HEPA 14) and two types of activated carbon/potassium permanganate (KMnO4) filters can improve implantation rates significantly. The efficiency of these activated carbon filters, however, is highly dependent on the relative humidity and work suboptimal above a humidity of 70%. Therefore, during periods with high relative humidity of outside air, VOC's can enter the IVF laboratory.

Study design, size, duration: In this retrospective cohort study, the influence of the mean daily relative humidity of the outside air near the clinic was correlated with the pregnancy outcome for all 1770 IVF/ICSI cycles with ET performed between January 2014 and September 2016 in a tertiary referral center.

Participants/materials, setting, methods: All 1770 IVF/ICSI transfers were divided into four groups dependent of the mean relative outside humidity on the day of oocyte pick-up. Humidity in Group I (N = 148) < 60%, Group II (N = 235) 60–70%, Group III (N = 992) 70–85% and Group IV (N = 395) > 85%, respectively.

Main results and the role of chance: Comparable figures for cause of infertility, cycle number, mean age, number of oocytes found, fertilization rate and number of embryos transferred were found in the different groups analyzed. IVF results were significantly impaired and inversely correlated to the degree of humidity in the outside air: +BHCG and clinical ongoing pregnancy rate per

embryo transfer were 39.7% and 31.0% for Group I, 36.9 and 27.8% for Group II, 31.3% and 22.5% for Group III and 29.4 and 17.4% for Group IV, respectively (P < 0.001). In Belgium, the mean relative humidity is above 70% during 80% of the time. The outside air quality near our clinic is highly polluted by the industry with VOC's such as benzene, toluene and heavy metals. If the outside air goes unconditioned for humidity through the active carbon filters, these filters work suboptimal to eliminate VOC's.

Limitations, reasons for caution: After multivariate analysis no confounding factors could be found which could have influenced these data.

Wider implications of the findings: Despite the presence of cleanroom air containing HEPA14- and active carbon/potassium-permanganate filters, Coda® tower and Coda® inline filter cartridges, air quality can influence ongoing pregnancy rates if outside air is not conditioned for humidity before filtering. ART centers with inexplicable fluctuating IVF results should control their filter system.

Trial registration number: Not applicable.

P-192   Comparison of differences in IVF outcomes between single frozen-thawed D5 and D6 blastocysts transfer cycles

Y. Li, W. Zhao, X. Liang

The 6th Affiliated Hospital of Sun Yat-sen University, Reproductive Medicine Center, Guangzhou, China

Study question: Are there differences in the IVF outcomes of frozen-thawed blastocysts on different developmental stages?

Summary answer: D5 blastocysts transfer resulted in higher pregnancy rate and lower ectopic pregnancy rate than D6 blastocyst, while live brith rate and neonatal outcomes were similar.

What is known already: The IVF outcomes of D5 and D6 blastocyst transfers in different studies using frozen-thawed cycles were contradictory. Some studies reported higher clinical pregnancy rate and higher live birth rate in D5 blastocyst transfer cycles, while others observed no differences between the two groups. Furthermore, none of these studies have addressed IVF outcomes only from single blastocyst transfer cycles.

Study design, size, duration: In this retrospective study, the data recorded during June 2010 to July 2016 were extracted from the database of the Reproductive Center of Sixth Affiliated Hospital, Sun Yat-Sen University in China and in total, 3179 single frozen-thawed blastocyst transfer cycles were analyzed.

Participants/materials, setting, methods: In total, 2337 D5 and 842 D6 single frozen-thawed blastocyst transfer cycles were retrospectively analyzed. The demographic parameters and IVF outcomes including HCG (+) rate, pregnancy rate, first trimester abortion rate, birth rate, birth weight and gender proportion of the D5 and D6 blastocyst transfer cycles were compared.

Main results and the role of chance: The HCG positive rate, mean HCG level, biochemical pregnancy rate and clinical pregnancy in the D5 group were significantly higher than those in the D6 group (P < 0.001, < 0.001, = 0.016, and < 0.001, respectively). The ectopic pregnancy rate in the D5 group was lower than that in the D6 group(P = 0.03). The first trimester abortion rate (per HCG positive cycle), live birth rate (per embryo transfer), birth weight and gender proportion did not significantly differ between these two groups.

Limitations, reasons for caution: Although 3179 cycles were included in our study, it is still limited by the retrospective nature and lack of randomization.

Wider implications of the findings: This study is the first to analyze IVF outcomes of single blastocyst cryopreserved during different developmental stages. In the clinic, D6 blastocysts in frozen-thawed cycles had similar birth rate and neonatal outcomes to those of D5 blastocysts.

Trial registration number: None.

P-193   When to decide for single (SBT) or double blastocyst transfer (DBT): the embryologist's view

B. Wirleitner[1], P. Vanderzwalmen[2], M. Schuff[1], A. Stecher[1], M. Murtinger[1]

[1]IVF-Centers Prof. Zech, Bregenz, Bregenz, Austria
[2]CHIREC IVF center, Braine 'alleud, Brussels, Belgium

Study question: What are the birth rates (BR) and the baby-take-home rates (BTHR) per blastocyst transferred in SBT or DBT in regard to blastocyst quality?

Summary answer: To increase the chance of transferred blastocysts to implant and give a healthy baby, SBT should be performed with exception of low quality blastocysts.

What is known already: Implantation rates are known to be related to blastocyst quality evaluated by morphological criteria. To increase the chance for a pregnancy, DBT is commonly performed, especially after a previous unsuccessful cycle, drastically augmenting the risk for twin pregnancies. Multiple pregnancies are associated with a higher risk for preeclampsia, placental problems, perinatal morbidity, preterm birth and low birth weight. In order to maximize the chance of a blastocyst to implant and result in a healthy baby and to minimize the risk for twin pregnancies, we analyzed clinical outcome of SBT and DBT in relation to blastocyst grading.

Study design, size, duration: A retrospective cohort study was conducted including 992 SBT and 1.768 DBT between January 2010 and December 2014 in our center. SET or DET were performed on basis of patient history, availability of blastocysts and recommendation of the physician, but also substantially on the patients wish. Data were extracted using DynaMed® software, data analysis was performed using SPSS-Statistics Patients with lost-of follow-up for clinical outcome were excluded.

Participants/materials, setting, methods: Blastocyst quality was assessed prior BT according to the Gardner criteria. Top quality (top) included blastocysts with AA, BA or AB grading for inner cell mass and/or trophectoderm, good quality (good) blastocysts BB, BC or CB grading, and low quality (low) included either CC grading or early blastocysts with no expansion. DBT were grouped according to the transferred qualities (e.g. top + good quality). BT was only performed after good endometrial build-up.

Main results and the role of chance: BR significantly increases with DBT when 2 top blastocysts were transferred as compared to 1 top blastocyst (48.8% vs. 38.7%; p-value < 0.05). However, in all other quality groups, DBT did not significantly augment BR compared to SBT. Further, we found in all DBT transfer groups vs. SBT significantly reduced BTHR per transferred blastocysts. BTHR/blastocyst decreased from top blastocyst SBT (39.1%) to 31.0% in top+ top DBT, 27.3% in top+ good, and 22.4% in top+ low quality DBT (p-value < 0.001). With good quality blastocysts BTHR/blastocyst was 33.2% in SBT; 22.7% in good+ good DBT, and 18.2% in good+ low quality. BT (p-value < 0.001). Solely for low quality blastocysts similar BTHR/blastocyst in SBT and DBT were observed (SBT 10.6% vs. 9.7% DBT of 2 low quality blastocysts). Maternal age was considered in statistical analysis. When analysing twin rates, we found twinning rates of 1% in SBT with top, 1.6% with good and 0% in SBT with low quality blastocysts. For DBT, the twinning rates were 27.3% (top+ top); 25.8% (top+ good), 20.5% (top+ low) and 23.5% (for both, good+ good and good+ low). However, DBT of 2 low quality blastocysts showed significantly reduced twinning rates (7.7%) compared to the other groups.

Limitations, reasons for caution: The increase the robustness of our results they should be verified in a larger data set.

Wider implications of the findings: In DET with at least one top or good blastocyst a meager increase in BR but a significant reduction in BTHR/blastocyst was found indicating to reconsider the policy of DBT. Chances to conceive increase with SBT and subsequent cryo-cycles. DBT should be recommended for low quality blastocysts only.

Trial registration number: not applicable.

P-194   Time-lapse Systems for ART – a systematic review

S. Armstrong[1], P. Bhide[2], N. Arroll[3], L. Cree[4], V. Jordan[5], A. Pacey[6], C. Farquhar[5]

[1]University of Sheffield, Department of Oncology & Metabolism, Sheffield, United Kingdom
[2]Homerton University Hospital NHS Foundation Trust, Obstetrics and Gynaecology, London, United Kingdom
[3]NHS England, Analyst, London, United Kingdom
[4]University of Auckland, Obstetrics and Gynaecology, Auckland, United Kingdom
[5]University of Auckland, Obstetrics and Gynaecology, Auckland, New Zealand
[6]University of Sheffield, Oncology and Metabolism, Sheffield, United Kingdom

Study question: Do time-lapse systems (TLS) improve live birth rates (LBR) for couples undergoing assisted reproductive technology (ART)?

Summary answer: There is insufficient evidence of a difference in LBR for couples using TLS versus conventional incubation of embryos.

What is known already: TLS take digital images of embryos at frequent time intervals within an incubator. This allows embryologists to assess the quality of the embryos without removing them from the incubator and potentially select a 'better' embryo. TLS has been widely introduced into clinical practice accompanied by claims of improved clinical outcomes. There is often an additional charge to patients for using the technology. The Cochrane review published in 2015 included 3 randomised controlled trials (RCTs) of 994 couples, and concluded insufficient evidence of differences in LBR, miscarriage, stillbirth or clinical pregnancy between TLS and conventional incubation.

Study design, size, duration: This systematic review has been undertaken using Cochrane methodology. A comprehensive search of published and unpublished RCTs was undertaken. Two authors scanned the titles retrieved by the search and extracted data (SA and PB). Authors were contacted directly to obtain further unpublished data and clarify study methodology. Risk of bias was assessed using the Cochrane tool and GRADE was used to evaluate the overall quality of the body of evidence for the review outcomes.

Participants/materials, setting, methods: This systematic review includes 5 RCTs of 1757 couples. In order to assess the potential advantage of TLS, the studies were grouped into three designs:

Study design 1: TLS with conventional morphological assessment of still images versus conventional incubation and assessment

Study design 2: TLS utilizing a cell-tracking algorithm versus TLS with conventional morphological assessment of still images

Study design 3: TLS utilizing cell-tracking algorithm versus conventional incubation and assessment.

Main results and the role of chance: Considering all trial designs together, there is insufficient evidence to determine a difference in livebirth OR 1.24 (95% CI 1.0–1.54), miscarriage OR 0.9 (95% CI 0.64–1.26,), stillbirth and clinical pregnancy OR 1.17 (95% CI 0.96–1.42,) between TLS and conventional incubation. The evidence was graded very low evidence for all outcomes because of the high risk of selection, performance and attrition bias in 2 studies (Kovacs 2013 and Rubio 2014). There is also significant heterogeneity and indirectness owing to the inclusion of donor oocytes in Rubio 2014.

Considering the results by subgroup, study design 1 and 2 reveal insufficient evidence to determine a difference for all outcomes (moderate quality for trial design 1 and low quality evidence for trial design 2). However, trial design 3 (TLSs utilising cell-tracking algorithms versus conventional incubation and assessment) has an improvement in livebirth (OR 1.48 95%CI 1.15–1.90 very low quality evidence) and clinical pregnancy (OR 1.30 95%CI 1.02–1.67) with TLS. There was insufficient evidence of a difference for miscarriage within this subgroup (OR 0.70 95%CI 0.47–1.05). Both the studies in this analysis were at high risk of bias for selection, performance and attrition bias and have been graded very low quality evidence.

Limitations, reasons for caution: The studies included in analysis for study design 3 are at high risk of bias and represent very low quality evidence. The largest, (Rubio 2014), included women receiving donor oocytes, and livebirth data are only available in abstract form. Another concern was some women were allowed to choose the TLS.

Wider implications of the findings: The high risk of bias in the studies included in subgroup analysis of trial design 3, requires caution. Further robust, well designed, independent and appropriately powered trials should be added to this analysis before purporting improved outcomes with TLS and recommending it to couples as part of an IVF cycle.

Trial registration number: Prospero: CRD42015019962.

P-195　Can follicular fluid anti-Müllerian hormone level be a determinant for pregnancy in women under 35 years of age?

T. Yilmaz[1], S. Tavukcuoglu[2], S. Tasdemir[3], S. Esenkaya[3], T. Irez[4]

[1]Istanbul, Turkey,
[2]Ferti-jin IVF Center, IVF Laboratory, İSTANBUL, Turkey
[3]Ferti-jin IVF Center, Gynecologist- MD, İSTANBUL, Turkey
[4]Biruni University- Medical Faculty, - Department of Histology and Embryology, İSTANBUL, Turkey

Study question: Can follicular fluid anti-Müllerian hormone level be a determinant for pregnancy in women under 35 years of age?

Summary answer: The FF AMH levels were found to have a predictive effect on pregnancy in women under 35 years of age.

What is known already: Anti-Müllerian hormone, which is also known as Müllerian-inhibiting substance, is a main regulator in the follicle development (Richardson SJ et. al.,1987; Faddy MJ et. al., 1992). It is probably produced by preantral and smaller antral follicles independent of follicle-stimulating hormone (FSH) (Hansen KR et al.,2008; Klein NA et al., 1996). It has been shown to inhibit the follicle growth and selection, as well as growth from the primordial follicle to the primary follicle (Klein NA et al., 1996). Recently, many study groups have adopted AMH as a new marker for ovarian reserve and the indicator of the response to gonadotropins.

Study design, size, duration: The samples were collected from each of 61 patients with the age range of 21 to 42 years separately. The oocytes were isolated from FF, which did not contain irrigation solution, of the follicles reaching 15 mm in diameter with the help of sterile injectors. The remaining FF was centrifuged at 1800 rpm (300 g) for 15 min. Two milliliters from the supernatant parts were stored in liquid nitrogen tanks to be studied later on.

Participants/materials, setting, methods: The study was carried out at Fertijin In Vitro Fertilization Center between November 2014 and June 2015. and the FF AMH levels of a total of 61 patients (mean age: 33.72 ± 4.82 years; range: 21 to 42 years) were analyzed. The AMH levels of the collected samples were studied using an AMH kit with Roche Cobas e601 autoanalyzer (Roche Diagnostics, USA) using electrochemiluminescence immunoassay (ECLIA).

Main results and the role of chance: Four groups were formed according to the AMH levels of the FF: very low level group with 27.9% (FF AMH ≤ 1.0 ng/mL, n = 17), low level group with 41% (FF AMH = 1.0—2.1 ng/mL, n = 25), moderate level group with 15% (FF AMH = $2.1 < X < 3.6$ ng/ mL, n = 11), and high level group with 13.1% (FF AMH > 3.6 ng/mL, n = 8). There was no statistically significant difference in the rates of fertilization between the AMH groups (p > 0.05). The AMH levels were found to be correlated with oocyte count (p < 0.01), female age (p < 0.05), embryo quality (p < 0.01), and clinical pregnancy rates (p < 0.035). The mean age of the group with moderate AMH level was found to be higher, compared to the low level group (34.5 years) (p < 0.05). The FF AMH levels in patients under 35 years of age were higher in women who were pregnant than non-pregnant women (p < 0.01).

In addition, AMH levels of pregnancies in women under 35 years of age were statistically higher than those of pregnancies (p = 0.019, p < 0.05). However, there was no significant difference between AMH levels of women who were over 35 years of age according to pregnancy status (p > 0.05).

Limitations, reasons for caution: The FF samples taken from the follicles larger than 15 mm were included in the study. The metaphase II (MII) oocytes obtained from these follicles were fertilized by intracytoplasmic sperm injection. Following the developing embryos, one or two embryo transfers were performed by choosing the best-quality embryo morphologically.

Wider implications of the findings: Several studies have shown that the morphological studies are insufficient to determine the oocyte quality (Lasiene K et al.,2009; Klani S et al 2011). The failure of oocyte morphological assessments to predict in vitro fertilization (IVF) outcomes has led the researchers to examine biochemical criteria of follicular fluid (FF).

Trial registration number: not applicable.

P-196　When multinucleated embryos create high quality blastocysts they have a high implantation rate

J. Masso[1], C. Castello[1], A. Garcia-Faura[2], M. Lopez-Teijon[2]

[1]Institut marques, Reproductive laboratory service, Barcelona, Spain
[2]Institut marques, Reproductive medicine service, Barcelona, Spain

Study question: Should we transfer high quality blastocysts (HQB) that are created from multinucleated embryos (MnE)?

Summary answer: The implantation and live birth rates obtained following transfer of HQB created from MnE indicate that their transfer is recommended if there aren't non-MnE available.

What is known already: The presence of multinucleated blastomeres in the first divisions of an embryo is associated with poor implantation rates, low possibilities of creating a blastocyst, an increased rate of chromosomal abnormalities (Van Royen 2003; Munné 1995; Parriego 2013) and miscarriage (Scott 2007; Fauque 2013).

It would appear that many MnE have the capacity to self-correct and form euploid blastocysts which then give rise to healthy live births (Balakier, 2016).

The multinucleation rate is significantly higher in the embryos of women ≥40 years of age than in women ≤35 of age (Balakier, 2016).

Study design, size, duration: Between January 2014 and March 2016, 1607 MnE of > 2 cells were cultivated to day+5. 42.9% of these embryos reached the blastocyst stage and only 8.1% created HQB. In the same period, 70.9% of the non-MnE reached the blastocyst stage and 39.1% created HQB. The pregnancy rate, implantation, miscarriage and live birth rates were analysed following transfer of 78 multinucleated HQB with known implantation data.

Participants/materials, setting, methods: All the embryos came from patients'oocytes aged ≤35 years. Culture was in EmbryoscopeTM incubator with single culture medium (Life Global) to day+5. The number of nuclei per blastomere on day 2 and 3 was assessed, with multinucleation defined as more than 2 nuclei in at least 1 blastomere from the 3 cell stage onwards.

The Gardner (1999) score was used to ascertain good quality: expansion grade ≥3, internal cell mass ≥B and trophoectoderm ≥B.

Main results and the role of chance: 71 embryo transfers took place with a total of 78 MnE transferred, and an average of 1,1 embryo per transfer. The multinucleated HQB had a pregnancy rate of 47.8%, an implantation rate of 44.9%, and a miscarriage rate of 20.6%. The live birth rate was 33.8%.

The results refer to transfers of MnE with known implantation data.

Limitations, reasons for caution: If non-MnE were available, the MnE were not transferred. For this reason the number of cases analysed was low.

Wider implications of the findings: Blastocyst culture selects potentially viable embryos, allowing MnE to self-correct and then create healthy live births. Our results support this. We suggest that HQB created from the MnE of women ≤35 years of age should not be destroyed; if not transferred, they should be vitrified.

Trial registration number: Not applicable.

P-197   Retrospective comparative study between KIDScore Day 3 and KIDScore Day 5

C. Escriba[1], **F. Garcia-Piñon**[2], **M. Xenariou**[1], **A. Srikantharajah**[1], **R. Homburg**[1]

[1]Homerton University Hospital, Fertility, LONDON, United Kingdom
[2]Hospital provincial de Catellon, Biostatistics and Clinical trials unit, Castellon, Spain

Study question: Is KIDScore Day 5 better than KIDScore Day 3 to predict the implantation outcome of an embryo?

Summary answer: KIDScore Day 5 has shown significant capacity to predict the embryo implantation outcome compared with KIDScore Day 3, whose capacity of prediction is not significant

What is known already: KIDScore Day 3 is an algorithm given by the embryo kinetics until day 3 widely used to predict the implantation potential of an embryo during a controlled ovarian stimulation cycle for IVF/ICSI treatment.

The new algorithm KIDScore Day 5 uses the same kinetics parameters until day 3 and adds new ones until day 5. Also includes a morphology quality assessment of the embryo on day 5 performed by an embryologist. This additional information could improve the capacity of the algorithm to predict the implantation outcome of the embryo.

Study design, size, duration: This comparative retrospective study was conducted at a university fertility centre over a period of 28 months from June 2014 to October 2016. The study involved 168 embryos with known implantation outcome transferred on day 5 or day 6 to women under IVF/ICSI treatment.

Participants/materials, setting, methods: 168 embryos were cultured in an 'Embryoscope', a time-lapse incubator. Embryo quality was assessed using the manufacturer's algorithm based on morphokinetic parameters to generate the KIDScore. For each embryo a KIDScore Day 3 was obtained, followed by a KIDScore Day 5, with subsequent transfer on day 5 or 6.

Statistical analysis was performed using SPSS. Multivariate and univariate logistic regressions were performed to determine the predictive capacity. The study was completed with an ROC curve.

Main results and the role of chance: Firstly a multivariate logistic regression was done to compare the predictive capacity of each KIDScore. Possible interactions between both variables were excluded, ensuring their independence. For the KIDScore D5, a statistically significant difference was shown in our logistic regression model (p-valor = 0,003) showing a capacity 35% higher than KIDScore D3 to evaluate the implantation potential of the embryos.

Subsequently, the univariate analysis for KIDScore D3 noted a lack of significación (p-valor = 0,412) for the evaluation of our embryos, whereas a statistically significant difference was shown with KIDScore D5 (p valor = 0,002) with an odds ratio of 1,355.

These results were also confirmed by a pertinent comparative ROC curve between KIDScore D3 and KIDScore D5 for the implantation outcomes. In an ROC analysis AUC (Area Under Curve) has been statistically significant for KIDScore D5 (AUC = 0,669; p-value < 0,001) but not-significant for KIDScore D3 (AUC = 0,570; p-value = 0,140).

KIDScore D5 showed better statistical results compared with KIDScore D3 for the implantation outcome. Therefore, we can conclude that it can be used as a better predictive indicator for viability of the embryo in the IVF/ICSI treatments.

Limitations, reasons for caution: The retrospective nature of the study introduces the inherent limitation of selection bias.

Further studies are needed to assess current outcome indicators.

Wider implications of the findings: This could help to select the best embryo to transfer, with a high implantation potential.

Trial registration number: Not applicable.

P-198   Meta-analysis on the effect of blastocyst collapse for human embryo vitrification

H. Joris[1], **A.M. Nilselid**[2], **C. Silversand**[3]

[1]Vitrolife, Medium Development, Frolunda, Sweden
[2]Vitrolife Sweden AB, Medical Affairs, V Frölunda, Sweden
[3]Vitrolife Sweden AB, Research, V Frölunda, Sweden

Study question: It is currently unclear if a blastocyst collapse adds to the results of cryopreservation. Does a meta-analysis of existing literature support inclusion of this procedure?

Summary answer: A meta-analysis on predominantly retrospective studies shows improved rates on post-warming survival and clinical pregnancy when performing blastocyst collapse before vitrification.

What is known already: Overall, results from human blastocyst vitrification are good. During vitrification many embryos collapse spontaneously but not all. Induction of blastocyst collapse for vitrification is debated but used frequently.

When blastocysts do not collapse spontaneously during vitrification procedures, water in the blastocoel may not be replaced sufficiently by cryoprotectants. This possibly results in increased risks for ice formation, increasing the risk of cell damage and suboptimal survival.

Study design, size, duration: A literature search was performed using Medline to identify articles published before January 1, 2017 involving a comparison with or without induced blastocyst collapse on human blastocysts before vitrification. Articles meeting these criteria were assessed and studies including data on morphological survival and clinical pregnancy were considered eligible for inclusion.

Participants/materials, setting, methods: Studies including a comparison of vitrification with or without induced blastocyst collapse including results on morphological survival and clinical pregnancy were identified. The outcomes from vitrification with or without collapse were summarized and compared in a meta-analysis with results presented as relative risk (RR) applying the random effect model. Categorical variables were presented as percentages and compared using a 2×2 Chi-square test. The analyses were performed using MedCalc® 17.0.4 with p-values < 0.05 considered statistically significant.

Main results and the role of chance: Six articles were identified comparing the effect of vitrification with or without blastocyst collapse including results on survival and pregnancy rates. Only 1 of the 6 publications was a prospective

randomised controlled trial (RCT). The meta-analysis involved 2761 and 1654 blastocysts with or without collapse respectively for the comparison of morphological survival and pregnancy was assessed on 1711 and 761 cases respectively. Survival rates were 97.4 % and 87.1 % (p < 0.0001) with or without collapse respectively (RR 1.143; CI 1.016–1.285; p = 0.027) and pregnancy rates were 50.0 % and 30.5 % (p < 0.0001) (RR 1.549; CI 1.273–1.884; p = 0.001) for the same groups. The prospective RCT observed a difference in survival favouring blastocyst collapse (p = 0.007) but did not show the anticipated increase in pregnancy rates, as obtained from their power calculation (P > 0.05).

Limitations, reasons for caution: It seems unlikely that post-warming survival from induced blastocyst collapse itself is affected by a retrospective analysis but other parameters, not controlled for in such an analysis can have an impact. Results on pregnancy outcome have to be taken with caution and should be controlled further in prospective RCTs.

Wider implications of the findings: Not all clinics obtain satisfactory success rates from blastocyst vitrification. Blastocyst collapse before vitrification seems to improve post-warming survival rates and can be considered when optimizing laboratory procedures. Increased post-warming survival may positively affect overall efficiency of an IVF treatment cycle, but this requires further confirmation from large prospective studies.

Trial registration number: not applicable.

P-199   Clinical outcomes of oocytes matured from Metaphase I to Metaphase II on the day of the egg retrieval in ICSI cycles

T. Kawamura[1], S. Katase[1], H. Koi[2], T. Yorimitsu[1], M. Ohara[2], H. Sasaki[1], M. Hasui[1], A. Arichi[1], H. Muramatsu[2], N. Omura[1], K. Itou[2], H. Komine[1], Y. Kudo[1], Y. Shimizu[1]

[1]Denentoshi Ladies' Clinic, OB/GYN, Yokohama, Japan
[2]Denentoshi Ladies' Clinic Futakotamagawa, OB/GYN, Tokyo, Japan

Study question: To investigate the clinical outcomes of oocytes matured from Metaphase I (M I) to Metaphase II (M II) on the day of the egg retrieval in ICSI cycles.

Summary answer: Clinical pregnancy rates were not different between oocytes matured from MI to MII on the day of the egg retrieval and M II oocytes.

What is known already: In vitro maturation of MI oocytes for a short period of time may increase the number of available embryos, however, overnight in vitro culture of MI oocytes did not improve results.

Study design, size, duration: This was a retrospective study at a reproductive center. To evaluate the clinical outcomes between MI→MII and M II.

   5,976 cycles of 3641 couples
   from January, 2010 to December, 2015

Participants/materials, setting, methods: ICSI was performed to MI→MII oocytes and M II oocytes.Day3 good embryo rates, Day5 good blastocyst rates, clinical pregnancy rates, live birth rates and miscarriage rates were compared between two groups.Day3 good embryos included 7–10 cells with grade 1 or 2 by Veeck's criteria. Day5 good blastocyst included better than 3BB by Gardner's criteria.

Main results and the role of chance: The fertility rates were greater in MII group (82.3%: 11958/14531) than MI → MII group (52.0%:183/352) (p < 0.05). Day3 good embryo rates were greater in MII group (63.0%: 7457/11845) than MI → MII group (47.0%: 86/183) (p < 0.05). Day5 good blastocyst rates were greater in MII group (43.0%: 4816/11197) than MI → MII group (22.5%: 38/169) (p < 0.05). Clinical pregnancy rates were 39.0% (2244/5755) in MII group, and 30.3% (10/33) in MI → MII group (n.s). Live birth rates were 23.2% (1338/5755) in MII group, and 27.3% (9/33) in MI → MII group (n.s). Miscarriage rates were 28.2% (633/2244) in MII group, and 10.0% (1/10) in MI → MII group (n.s).

Limitations, reasons for caution: Confirmation of our preliminary data on a large population should be required.

Wider implications of the findings: Although fertility rates, Day3 good embryo rates and Day5 good blastocyst rates were significantly low in MI → MII group, clinical pregnancy rates and miscarriage rates were not different between two groups. Therefore, it was worth transferring blastocysts from MI → MII oocytes, if they developed to good ranked blastocysts.

Trial registration number: Not applicable.

P-200   Subsequent (day 3 and day 5) vitrification/warming does not adversely affect the clinical outcome: A retrospective cohort analysis of 556 cases

M. Kavrut[1], M. Gultomruk[2], N. Findikli[3], T. Aksoy[3], A.P. Cil[1], G. Karlikaya[1], K. Boynukalin[1], R. Abali[1], C. Celik[4], M. Bahceci[1]

[1]Bahceci Fulya IVF Center, Infertility Clinic, Istanbul, Turkey
[2]Bahceci Fulya IVF Center, R&D Laboratory, Istanbul, Turkey
[3]Bahceci Fulya IVF Center, Embryology Laboratory, Istanbul, Turkey
[4]Bahceci Umut IVF Center, Infertility Clinic, Istanbul, Turkey

Study question: This study is performed to evaluate the clinical **outcome** of re-vitrification of surplus blastocysts developed from frozen cleaved embrios and transfer at the blastocyst stage

Summary answer: Refreezing surplus blastocysts developed from vitrified/ warmed cleavage-stage embryos does not adversely affect the clinical outcome comparing with once-frozen surplus blastocysts transfers in good responder patients.

What is known already: Many IVF clinics lead to use cryopreservation increasingly due to high survival and pregnancy rates after transfer of vitrified embryos. Embryos can be cryopreserved successfully at cleavage or blastocyst stage. There is a tendency to transfer embryos at the blastocyst-stage independently of cryopreservation stage of embryos especially in good responder patients. In many cases surplus embryos are available for re-freezing after transfer. Several studies have already shown good results with frozen embryo transfer cycles in comparison with fresh embryo transfers. However there is little data on re-cryopreservation of human blastocyst developed from vitrified/ warmed cleavage-stage embryos.

Study design, size, duration: This retrospective cohort study includes 556 antagonist cycles performed between January 2013 and December 2016 in Bahceci Fulya IVF Centre. Good responder female patients with ≤38 years of age and male partners with normo-oligospermia were enrolled into the study. Exclusion criteria included poor response to controlled ovarian hyper stimulation, repeated implantation failure (≥3 IVF failure), pooling embryos ((≥2 oocyte pick-up cycles without embryo transfer), embryo biopsy for PGD and using testis sperm for ICSI.

Participants/materials, setting, methods: Cycles included in the study were grouped into three: Group I consisted of cycles in which transferred embryos were re-vitrified surplus blastocysts developed from frozen cleaved embryos; Group II included cycles in which surplus embryos were cryopreserved & warmed on day 5/ transferred on day 5; and Group III consisted of cycles in which embryos were transferred on day 5 as fresh, without any prior cryopreservation. Every patient involved in the study only once.

Main results and the role of chance: The differences in clinical outcome among three study groups were compared. Patient characteristics such as age, BMI and sperm parameters were comparable among groups (p > 0.05). There were no statistical significant differences among biochemical (BPR), clinical (CPR) and ongoing pregnancy rates in all groups (p > 0.05). BPR were similar in Group I (68.2%), Group II (66.5%) and Group III (59.5%) respectively (p = 0.176). Similar CPR were observed between Group I (62.9%), Group II (60.0%) and Group III (53.2%) respectively (p = 0.151). OPR were not significantly different in Group I (51.7%), Group II (48.0%) and Group III (41.0) respectively (p = 0.116). There were no statistical significant differences among biochemical abortion rates in all groups (16.5 %, 18.0% and 20.5% respectively; P = 0,849). Clinical abortion rates also were not significantly different in Group I (7.8%), Group II (9.8%) and Group III (10.7%).

Limitations, reasons for caution: The main limitation of our study was its retrospective nature, since numerous confounding factors that can affect the ART outcome may be overlooked. Also, cumulative pregnancy rates of cycles included in the study have not been taken into account in this analysis.

Wider implications of the findings: Our study indicates that subsequent (day 3 and day 5) vitrification/warming does not adversely affect the clinical outcome. Repeated cryopreservation can be done successfully by vitrification. However, well-designed additional studies with large sample sizes will be needed to draw a firm conclusion on the efficiency and impact of re-cryopreservation.

Trial registration number: None.

P-201 The higher incidence of cleavage failure in oocytes with smooth endoplasmic reticulum clusters (sERC) than in oocytes without sERC in sERC positive cycles

J. Otsuki, T. Iwasaki, Y. Tsuji, Y. Katada, H. Sato, Y. Tsutsumi, K. Hatano, K. Furuhashi, Y. Matsumoto, S. Kokeguchi, M. Shiotani

Hanabusa Women's Clinic, Reproductive Medicine, Kobe- Hyogo, Japan

Study question: Are there any abnormal patterns of embryo development in oocytes with smooth endoplasmic reticulum clusters (sERC)?

Summary answer: Yes. A higher incidence of cleavage failure was seen in oocytes with sERC than in their cohort oocytes without sERC.

What is known already: In human embryos, several abnormal cleavage patterns, such as direct cleavage and reverse cleavage, can be observed during embryo development by means of time-lapse systems. sERC is one of the dysmorphic phenotypes which appears in human oocytes. Significantly reduced pregnancy rates and a comparatively higher number of abnormities in live-birth babies derived from sERC+ oocytes and / or sERC+ cycles have been reported. However, the opposite results have also been reported: showing that healthy babies, derived from sERC+ oocytes, can be born, without any reduced pregnancy rates. Thus, the clinical and scientific impact of sERC+ oocytes remains controversial.

Study design, size, duration: This was a retrospective observational cohort study, involving a total of 361 oocytes, obtained from 68 sERC+ cycles, which had at least one sERC+ oocyte among the retrieved oocytes, observed between January 2011 and December 2016. Unfertilized oocytes and embryos which were not captured by time-lapse observation up to day 4 were excluded from this study.

Participants/materials, setting, methods: Time lapse images were captured automatically every 15 mins, at 7 focal planes using an EmbryoScope®Time-lapse system (Vitrolife, Tokyo, Japan). Any changes in the configuration of the embryos observed by time lapse system were retrospectively analyzed. Statistical analyses were carried out to explore the nature of problems in embryos derived from sERC+ oocytes.

Main results and the role of chance: By careful observation, we have found that reverse cleavage has two different patterns. In one pattern, a cell cleaves into a number of cells greater than three cells. Then the cleaved cells reverse to a normal count of 2 cells or a reduced number of cells from the greatest number of cleaved cells. In the other pattern, a cell cleaves into 2 cells or more, but shortly after, the cleavage reverses to a single cell. The first pattern is considered to be reverse cleavage with completion of mitosis. On the other hand, the latter pattern is considered to be cleavage failure. This includes cells which have had an initiation of cleavage, but failed to cleave completely. In this study, we found that the incidence of mitotic cleavage failure in oocytes with sERC was 31.5% (29/92), which was significantly higher than that of 8.6% (24/279) in oocytes without sERC (p < 0.0001). Furthermore, the incidence of meiotic cleavage failure during the second polar body extrusion in oocytes with sERC was 9.8% (9/92), which was significantly higher than that of 2.5% (7/279) in oocytes without sERC (p = 0.0073).

Limitations, reasons for caution: Detecting cleavage failure is only possible up to and including the third mitosis due to the difficulty of detection during the fourth mitosis. The study of the incidence of cleavage failure among embryos in sERC negative cycles is under investigation following this study.

Wider implications of the findings: In the case of cleavage failure, a cell can theoretically be tetraploid and may cause abnormal chromosomal configurations. Even if cells with cleavage failure become trophectoderm cells, the embryo can be susceptible to further cleavage failure. For this reason, it is necessary to follow up babies derived from sERC+ oocytes.

Trial registration number: Not applicable.

P-202 Instability of osmotic pressure in microdrops cultured in non-humidified incubators

K. Yumoto, M. Sugishima, K. Iwata, J. Yamauchi, S. Miyazaki, M. Nakaoka, M. Tsuneto, Y. Mio

Mio Fertility Clinic, Reproductive Centre, Yonago, Japan

Study question: Is the osmotic pressure of culture media stable when using a non-humidified incubator?

Summary answer: The osmotic pressure of microdrops covered with mineral oil was stable in humidified incubators, however, it increased significantly in non-humidified incubators on a daily basis.

What is known already: Humidified incubators are widely used for culturing human embryos. However, recently, non-humidified benchtop incubators have also been used due to their smaller size and lower risk of fungal contamination. Mineral oil is typically used to cover microdrops of culture medium in dishes so as to prevent changes in the osmotic pressure, pH, and temperature of the medium. Although the stability of pH and temperature in microdrops in non-humidified incubators has been verified, it is unclear whether osmotic pressure remains stable. In this study, we measured the osmotic pressure of different-sized microdrops in humidified and non-humidified incubators.

Study design, size, duration: Basic clinical study.

Participants/materials, setting, methods: We compared three incubators: (i) humidified benchtop, (ii) non-humidified benchtop, and (iii) humidified water jacket. Microdrops (50-μl, 100-μl, 200-μl) of a single step medium (A) (standard value, 265 ± 10 mOsm/kg) or a sequential medium (B) (standard value, 290 ± 10 mOsm/kg) were prepared in 35-mm culture dishes and then covered with mineral oil (Naka Medical Co. Japan). After one and two days' incubation, osmotic pressure was measured using an osmometer (Fiske 210®).

Main results and the role of chance: In the humidified benchtop and water jacket incubators, there were slight but non-significant increases in osmotic pressure of up to 4 mOsm/kg over 1 day in both media, regardless of microdrop volume. In contrast, there were significant increases in osmotic pressure in the non-humidified benchtop incubator. In 200-μl drops of medium A, the osmotic pressure increased from 267 to 274 ± 0.4 mOsm/kg after 2 days, while in medium B, it increased from 289 to 299 ± 0.5 mOsm/kg after 2 days. The increase in osmotic pressure of the 50-μl drops was more than in the 100-μl and 200-μl drops. In medium A, 50-μl drops increased from 267 to 283 ± 0.9 mOsm/kg after 2 days, while in medium B, the 50-μl drops increased from 289 to 310 ± 0.8 mOsm/kg after 2 days. In the 50-μl microdrops, the increases in osmotic pressure in the non-humidified benchtop incubator were significantly greater than in the humidified incubators (P < 0.01).

Limitations, reasons for caution: In this study, biological data was not collected, e.g. survival rate or growth rate of the embryos under each condition. However, it is generally obvious that large increases in osmotic pressure would be harmful to embryos.

Wider implications of the findings: Since different incubators and culture media may be used in different clinics, careful selection of the appropriate conditions for human embryos is very important for successful treatment at each clinic. Furthermore, it is necessary to describe the details of the culture environment in all publications to compare the data adequately.

Trial registration number: Not applicable.

P-203 Low lactate culture medium improves the development of human preimplantation embryos in vitro

E. White[1], T. Popoff[2], H.T. Ni[1]

[1]*Irvine Scientific, Research and Development, Santa Ana, U.S.A.*
[2]*Irvine Scientific, Sales and Marketing, Santa Ana, U.S.A.*

Study question: Does low lactate culture condition benefit human embryo development in vitro?

Summary answer: Continuous culture using low lactate medium improves in vitro human embryo development over higher lactate concentrations.

What is known already: Mammalian cleavage stage preimplantation embryos characteristically metabolize primarily pyruvate. Glucose consumption is low during the cleavage stage, and increases throughout compaction until becoming the blastocyst's primary metabolite. Lactate and pyruvate concentrations play critical roles in regulating pyruvate and glucose metabolism at different stages during embryo development. The lower concentration of lactate has been suggested to be beneficial for early stage of embryo development. Several groups including our own have demonstrated low lactate culture improved in vitro embryo development in mouse or bovine studies.

Study design, size, duration: A prospective split-case trial of media with low lactate or six times higher lactate was conducted using sibling-oocytes from total of 107 patients ages 23 to 40 at three different clinics. Embryos were

cultured continuously in microdops overlaid with light mineral oil to blastocysts without media refreshment. Blastocyst development rates and transfer rates were determined after five days of culture. Pregnancy and ongoing pregnancy were monitored after transfer.

Participants/materials, setting, methods: Superovulation, oocyte collection and fertilization by conventional in vitro fertilization or intracytoplasmic sperm injection, embryos culture, freeze, and transfer to recipients were performed per the protocols of each clinic approved under IRB. 2PN zygotes from each patient were randomly allocated into media with low lactate or high concentrations of lactate and cultured under oil. Clinics reported blastocyst rates and transfer rates. Pregnancy and ongoing pregnancy rates were determined by blood test and ultrasound, respectively.

Main results and the role of chance: The blastocyst rate was normalized to the control for each patient at all three clinics collectively, where the high lactate control medium was set to 100%. The low lactate medium normalized average blastocyst rate was 120% over the high lactate control medium. Of all transfers made, 60% were from embryos cultured in the low lactate medium compared with 40% from the high lactate control medium. Of all the pregnancies, 60% were from embryos cultured in the low lactate medium compared with 40% from the high lactate control medium. Of all the ongoing pregnancies, 55% were from embryos cultured in the low lactate medium compared with 45% from the high lactate control medium.

Limitations, reasons for caution: These results suggest that culture media with lower lactate can benefit in vitro human embryo development. Additional studies are required to determine if the low lactate benefit is statistically significant.

Wider implications of the findings: The observed improvement from low lactate medium helps in the exploration and demonstration of how embryo culture media can be optimized to provide an ideal metabolic environment that is more suitable for human embryo development in vitro.

Trial registration number: IRB ID # 5454.

P-204   Clinical application of day 4 embryo biopsy for preimplantation genetic screening and diagnosis (PGS and PGD). A retrospective analysis of our current practice

G. Liperis[1], J. Crittenden[1], M. Thymi[1], A. Hellani[2], C. Sjoblom[1]

[1]Institute of Reproductive Medicine- University of Sydney, Westmead Fertility Centre, Sydney, Australia
[2]Viafet, Genomics Centre, Sydney, Australia

Study question: To evaluate the efficacy and outcome of day 4 embryo biopsy.

Summary answer: Embryo developmental potential, pregnancy result and overall cycle outcome suggest that day 4 biopsy can be an alternative stage at which to perform embryo biopsy.

What is known already: Embryo biopsy routinely takes place on day 3 (cleavage stage) or day 5-6 (blastocyst stage); with the latter preferred due to the ability of biopsying more cells, providing increased genetic material for analysis. A limitation of blastocyst biopsy is that several embryos capable of generating a pregnancy may not be biopsied if they fail to reach the blastocyst stage. In two recent studies, embryos biopsied on day 4 have shown no significant difference in embryo development and pregnancy rates compared to embryos that were not biopsied.

Study design, size, duration: A retrospective analysis was undertaken of patients having day 4 embryo biopsy for PGS and/or PGD at Westmead Fertility Centre between February 2014 and December 2017. The cause of PGS included implantation failure, history of recurrent miscarriages and advanced maternal age, whilst PGD was employed for specific gene defects. Average patient age was 37.3 years. A total of 104 PGS and/or PGD cycles were undertaken and 1214 day 4 embryos were biopsied.

Participants/materials, setting, methods: Participants were consented patients undergoing IVF/ICSI cycles combined with PGS and/or PGD. Following fertilisation, fresh or frozen-thawed embryos, cryo-preserved at the 2PN stage for banking purposes, were cultured to day 4. On day 4, all embryos suitable for biopsy were decompacted using Ca/Mg free medium and 2–6 cells

were removed for analysis. The genetic analysis was performed on the same day and euploid/non affected embryo(s) were transferred on day 5.

Main results and the role of chance: Of the 1214 biopsied embryos, a total of 864 (71.1%) were at the compaction stage on day 4 with 653 (53.8%) reaching the blastocyst stage by day 5. Following the biopsy, 137 (11.3%) embryos had no amplification of their genetic material, with amplification failure correlated to poor embryo quality. A total of 297 out of the 1214 biopsied embryos (24.5%) had no abnormalities detected following PGS and/or PGD. From those, 102 (34.3%) were transferred on day 5, 138 (46.5%) were vitrified on day 5 and 57 (19.2%) were discarded due to poor quality. Out of the 240 embryos that were utilised, 117 (48.8%) were not expanded blastocysts at day 5 and would not have been biopsied if we were employing a blastocyst biopsy approach. From the 104 patients, 94 had at least one embryo with no abnormalities detected and an average of 1.1 embryos was transferred each time either on day 5 or in subsequent frozen cycles. A total of 61 pregnancies were recorded from 116 embryo transfers (52.6%) with 55 (47.4%) resulting in foetal heart at the 7 week scan. So far 19 live births have been reported with no malformations recorded and within the normal birthweight range.

Limitations, reasons for caution: The results represent the experience gained from current practice at Westmead Fertility Centre and not of a prospective controlled study. No embryos were cultured to day 6, therefore the developmental potential of certain embryos classified as not expanded blastocysts at day 5 of embryo development is unknown.

Wider implications of the findings: Day 4 embryo biopsy provides screening results in a timely fashion, allowing for a day 5 transfer within the same treatment cycle. The combination of this option with embryo developmental potential and pregnancy outcomes, provides an alternative approach to current embryo biopsy practices.

Trial registration number: N/A.

P-205   Morphokinetics in the early cleavage stage predicts formation and quality of the blastocyst stage

H.J. Kim[1], H.J. Yoon[1], W.D. Lee[2], S.H. Yoon[3], D.H. Lee[4], Y.J. Kang[5], J.H. Lim[3]

[1]Maria Fertility Hospital, Research Center, Seoul, Korea- South
[2]Maria Fertility Hospital, Ob/Gyn, Seoul, Korea- South
[3]Maria Medical Foundation, Research Center, Seoul, Korea- South
[4]Maria Fertility Hospital, Ob/Gyn, Daejeon, Korea- South
[5]Maria Fertility Hospital, Ob/Gyn, Pyungchon, Korea- South

Study question: The aim of our study was to compare whether the morphokinetic data obtained until day 2 could predict the formation and quality of the blastocyst.

Summary answer: The morphokinetic parameters of day 2 embryos are sufficient to predict both blastocyst formation and quality.

What is known already: It has been reported that significant differences in cleavage patterns and morphokinetic parameters between embryos that reached the blastocyst stage and those which arrested their development before the blastocyst stage or which lead to a poor quality blastocyst. Embryos cleaving earlier have a significantly higher chance of achieving optimal blastocyst stage (Meseguer et al, 2011). The blastocyst formation was found to correlate with cc2 (time between division to 2 cells and division to 3 cells), s2 (time between division to 3 cells and subsequent division to 4 cells) and with the duration of the first cytokinesis (Wong, 2010).

Study design, size, duration: This retrospective study performed on 524 patients between August 2013 and September 2016. Embryos were cultured in time-lapse incubator (EmbryoScope[TM]) and blastocysts were scored according to Gardner's classification.

Participants/materials, setting, methods: This study was performed in 586 cycles (n = 4808) that had undergone ICSI treatment in an unselected population. All embryos were cultured after ICSI insemination and assessed in EmbryoScope[TM] until day 6 and annotated for the pattern time of cleavage. Statistical analysis was performed with SPSS ver. 12.0 (SPSS Inc., Chicago, IL, USA). Student's t-test was used for statistical analyses. Average hour ± SD from ICSI insemination are reported for all stages.

Main results and the role of chance: We analyzed 8 parameters and abnormal cleavage events correlated with subsequent blastocyst formation and quality. The mean timings of the tPB2, tPNa, tPNf, t2, t3, and t4 for the embryos those developed into blastocysts were statistically significantly faster than the arrested embryos (respectively; P < 0.001). Moreover, the cell cycle of cc2 and synchrony of the cell cycle of s2 were also significantly different (respectively; P < 0.001). We compared abnormal cleavage events in embryonic development. There was no difference in the rate of multinucleation at the 2-cell stage (46.1% vs. 49.0%, P = 0.092). However, the uneven blastomere size at the 2-cell stage (15.2% vs. 34.2%, P < 0.001) and the direct cleavage from 1 to 3-cell (16.5% vs. 40.0%, P < 0.001) showed statistically significantly lower rates. We also examined whether the kinetic parameters of early embryos affect the quality of blastocyst. This study showed that cc2, s2 and t2 have the greatest effect on the blastocysts quality (respectively; P < 0.001). The quality of the blastocysts was also significantly affected by abnormal cleavage events.

Limitations, reasons for caution: The study was monocentric and retrospective.

Wider implications of the findings: This study is the first observation of a total analysis about the formation and quality of blastocysts using kinetic parameters and abnormal cleavage events collected until day 2. In particular, abnormal cleavage events have a considerable effect on the formation and quality of blastocysts.

Trial registration number: We don't need to trial registration number.

P-206 Are there any morphokinetic difference between euploid embryos those resulted with live birth and miscarriage?

I.O. Olcay[1], T. Aksoy[1], F.K. Boynukalin[2], M. Gultomruk[3], N. Findikli[1], M. Bahceci[2]

[1]Bahceci Fulya IVF Center, Embryology Laboratory, istanbul, Turkey
[2]Bahceci Fulya IVF Center, Reproductive Endocrinology, istanbul, Turkey
[3]Bahceci Health Group, Research and Development, istanbul, Turkey

Study question: What are the morphokinetic factors affecting the miscarriage after euploid embryo transfer?

Summary answer: The T2, blastulation and hatching time of the embryos those resulted with live birth and miscarriage were different.

What is known already: Time-lapse monitoring of embryo development may represent a superior way to culture the embryos and it seems to be a new tool for selecting the embryos within the highest implantation potential. The morphokinetic behavior of the euploid and aneuploid embryos seems to be different.

Study design, size, duration: This retrospective analysis compiled 263 controlled ovarian stimulation(COH) cycles of 247 patients with a blastocyst biopsy in which comprehensive genomic hybridization(CGH) was performed and embryos were monitored with time-lapse technology, from January 2014 to November 2015. Clinical indications for CCS based trophectoderm biopsy were advanced maternal age and reccurent implantation failure. Only euploid embryos resulted with clinical pregnancy were enrolled in the study.

Participants/materials, setting, methods: All patients underwent COH with the GnRH antagonist and recombinant FSH or hMG. Endometrial preparation was done by artificial hormone replacement treatment for ET. Single euploid embryos were transferred in frozen ET cycles.

Main results and the role of chance: The 135 embryos resulted with clinical pregnancy was analysed. Of these 99 embryos transferred were resulted with live birth and 36 embryos were resulted with miscarriage. There were no statistical differences between live birth group and miscarriage group regarding age (31,1 ± 3,6 and 30,4 ± 2,3 years, respectively), female BMI (22,6 ± 3,9 kg/m[2] and 22,9 ± 4 kg/m[2] respectively), antral follicle count (12,6 ± 6,3 and 13,3 ± 5,9 respectively), previous IVF attempt (2,8 ± 1,7 and 3,2 ± 3,1 respectively), day of stimulation (9.5 ± 0.73 and 9.7 ± 0.65 days, respectively), peak E2 (1919 ± 1172 and 2132 ± 1140 pg/ml, respectively), and peak P4 (0.88 ± 0.53 and 0.92 ± 0.49 ng/ml, respectively). The two groups also were similar in the number of oocyte retrieved, and the number of injected MII oocytes. Only T2 time was statistically different between two groups (25,4 ± 2,6 and 23,4–33,2 hours respectively) No difference was found in the synchrony parameters. Blastulation and hatching time of the embryos were different between two groups (92,8 ± 8,1; 101,4 ± 8,6 and 112,8 ± 5,4; 106,8 ± 7,6 respectively p: < 0,001 and p: 0,003).

Limitations, reasons for caution: The study is limited by its retrospective nature. A higher sample size or a prospective design could be used in future studies to corroborate the current findings.

Wider implications of the findings: Our results suggest that morphokinetic parameters have difference in euploid embryos within live birth and miscarriage.

Trial registration number: None.

P-207 Poor quality embryos may interfere with implantation when transferred together with good quality embryos

J.H. Eum[1], T.H. Kim[1], J.K. Park[1], W.Y. Choi[1], E.M. Chang[2], I.P. Kwak[2], D.R. Lee[3], J.J. Ko[3], W.S. Lee[2]

[1]CHA Gangnam Medical Center, IVF and Research Lab of Fertility, Seoul, Korea-South
[2]CHA Gangnam Medical Center, Fertility Center, Seoul, Korea- South
[3]CHA University, Biomedical Science, Seoul, Korea- South

Study question: Do poor quality embryos impede implantation when transferred together with good quality embryos?

Summary answer: It seems to be that embryo of poor quality can disrupt implantation of the embryos of good quality in human.

What is known already: Interactions between the competent embryo and maternal endometrium are essential for successful implantation of embyos. In human co-culture model, it was reported that human endometrial stromal cells are biosensors of embryo quality upon differentiation into decidual cells. However, it was not known whether poor quality embryos transferred with good quality embryos interfere with implantation of good quality embryos.

Study design, size, duration: This study was performed from January 2014 to December in our fertility center. In this study, we analyzed the clinical outcomes of 649 cycles transferring 1 or 2 vitrified-warmed blastocyst. The quality of blastocyst was classified into good or poor depending on the cell number of inner cell mass and trophectoderm.

Participants/materials, setting, methods: Cryopreservation was performed using vitrification protocols at blastocyst stage on day 5 of 6 after oocyte retrieval. The day before transfer, warmed blastocysts were cultured in blastocyst medium. One or two blastocysts were transferred using ultrasound-guide. Clinical pregnancy and implantation outcomes were compared between those groups.

Main results and the role of chance: The clinical pregnancy rate of double good blastocysts group was significantly higher than that of mixed quality blastocysts group (64.4% vs. 51.7%, p = 0.004); however, there was no significant difference between mixed quality group and single good quality group (51.7% vs. 56.6%, p = 0.37). Implantation rate of mixed quality group was significantly lower than double good quality group (36.7% vs. 46.4%, p = 0.002) and single good quality group (36.7% vs. 58.1%, p < 0.001). This result shows that the poor embryo may interfere with the implantation of the good embryo.

Limitations, reasons for caution: It was reported that endometrium cells in patients experienced recurrent loss fail to distinguish poor embryos. Therefore, it is necessary to confirm the clinical result according to the indication.

Wider implications of the findings: Our study showed that poor quality embryos could interfere with implantation of good quality embryos. Therefore, when only one good quality embryo and the other poor quality embryos were present, transfer of only one good quality embryo seems to be effective in prevention of multiple pregnancy and clinical outcome.

Trial registration number: NA.

P-208 The impact of blastocyst development stage at the time of embryo transfer (ET) on serum human chorionic gonadotropin (HCG) level

W. Zhu[1], J. Huang[2], Q.S. Yeung[2], D.Y. Chan[2], C. Ling[2], T.C. Li[2]

[1]Department of Obstetrics and Gynaecology- Prince of Wales Hospital, Obstetrics and Gynaecology, NT, Hong Kong
[2]The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Does the development stage of the blastocyst on ET day affect the serum human chorionic gonadotropin (HCG) level 9 days later?

Summary answer: Faster growing embryos produced higher serum HCG level.

What is known already: HCG is secreted by the trophectoderm (TE) of the embryo. Following ET, serum HCG level in women who conceive is affected by a number of factors. Several studies suggested that the HCG levels in frozen ET cycles were higher than that in fresh ET cycles. The HCG levels after the transfer of day-3 or day-5 embryo were similar. It is not known if the transfer of faster growing embryos produces higher serum HCG level than that of slower growing embryos.

Study design, size, duration: The retrospective study involved 283 cycles after single blastocyst transfer in a teaching hospital IVF clinic from January 2015 to July 2016.

Participants/materials, setting, methods: Women who conceived after IVF following the transfer of a single blastocyst were included. The blastocyst was divided into four different stages of development: cavitating, full blastocyst, expanded blastocyst and hatching blastocyst. As part of routine clinical practice, a blood sample was obtained 9 days after blastocyst transfer for HCG measurement to verify if pregnancy has occurred.

Main results and the role of chance: Overall, the median serum hCG level 9 days after a single blastocyst transfer in women who conceived a singleton ongoing intrauterine pregnancy was 177.2 IU/L. The corresponding median HCG levels in the 4 subgroups were: I, cavitating: 98.0 IU/L; II, full blastocyst: 159.0 IU/L; III, expanded blastocyst: 182.5 IU/L; and IV, hatching blastocyst: 201.1 IU/L. There was a significant trend towards higher hCG levels as the stage of blastocyst development on the day of ET become more advanced. The HCG level in subgroup I was significantly ($p < 0.05$) lower than that of group IV, but not significantly different from groups II or III. To conclude, faster growing embryos appeared to produce higher hCG levels 9 days after transfer.

Limitations, reasons for caution: This is a retrospective study; the findings should be considered preliminary pending confirmation from a properly powered prospective study.

Wider implications of the findings: Our data showed that, among embryos that successfully implanted, faster growing ones appeared to be associated with higher hCG levels 9 days after the transfer.

Trial registration number: not required, as the data were collected as part of routine clinical practice.

P-209   Faster and more accurate improved rescue ICSI by using polarization microscope (PLM) and differential contrast microscope (DCM)

M. Nagayoshi, A. Tanaka, T. Yamaguchi, T. Ichiyama, M. Ohno

Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan

Study question: Is faster and more accurate improved rescue ICSI by observing changing size and position of chromosome and spindle using polarization microscope (PLM) and differential contrast microscope (DCM) possible?

Summary answer: The early and accurate identification of fertilization with DCM and PLM is beneficial for rescue unfertilized oocytes following conventional IVF.

What is known already: Unfertilization after conventional IVF is confirmed by the existence of Metaphase-II (M-II) chromosome and first polar body. Spindle examination in unfertilized eggs using the polarization microscope is useful to assist rescue ICSI. However it has limitations since this apparatus observes only the existence of spindle not the stage of nuclear maturation (M-II, Anaphase-II or Telophase-II). Nomarski differential interference contrast microscopy clarifies each stage of second meiotic cell division.

Study design, size, duration: We performed this retrospective study to investigate the usefulness of chromosomal examination with a differential interference contrast microscope to rescue unfertilized eggs after insemination without using the polarization microscope in 425 M-II oocytes after insemination from 38 couples from January 2015 to December 2016.

Participants/materials, setting, methods: Unfertilized oocytes were identified by the normal width of chromosomes at M-II stage without extrusion of second polar body or white colored spindle with full length adjacent to the cytoplasmic membrane. Fertilized oocytes showed half width of chromosome

in a line and shortening spindle 2-3 hours after the start of the fertilization (Anaphase-II).

Main results and the role of chance:
1. The 425 freshly ovulated M-II oocytes were examined. The proportion of unfertilized oocytes that remained at M-II stage was 20.4% (87/425), fertilized oocytes after completion of second meiosis was 79.5% (338/425).

2. The fertilization, cleavage, blastocyst stage rates, pregnancy and miscarriage rates in fertilized oocytes (A) and unfertilized oocytes followed by new rescue ICSI (B) are listed in Table. No 1PN or 3PN oocytes could be observed both in group A and B.

Table Clinical outcome following new rescue ICSI.

	Fertilization rates (%)	Cleavage rates (%)	Blastocyst rates (%)	Pregnancy rates (%)	Miscarriage rates (%)
A(n = 328)	78.5	64.5	45.3	33.4	20.5
B(n = 87)	52.4	62.3	33.2	25.5	25.6

Limitations, reasons for caution: Not all of M-II oocytes could be identified as having completed second meiosis after insemination. Some chromosomes were scattered or degenerated. If spermatozoon penetrated the not fully activated oocyte it showed premature chromosome condensation. These chromosomes are more easily identified with a PLM.

Wider implications of the findings: The identification of nuclear maturation with DCM and PLM beneficial not only for rescue ICSI but also for other procedures that need to identify the nuclear maturation division. Particularly, this procedure could become indispensable in cytoplasmic exchange for the treatment of mitochondrial disease.

Trial registration number: None.

P-210   Successful and safe cryopreservation of low sperm number

I. Mateizel[1], R. Janssens[2], H. Tournaye[2], G. Verheyen[2]

[1]*UZ Brussel, CRG, Jette, Belgium*
[2]*UZBrussel, CRG, Jette, Belgium*

Study question: Can small numbers of spermatozoa be successfully cryopreserved for later use without risk of cross-contamination?

Summary answer: Using the commercial device SpermVD and CBS High-Security tubes, small numbers of spermatozoa can be successfully frozen, without the risk of cross contamination.

What is known already: In cases with low sperm numbers, e.g. extreme oligozoospermia or testicular sperm of non-obstructive azoospermic patients, the standard slow freezing procedure for human sperm remains suboptimal. A methodology that allows the successful freezing of low numbers of individually isolated sperm will provide benefits for the management of male infertility. To date, few attempts have been reported using empty zonae or adapted devices with various recovery and motility rates. Nevertheless, none of these excludes the risk of cross-contamination when stored in liquid nitrogen (LN2).

Study design, size, duration: A new commercial device (SpermVD, MFC Global ltd.) was used as sperm carrier, and stored in two different types of sterile vials: Cryotubes with a screwcap (Thermo-Scientific; closed group) and heat-sealed CBS High-Security tubes (Cryo Bio System; sealed group). The recovery and motility rates were investigated. In cases of immotile spermatozoa, the Hypo-Osmotic-Swelling (HOS) test was performed to indicate sperm viability. The aspiration/deposition of sperm was performed with a Narishige micromanipulator.

Participants/materials, setting, methods: Motile spermatozoa were individually plated in 0.5 μl cryopreservation solution (50:50/Sperm-freezing solution:G-MOPS, Vitrolife) on the 3 wells of the SpermVD device. After 15 min at room temperature (RT), each device was placed inside a vial, closed or sealed and submerged in LN2. For thawing, the vials were removed from LN2, and after 5 min at RT, the spermatozoa were plated in G-MOPS medium. Recovery

and viability rates were compared (χ^2-test) between the closed and sealed groups.

Main results and the role of chance: A total of 809 spermatozoa were plated on SpermVD devices (n = 20), of which 394 spermatozoa were frozen in closed (n = 10) and 415 spermatozoa were frozen in sealed (n = 10) vials. After thawing, a significantly higher sperm number was recovered from the closed devices (365/394, 92.6% vs 353/415, 85.1%; p = 0.0007). However, a significantly higher motility rate was found in the sealed group as compared to closed group (43/353, 12.2% vs 8/365, 2.2%; p < 0.0002). After performing the HOS test on the immotile spermatozoa upon thawing, the total number of viable sperm (motile + HOS-positive sperm) was still higher in the sealed group (90/353, 25.5% vs 47/365, 12.9%; p < 0.0002). In conclusion, although the recovery rate was higher in the closed vials, the sealed vials performed better in preserving the sperm viability during the freezing/thawing procedure. Taking into account that the sealed vials do not allow cross-contamination in LN2, the combination of the SpermVD as sperm carrier with the CBS High-Security tubes as freezing vials, provides a safe solution for cryopreserving individual spermatozoa in cases with few sperm available.

Limitations, reasons for caution: This study represents the first step in validating the combination between SpermVD and CBS High-Security tubes as a suitable tool for routine cryopreservation of low numbers of spermatozoa. Before implementation in routine clinical practice, the embryological and clinical outcome of the embryos obtained after using this methodology should be evaluated.

Wider implications of the findings: Effective methods to safely cryopreserve single spermatozoa would allow the patients with very low sperm numbers to benefit from multiple ICSI treatments avoiding repetitive surgeries and cancellation of cycles due to the lack of sperm.

Trial registration number: not applicable.

P-211   Clinical outcomes using human euploid embryos after quantification of mitochondrial DNA content as a viability predictor tool

P. Shah[1], M. Banker[2], S. Singh[3], D. Patel[3], A. Kotadawala[3]

[1]Pulse women's Hospital, IVF Lab, Ahmedabad- Gujarat, India
[2]NOVA IVI, Gynaecology, Ahmedabad, India
[3]NOVA IVI, ivf lab, Ahmedabad, India

Study question: Does transfer of euploid embryos with lower mitochondrial DNA (mtDNA) copy number improve the clinical outcomes in elective single embryo transfers (eSETs)?

Summary answer: Transferring of euploid embryos with lower mitochondrial DNA (mtDNA) copy number does not show a statistical improvement in clinical outcomes in eSETs

What is known already: The mtDNA copy number can be quantified in human euploid embryos during pre-implantation genetic screening (PGS) using real-time PCR to predict the viability of the embryos. Based on the results, a transfer priority list can be prepared, where the priority of euploid embryo(s) getting transferred is inversely proportional to the mtDNA copy number present.

Study design, size, duration: This was a retrospective, cohort, pilot study including 45 patients who underwent PGS between the months of March and December 2016 at NOVA IVI Fertility, Ahmedabad, India. 4 patients with Day-3 biopsy, 3 with pending embryo transfers (ETs) and 10 with double ETs were excluded from the study. 28 patients who underwent Day-5/6 trophectoderm biopsy for PGS followed by eSETs in subsequent frozen-thawed cycle were included in the study.

Participants/materials, setting, methods: Post – biopsy, blastocysts (n = 143) from patients (n = 28) with indications such as advanced maternal age, recurrent implantation failure and recurrent pregnancy losses were vitrified individually on carriers. Euploid embryos with least mtDNA content were then thawed for eSETs and transferred in frozen-thawed cycles. For the study, 4 groups (upto 20, upto 30, upto 40 and > 40) were made based on the mitoscore (MS) values calculated by Igenomics

Main results and the role of chance: The total number of blastocysts biopsied for 45 patients were 202, out of which 121 were found to be euploid (59.9%). To evaluate the efficacy of MS the transferred embryos were divided

into four groups viz upto 20, upto 30, upto 40 and > 40. The pregnancy rates (PR) for these groups were 50.0%, 43.8%, 100.0% and 0 % respectively; while the implantation rates (IR) were 16.6%; 37.5%, 33.3% and 0 % respectively.

The present study shows no significant difference in pregnancy rates (PR) on transferring embryos with proper morphology and least MS values as compared to the group with an MS of upto 40 (PR: 50.0 versus 100.0%, P > 0.5; MS upto 20 versus upto 40 group). The mean age (± SD) of female patients undergoing the treatment was 34.35 ± 3.05 years.

Limitations, reasons for caution: Given the retrospective nature of the study, limited information was available. A prospective, multi-centre study with a large sample size can be designed to look into the predictive value of MS. Results from Day-3 blastomere biopsy should also be analyzed.

Wider implications of the findings: Along with traditional methods of embryo selection, novel methods that are non-invasive and cost-effective but have higher predictive value for embryo selection should be developed. This would help in escalating the live birth rates in ART, especially in eSETs and would thus help in decreasing the risk of multiple pregnancies

Trial registration number: not applicable.

P-212   The dynamics of in vitro maturation (IVM) and their optimal ICSI timing of germinal vesicle oocytes retrieved from IVM cycles

D. Gunasheela[1], H. Nirmala Hiremath[2], G. Uttur[3], G. Deepanjali[4], W.Y. Son[5]

[1]Gunasheela Surgical & Maternity Hospital, Obst & Gyne, Bangalore, India
[2]Gunasheela Surgical & Maternity Hospital-, Embryology, Bengaluru- India, India
[3]Gunasheela Surgical & Maternity Hospital, Embryology, Bengaluru- India, India
[4]Gunasheela Surgical & Maternity Hospital, Embryology, Bengaluru-, India
[5]McGill University, Embryology, Montreal, Canada

Study question: What is the most favorable ICSI timing after the first polar body (1st PB) extrusion in relation to the fertilization and embryo development?

Summary answer: The optimal ICSI timing of the IVM oocytes is 3–6 hours after the polar body extrusion in terms of fertilization and embryo developmental competence.

What is known already: IVM has been less successful than standard IVF in terms of embryo development and clinical outcomes. It has been known that it's because of asynchronous nuclear and cytoplasmic maturation. Although a study has reported the dynamics of IVM of GV oocytes obtained from IVF cycles using time-lapse system (TLS), to date there is no report of dynamics of maturation of the GV oocytes retrieved from regular IVM cycles. In addition, what has not been reported is the optimal ICSI timing after the 1st PB extrusion using the TLS equipment.

Study design, size, duration: The maturation timing process from GV-stage oocytes (n = 162) was recorded following culture in the TLS equipment. Intra Cytoplasmic Sperm Injection (ICSI) was performed at different times after the 1st PB extrusion (n = 100). Fertilization and embryo utilization rates were analyzed to see the optimal ICSI timing after the 1st PB extrusion.

Participants/materials, setting, methods: The oocytes were obtained from PCO(S) patients undergoing FSH/hCG-primed IVM cycles. After removing most of the cumulus cells, GV-stage oocytes were cultured for maximum 30 hours in the TLS. The elapsed time between the 1st PB extrusion and ICSI was recorded. The data was divided into 3 groups depending on ICSI timing after the 1st PB extrusion (< 3 h, 3–6 h and > 6 h). Fertilization and embryo utilization rates were analyzed with ANOVA test.

Main results and the role of chance: Overall maturation rate in vitro was 61.7 % (100/162). The nuclear maturation rate was 0 %, 3.0 %, 40.0 %, 60.5 % and 61.7 % after culturing for 6 h, 12 h, 18 h, 24 h and 30 h respectively. The average time from GV- to Germinal vesicle breakdown (GVBD)-stage was 3.3 hours (± 2.3, range: 0.5–9.3 hours) and GVBD- to MII-stage was 12. 5 hours (± 1.5, range: 7.7–15.6 hours) after beginning culture in IVM media. The fertilization rate of the group who had ICSI 3–6 hours after the 1st PB extrusion was higher (83.1%) than those of other groups (< 3 h: 40%, > 6 h: 64 %). The lower number of good quality morula/blastocyst embryos (0%) developed from the group where ICSI was performed < 3 h after the 1st PB extrusion compared to other groups. There was no difference of embryo utilization rate between 3–6 h and > 6 h groups (47.1% vs. 56.3%).

Limitations, reasons for caution: Most of CC at GV-stages were removed to see the first PB extrusion in TLS system, which may act differently than oocytes with intact CC. As this was pilot study, the number of oocytes in the study is small.

Wider implications of the findings: This is the first observation describing extensively the IVM timing process of GV-stage oocytes derived from IVM cycles using TLS and suggesting the optimal ICSI timing to improve fertilization and further embryo development. This study may provide essential information for improving laboratory process for human IVM program.

Trial registration number: not applicable.

P-213   Outcomes of cleavage-stage versus blastocyst transfers in patients with low number of fertilized oocytes in two subsequent cycles

C. Pirkevi, Y. Kumtepe Colakoglu, H. Yelke, S. Kahraman

Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: What is the more successful transfer strategy to adopt in patients with a low number of fertilized oocytes: cleavage-stage or blastocyst transfer?

Summary answer: Ongoing pregnancy rates (OPR) are nearly doubled in patients with blastocyst transfers, either in the first or second ICSI cycle.

What is known already: Cleavage stage versus blastocyst stage embryo transfer in assisted reproductive technology has been covered by a *Cochrane* review (Glujovsky *et al.*, 2012). These authors provided evidence for a slight benefit in live birth rates of blastocyst transfers, but looking at cumulative pregnancy rates, day 2/3 transfers were more efficient. However, the use of blastocyst culture as a standard treatment option for all patients and especially for poor prognosis patients is still under discussion. As being characterized by a low ovarian reserve, poor prognosis patients may be at risk of being harmed by prolonged embryo culture and having their transfer cancelled.

Study design, size, duration: This retrospective study comprised a period between August 2011 and December 2016. Patients with 1-2 fertilized oocytes and no embryo to vitrify were either transferred on day 2/3 (n = 1418) or on day 5/6 (n = 186) in their first cycle. For their second attempt, patients who received previously a cleavage stage embryo transfer were either transferred on day 2/3 (n = 188) or on day 5/6 (n = 151). Embryos were cultured in low oxygen tension using a single-step culture medium.

Participants/materials, setting, methods: The mean age of patients receiving a cleavage-stage embryo transfer was 36.92 ± 5.46 for the first and 38.28 ± 4.72 for the second cycle. The mean age of patients having a blastocyst stage embryo transfer was 35.52 ± 5.19 for the first and 35.8 ± 4.9 for the second attempt. After a failed cleavage-stage embryo transfer, in the second cycle, the mean number of fertilized oocytes was 1.87 ± 0.98 for cleavage-stage and 4.05 ± 2.64 for blastocyst transfers.

Main results and the role of chance: The OPR was nearly doubled in blastocyst transfers when compared to cleavage-stage transfers, either for the first (33.15% vs. 18.05%; p < 0.0001) or for the second cycle (32.45% vs. 18.61%; p = 0.0034). The clinical miscarriage rate were higher in cleavage-stage transfers (23.12% and 25.5%, for the first and second cycle, respectively), when compared to blastocyst transfers (18.91% and 16.95%, for the first and second cycle, respectively), although not reaching statistical significance. The cancellation rate between day 3 and 5 was of 39.8% for the first attempt (n = 123) and of 8.48% for the second attempt (n = 14), indicating that prolonging embryo culture two more days allows the selection of poor prognosis patients who will ultimately fail to achieve the blastocyst stage. Moreover, the number of fertilized oocytes doubled in a subset of patients having a blastocyst-stage transfer in their second cycle, when compared to those receiving a second cleavage-stage transfer, showing that a failure after a cleavage-stage embryo transfer does not reduce chances of achieving the blastocyst stage in subsequent cycles for a younger group of poor prognosis patients.

Limitations, reasons for caution: Inclusion criteria favored a group of poor prognosis patients with reduced outcomes. Results were obtained in an IVF program aiming prolonged culture and blastocyst transfer to select viable embryos.

Wider implications of the findings: Blastocyst stage transfers are more successful than cleavage-stage transfers in our cohort of poor prognosis patients. However, transfer cancellation rates are undeniably high when aiming for blastocyst culture, which may be regarded as nonviable pregnancies. The effect of prolonged culture needs to be addressed in prospective randomized trials.

Trial registration number: Not applicable.

P-214   Clinical validation of extend algorithm from embryo viability assessment system; a blastocyst analysis

S. Perez Albala[1], B. Aparicio-Ruiz[1], T. Viloria[1], L. Romany[1], J. Remohi[2], M. Meseguer[3]

[1]*IVI Valencia, IVF Laboratory, Valencia, Spain*
[2]*IVI Valencia, Reproductive Medicine, Valencia, Spain*
[3]*IVI Valencia. INCLIVA, IVF Laboratory, Valencia, Spain*

Study question: Is there a correlation between the automatic classification provided on Day3 by the Eeva-Xtend algorithm (Early embryo viability assessment) with blastocyst rates and quality?Is this model useful for embryo selection?

Summary answer: There is a direct correlation according to the automatic test for blastocyst formation and quality.This test is potentially useful to distinguish embryos with similar morphology.

What is known already: Wong et al(2010) developed an algorithm to classify embryos according to their probability of reaching blastocyst stage based on the combination of: P2(t3-t2) and P3 (t4-t3). Using these two parameters, a first algorithm was developed classifying embryos according to their probability of reaching blastocyst stage as High or Low, with an improved version that included a Medium category. Different groups have demonstrated the utility of this classification as an improvement for embryo selection and reduction in variability among embryologists(VerMilyea et al 2014,Conaghan et al 2013,B. Aparicio-Ruiz et al 2016).Recently an improved version of the algorithm (Xtend) has been up-graded on Eeva-system

Study design, size, duration: Retrospective cohort study, from June 2016 to January 2017.

Participants/materials, setting, methods: University-affiliated infertility clinic. An improved version of this algorithm was developed taking into account new parameters to select embryos. The values of P2 and P3 are complemented with egg age, number of cells on day3 and a texture image analysis that is correlated with fragmentation.The study includes 96 consecutive ICSI cycles from the egg donation program in which embryos were incubated in a conventional incubator with especially designed scopes that used an automatic cell-tracking software.

Main results and the role of chance: A total of 96 patients generated 776 embryos. Out of those, 68.4% developed to the blastocyst stage. When categorizing according to EEVA: 19.7% embryos were labelled as 1, 17.9% were labelled as 2, 16.7% were labelled as 3, 23.7 % were labelled as 4 and 22.0% were labelled as 5. The blastocyst formation rate according to the five EEVA categories was: 1 = 89.1%; 2 = 82.4%; 3 = 80.3%; 4 = 61.3%: 5 = 40.9 % p < 0.0001. Development to "good morphology" blastocyst (defined by A /B inner cell mass and trophectoderm morphology) from total embryos was also analysed with decreasing percentages as we moved on between categories. More specifically: 1 = 55.9%; 2 = 52%; 3 = 40%; 4 = 25.6%; 5 = 13.2% p < 0.001.

Limitations, reasons for caution: The retrospective nature of this study may be a reason for caution; nevertheless, we are presenting the first results of this new algorithm. The classification system itself has some errors due to difficulties in cell tracking, generating "none result", however we only included cases where a classification was provided.

Wider implications of the findings: Our study demonstrates that embryo selection by an automated time-lapse system supported by the use of a new algorithm is related with higher probability not only of reaching blastocyst stage but of developing into good quality blastocysts. Our aim is to keep increasing the sample size to consolidate our hypothesis.

Trial registration number: 1406-VLC-045-BA

P-215   Patient over 40 can be treated more effectively with conventional IVF compared to ICSI in many of the cases

A. Lehner[1], Z. Kaszás[2], A. Murber[2], J. Rigó Jr.[2], J. Urbancsek[2], P. Fancsovits[2]

[1]Semmelweis University, First Department of Obstetrics and GynaecologyDivision of Assisted Reproduction, Budapest, Hungary
[2]Semmelweis University, 1st Department of Obstetrics and Gynaecology, Budapest, Hungary

Study question: Is increased female age really an indication of intracytoplasmic sperm injection (ICSI) or can be conventional in vitro fertilization (IVF) applied effectively?

Summary answer: Increased female age does not seem to be an indication of ICSI.

What is known already: Although ICSI was originally developed to treat severe male factor infertility, nowadays, it is commonly used in many other cases such as poor responders and advanced patient age. According to the literature, fertilization rate following ICSI is lower compared to conventional IVF. ICSI may have more potential risks too. There seems to be an increase in de novo sex and autosomal chromosome aberrations after ICSI. Increased risk of imprinting disorders in ICSI children has also been reported. However, in Europe ICSI is used in about 70% of the cases, far more than what the frequency of the male factor explains.

Study design, size, duration: Data of 559 IVF cycles performed at our division between 2011 and 2016 were retrospectively analyzed. Cycles were only included in the study if patient age exceeded 40, and ejaculated semen was used for the fertilization. Oocytes were fertilized by ICSI in 465 cases and by conventional IVF in 94 cases.

Participants/materials, setting, methods: Cycles were classified into two groups according to the fertilization method (IVF and ICSI Groups). In order to be able to compare fertilization rates, it was calculated as the number of retrieved oocytes divided by the number of normally fertilized ones (2PN). Clinical pregnancy rate and embryology data were also assessed. The formers were analyzed using Pearson's Chi-squared test, while cell numbers, fragmentation rates and morphology scores were compared using Mann–Whitney U test.

Main results and the role of chance: Patient age was lower (41.4 ± 1.6 vs. 42.4 ± 1.9; $p < 0.001$), total oocyte count was higher (9.7 ± 3.7 vs. 5.0 ± 3.8; $p < 0.01$) in the IVF group. Fertilization rate was significantly higher following conventional IVF compared to ICSI (63.7% vs. 56.0%; $p < 0.01$). Quality of the developing embryos did not show any difference on Day 2 and 3. No differences were found between neither the numbers of blastomeres (Day 2: 3.7 ± 1.4 vs. 3.8 ± 1.4; $p = 0.410$; Day 3: 6.5 ± 2.2 vs. 6.8 ± 2.3; $p = 0.128$) nor fragmentation rates (Day 2: 15.1 ± 10.7% vs. 15.4 ± 10.5%; $p = 0.539$; Day 3: 16.1 ± 11.8% vs. 15.6 ± 10.7%; $p = 0.648$). Morphology scores were also similar (Day 2: 2.1 ± 0.9 vs. 2.1 ± 0.8; $p = 0.954$; Day 3: 2.1 ± 0.8 vs. 2.2 ± 0.7; $p = 0.084$). Multinucleated embryos occurred in the same proportion (18.9% vs. 16.2%; $p = 0.144$). Clinical pregnancy rate however, was significantly higher following conventional IVF (39.1% vs. 17.6%; $p < 0.01$).

Limitations, reasons for caution: Differences in oocyte count and age affect the outcomes, however the latter should not explain the higher fertilization rate following IVF. These could be eliminated by the matching of the cycles, but that would have cause an even more significant bias: the difference in the quality of the sperm samples.

Wider implications of the findings: ICSI should not be chosen evidently as the method of fertilization in case of patients over 40. However, we have to stress the strong need of prospective randomized trials to confirm this finding and to clarify the evident indications of ICSI once and for all.

Trial registration number: -.

P-216   No benefit of transferring more than one embryo even without using preimplantation genetic screening

L. Nanassy[1], G. Teglas[1], A. Vereczkey[2]

[1]Human Reproduction Institute Versys Clinics, Embryology, Budapest, Hungary
[2]Human Reproduction Institute Versys Clinics, Surgery, Budapest, Hungary

Study question: Does double embryo transfer (DET) result in increased clinical pregnancy rate compared to elective single embryo transfer (eSET) when embryo selection is solely based on morphology?

Summary answer: It does not seem to have any benefit of transferring more than one embryo even when preimplantation genetic screening (PGS) is not available.

What is known already: There is a growing body of evidence that elective single embryo transfer (eSET) does not reduces the chance of pregnancy when embryo selection is supported with preimplantation genetic screening. Alhtough, eSET is widely promoted by scientific societies and health care professionals because of the associated adverse events of twin pregnancies, the main concern expressed by patients is still the potential decrease of chance due to the reduced number of embryos transferred. Here we analyze data from four consecutive years evaluate the efficiency of eSET in fresh and frozen cycles without using PGS for embryo selection.

Study design, size, duration: Data from all stimulated eSET (having at least two embryo available for ET) and double embryo transfer (two embryos were transferred) cycles were retrospectively analyzed between 2013 and 2016. Cycles with donor oocytes, day 3 ET and PGS were excluded. Also, frozen embryo transfer (FET) cycles where no embryo was transferred in the fresh cycle were analyzed using the same inclusion criteria.

Participants/materials, setting, methods: From all ETs, 86,57% (290/335) of fresh, autologous, non-PGS cycles resulted in a day 5 ET, and 97,93% (284/290) was either a single or double embryo transfer. Eighty-seven ETs were excluded due to only one embryo available for ET. A total number of 29 FET with eSET and 30 with DET were also analyzed. Clinical pregnancy, implantation and twin pregnancy rates were compared using Fisher exact test. A $p < 0.05$ was considered significant.

Main results and the role of chance: We did not find any significant difference in female age ($35,53 \pm 5,093$ in eSET vs. $35,43 \pm 4,472$ in DET) between the two groups. Clinical pregnancy (CPR) and implantation rates (IR) were similar (44,44% (52/107) CPR and 44,44% (52/107) IR in eSET group vs. 52,52% (73/139) CPR and 35,25% (98/278) IR in DET group, respectively; $p > 0.05$). Also, CPR and IR did not differ when patients were further stratified based on their female age. Patients with advanced maternal age (≥ 38) showed no difference in CPR and IR in eSET and DET groups (34,21% (13/38) CPR and 34,21% (13/38) IR in eSET group vs. 41,67% (20/48) CPR and 29,16% (28/96) IR, respectively; $p > 0.05$). A similar phenomena was observed analyzing data from the younger age (≤ 37) group (49,37% (39/79) CPR and 49,37% (39/79) IR in eSET group vs. 58,24% (53/91) CPR and 38,46% (70/182) IR, respectively; $p > 0.05$). A significantly increased twin pregnancy rates were observed in the DET group compared to the eSET group (none (0/52) in eSET group vs. 34.24% (25/73) in DET group; $p < 0,0001$).

Limitations, reasons for caution: Although, data from four consecutive years were analyzed the number of cycles is still below the desired number of procedures.

Wider implications of the findings: These results show that in our setting adding another embryo to the embryo transfer does not seem to markedly increase clinical pregnancy rate but dramaically increses twin pregnancy rate. This is an important piece of information advising patients before ET even when advanced embryo selection techniques are not available.

Trial registration number: -.

P-217   ART media act as modifiers that substantially influence embryo survival

E. Casser[1], S. Israel[1], S. Schlatt[2], V. Nordhoff[2], M. Boiani[1]

[1]Max Planck Institute for Molecular Biomedicine, Cell and Developmental Biology, Münster, Germany
[2]University Hospital Münster, Centre of Reproductive Medicine and Andrology, Münster, Germany

Study question: Do monozygotic twin embryos become functionally different if cultured in different ART media?

Summary answer: Genetically identical mouse embryos from the same fertilization event accrue different cell numbers in the three founder lineages, and progress differently after implantation.

What is known already: While there is growing consensus that in vitro culture influences the biological properties of the embryo, a direct and specific effect of ART culture media is subject of debate. A major confounder is

represented by inter-embryo heterogeneity, whereby potential effects of media are superimposed with the different qualities of embryos arising from independent fertilization events of distinct oocytes. A critical parameter that contributes to define an embryo's potential is the formation of the epiblast among the founder cell lineages.

Study design, size, duration: Mechanical bisection of two-cell mouse embryos resulting in monozygotic twins, cultured in parallel in different media and then transferred to the uterus as blastocyst pairs. Transfer to uterus puts the quality of these embryos to the ultimate test of totipotency. Embryos are handled and analyzed respecting the pair associations.

Participants/materials, setting, methods: Two-cell embryos were derived from hybrid inbred oocytes (B6C3F1; stimulated cycle) and outbred sperm (CD1). Seventy-two pairs of sister blastomeres were cultured individually zona-free in pair combinations of three media (GM501, SAGE 1-step, KSOM(aa)), yielding 131/144 blastocysts. The blastocyst pairs were assessed immunocytochemically for the number of cells present in the founder lineages (epiblast, NANOG-positive; primitive endoderm, SOX17-positive; trophectoderm, CDX2-positive). Additional 164 pairs of monozygotic blastocysts were transferred to the uterus (1 pair/recipient).

Main results and the role of chance: Multivariate analysis of variance revealed that the effects of media (p = 0.0043) exceed those of inter-embryo heterogeneity associated with the independent fertilization events (p = 0.0540). The number of 4 epiblast cells which is considered as the minimum threshold for further development is achieved more often in twin blastocysts cultured in ART media (GM501 = 5.33 ± 0.46 cells; SAGE 1-step = 3.92 ± 1.08 cells) compared to the mouse medium KSOM(aa) (3.58 ± 1.08 cells). Preliminary embryo transfer data show that more twins are delivered to term when ART media are used. When both twins developed in the same ART medium, 86 pairs were transferred to uterus resulting in 28 liveborns of which 6 were monozygotic pairs. When both twins developed in KSOM(aa) medium, 48 pairs were transferred to uterus resulting in 10 liveborns of which 1 was a pair. When twins developed one in ART and the other in KSOM(aa) medium, 30 pairs were transferred to uterus resulting in 9 liveborns of which 2 were a pair. Experimental control is inherent in this setting, given the same zygotic origin and genetic identity of the twin and cotwin, and the same uterus for both twins. Therefore, the functional responses observed in this study can only be driven by the respective culture media.

Limitations, reasons for caution: This study was conducted in both an experimental twinning model and an animal model. Naturally, monozygotic twins are, other than in humans, exceptional in mice. Our mouse results suggest that medium-induced embryo diversification could happen also in human ART, however, the final effect may or may not be the same.

Wider implications of the findings: These results, if reproduced in independent studies in other species including human, would prove beyond reasonable doubt that embryo culture media are modifiers, since they cause monozygotic twins to diversify. As such, ART media have a substantial influence on survival of embryos, and diminish their natural selection.

Trial registration number: Not applicable.

P-218 Nucleolar morphology, aneuploidy and maternal age: are they correlated?

M.I. Roos Kulmann[1], A. Bos-Mikich[2], C. Basso[1], G. Frantz[1], N. Pagnoncelli[1], C. Dutra[1], M. Höher[1], N. Frantz[1]

[1]Nilo Frantz, Centro de Reprodução Humana, Porto Alegre, Brazil
[2]Universidade Federal do Rio Grande do Sul,,

Study question: Could nucleolar morphology be correlated with embryo ploidy?

Summary answer: Poor nucleolar morphologic scores were associated with higher aneuploidy rates in < 40, but not in ≥40, year old patients.

What is known already: The single euploid embryo transfer has been shown to increase the implantation rate and decrease the risk of multiple pregnancies. Nevertheless, many patients do not have access to Preimplantation Genetic Screening (PGS) technologies. In this sense, a better understanding of the correlations between morphology and ploidy can be useful to select the embryo more likely to be euploid. Despite the great interest that blastocyst morphology

has received, a very few number of studies have related the nucleolar morphology to chromosomal content of embryos.

Study design, size, duration: This is a retrospective observational study performed from January 2013 to December 2016 in order to assess the relationship between maternal age, standard morphology and ploidy. The morfology parameters of 338 embryos (zygote, cleavage stage and blastocyst) from 129 PGS cycles (array-CGH or NGS) were analyzed. Besides, frozen embryo transfers (FET) of 77 euploid blastocysts were analyzed, where it was possible to track the implantation outcome.

Participants/materials, setting, methods: Advanced maternal age (> 35; 48.1%) and repeated implantation failure (19.2%) were the main PGS indications. Prior to trophectoderm biopsy (day-5 or day-6), zygotes were classified according to the Z-score system and cleavage stage embryos (day-3) based on number of blastomeres and fragmentation (top, average and poor quality). Furthermore, blastocysts were scored according to Gardner and Schoolcraft grading system and categorized in BL1 (AA, AB or BA), BL2 (BB or CB) and BL3 (BC or CC).

Main results and the role of chance: The mean maternal age was 37.1 ± 4.1 years old. The overall euploid rate was 56.8%. Poor nucleolar and blastocyst morphology, but not cleavage stage embryo morphology, were associated with higher aneuploidy rates. Z1 = 34.6%, Z2 = 43.2% and Z3/Z4 = 71.8%; (p < 0,001); Top = 44.1%, Average = 41.1% and Poor = 25% (p = 0,6871); BL1 = 35.2%, BL2 = 42.8% and BL3 = 67.4% (p < 0,005). A strong correlation was observed between advanced maternal age and higher aneuploidy rates, especially in women aged 40 years or older (71,8%; p < 0,0001). Therefore, patients were divided into two groups (< 40 years old and ≥40 years old) to assess the influence of maternal age on the correlation between morphology and ploidy. While nucleolar morphology was predictive of aneuploidy rate in the < 40 years old group (Z1 = 26.9%, Z2 = 36.4% and Z3/Z4 = 69.2%; p < 0,001), this association was not present in the ≥40 years old group (Z1 = 71.4%, Z2 = 67.5%, Z3 = 76.9%; p = 0,8042). The same pattern was observed for blastocyst morphology as reported before. Interestingly, a trend towards increased aneuploidy rates, correlated with poor nucleolar scores, was observed even when comparing same quality blastocysts. BL1/Z1 = 31.2%, BL1/Z2 = 35.9%, BL1/Z3,Z4 = 60% (p = 0,2015); BL2/Z1 = 33.3%, BL2/Z2 = 42.1%, BL2/Z3,Z4 = 72.7% (p < 0,01); BL3/Z1 = 60%, BL3/Z2 = 66.6%, BL3/Z3,Z4 = 83.3% (p = 0,3469). Finally, nucleolar and blastocyst morphology did not affect the implantation rate in FET of euploid blastocysts.

Limitations, reasons for caution: The study is limited by its retrospective nature and by the subjective assessment of morphology. A higher sample size or a prospective randomized design could be used in future studies to corroborate the current findings.

Wider implications of the findings: The present data suggest that a combined assessment of nucleolar and blastocyst morphology should be used when selecting embryos for transfer in < 40 year old patients who do not have access to PGS. Moreover, nucleolar and blastocyst morphology should be applied to choose the embryos undergoing biopsy and chromosomal analysis.

Trial registration number: NA.

P-219 Supernumerary vitrified blastocysts can be effectively diagnosed after warming by fast qPCR-based aneuploidy testing and transferred without the need of a second vitrification round

C. Scarica[1], D. Cimadomo[2], L. Dovere[1], M. Stoppa[1], F. Sanges[1], L. Albricci[1], S. Romano[1], R. Maggiulli[1], A. Capalbo[1,2], F.M. Ubaldi[1], L.F. Rienzi[1]

[1]Genera c/o Clinica Valle Giulia GENERA center for Reproductive medicine, Reproductive Medicine, ROME, Italy
[2]GENETYX, molecular genetics laboratory, Marostica, Italy

Study question: Is qPCR-based chromosomal analysis on vitrified blastocysts with subsequent euploid single embryo transfer (SET) an efficient approach for patients needing preimplantation genetic diagnosis for aneuploidies (PGD-A)?

Summary answer: In patients with previous fresh IVF-failure(s), supernumerary vitrified blastocysts can be effectively diagnosed after warming and transferred without the need of a second vitrification round.

What is known already: PGD-A is a technique whose application in IVF treatments is constantly growing nowadays, while vitrification is a consolidated, safe and efficient strategy for oocytes/embryos cryopreservation. Since supernumerary embryo cryopreservation is a common strategy in IVF, many patients have a cohort of untested cryopreserved embryos. Thus, for patients with a history of fresh IVF failures and/or miscarriages, an attractive approach may involve the warming and chromosomal testing of those embryos with subsequent euploid SET

Study design, size, duration: Longitudinal cohort study involving 51 patients (female age at oocyte retrieval:35.9 ± 3.5,23.6–42.0). Candidate patients had untested vitrified embryos from a previous IVF cycle and a history of IVF failures (1.4 ± 1.5,0–6) and/or miscarriages (0.5 ± 0.7,0–3). All PGD-A cycles on warmed blastocysts with subsequent euploid SET between April2013-October2016 were included. The primary outcome measure was ongoing pregnancy rate per euploid SET (> 12 weeks of gestational age). Secondary outcomes included biochemical pregnancy loss and miscarriage rates

Participants/materials, setting, methods: Trophectoderm biopsy was performed after warming and blastocyst full re-expansion. Chromosomal analysis was conducted by qPCR in 4 hours and subsequent euploid SET was performed with no need for a further vitrification-warming cycle. Clinical outcomes were compared to vitrified-warmed euploid SETs from 447 patients (female age:36.5 ± 2.8,25.6–44.0) undergoing PGD-A with an indication of history of IVF failures (1.9 ± 1.8,0–11) and/or miscarriages (0.7 ± 1.0,0–5) between April 2013-October 2016.

Main results and the role of chance: 115 blastocysts survived warming (survival rate after warming: 98.3%; n = 115/117,95%CI = 93.9%-99.8%) and underwent trophectoderm biopsy after full re-expansion. No blastocyst degenerated after biopsy. 66 blastocysts were diagnosed euploid by qPCR and 40 subsequent euploid SETs were performed. 26 euploid blastocyst were re-vitrified. Ongoing pregnancy rate for the study group was similar to the historical control group, namely 42.5% (n = 17/40; 95%CI = 27.0%-59.1%) and 40.9% (n = 244/597; 95%CI = 37.7%-45.8%), respectively (NS). No differences between the two groups were also found for the biochemical pregnancy loss rates: 5.0% (n = 1/20; 95%CI = 0.1%-24.8%) and 7.7% (n = 23/300; 95% CI = 4.9%-11.3%) and miscarriage rates: 10.5% (n = 2/19;95%CI = 1.3%-33.3%) and 11.9% (n = 33/277; 95%CI = 8.3%-16.3%) for the study group and the historical control, respectively (NS).

Limitations, reasons for caution: Data are needed to assess implantation potential for those blastocysts undergoing a second round of vitrification. Vitrified oocytes or embryos cryopreserved at earlier preimplantation developmental stages were not included.

Wider implications of the findings: Trophectoderm biopsy after warming and fast qPCR aneuploidy testing with subsequent euploid SET is an efficient strategy to rescue untested cryopreserved embryos when indicated.

Trial registration number: none.

P-220 BMP4 plays a role in apoptosis during early human embryonic development

C. De Paepe[1], **D. Dewandre**[1], **K. Sermon**[1], **G. Verheyen**[2], **H. Tournaye**[2], **H. Van de Velde**[2]

[1]Vrije Universiteit Brussel, Reproduction and Genetics, Jette, Belgium
[2]UZ Brussel, Centre for Reproductive Medicine, Jette, Belgium

Study question: Does BMP4 preferentially induce differentiation of the cleavage stage blastomeres towards trophectoderm (TE) or inner cell mass (ICM) in the blastocyst?

Summary answer: BMP4 has no effect on first lineage differentiation, but triggers apoptosis in the early embryo. Apoptotic embryos express higher levels of *BMP4* than control blastocysts.

What is known already: Bone morphogenetic proteins (BMPs) are multifunctional growth factors that belong to the TGFβ family. Several BMP pathway components are expressed at early stages of development but their role during human preimplantation development remains unknown.

Study design, size, duration: Cryopreserved cleavage-stage day 3 embryos were warmed and cultured for 1, 2 or 3 days with human recombinant BMP4 protein (100 ng/ml) (n = 46). Control embryos (n = 42) were cultured in parallel without BMP4 supplementation.

Participants/materials, setting, methods: The experiments were approved by the Local Ethical Committee and the Federal Committee for research on human embryos. The embryos were donated for research after the legal storage period of 5 years by patients who signed an informed consent. Post-warming, the further developmental rate of the embryos was assessed in both groups. Gene expression was analyzed after 24 and 48 h of culture using qRT-PCR and immunocytochemistry. TUNEL-assay was performed after 72 h to evaluate apoptosis.

Main results and the role of chance: Supplementation of BMP4 to the culture medium significantly decreased the blastocyst rate (P < 0.01) (11.76% vs 50%). A significant increase in the amount of TUNEL positive cells was observed after 72 h of BMP4 supplementation (P < 0.01) (100% vs. 3.77%). No differences in the expression of differentiation genes were found between control and BMP4-treated embryos after 72 h. Immunocytochemistry for the ICM marker NANOG and the TE marker CDX2 was performed to confirm that BMP4 does not influence the first lineage differentiation, i.e. the segregation of the ICM and TE. Remarkably, a significant increase in *MSX2* expression (p < 0.05) after 24 h of culture and a significant decrease of *SIRT1* expression (p < 0.05) after 48 h of culture were found. MSX2 has been shown to be a transcriptional regulator in the programmed cell death pathway and SIRT1 is a deacetylase controlling P53 activity inducing the transcription of proapoptotic genes. Finally, apoptotic embryos (n = 5) expressed significantly (p < 0.05) higher levels of *BMP4* than control blastocysts (n = 5). These results suggest that BMP4 plays a role in apoptosis during early human preimplantation development.

Limitations, reasons for caution: This study is descriptive as functional studies are difficult to perform in human embryos. Currently, we do not have the possibility to knock down or over-express genes in human preimplantation embryos.

Wider implications of the findings: Comprehensive understanding of differentiation and apoptosis processes will help us to understand causes of unsuccessful human preimplantation development *in vitro* and potentially lead to predictive markers for embryos that show DNA damage, early signs of apoptosis and/or developmental arrest.

Trial registration number: /.

P-221 Influence of culture length on blastocysts implantation potential: analysis of 781 euploid blastocysts obtained in 629 PGS cycles

A. Ruberti[1], **R. Polese**[2], **M.G. Minasi**[2], **E. Cursio**[2], **A. Colasante**[2], **V. Zazzaro**[2], **P. Greco**[2], **C. Mencacci**[2], **M.T. Varricchio**[2], **F. Spinella**[3], **A. Biricik**[3], **F. Fiorentino**[3], **E. Greco**[2]

[1]European Hospital, Medicina della Riproduzione, Rome, Italy
[2]European Hospital, reproductive medicine, Rome, Italy
[3]genoma, Molecular Genetics Laboratory, Rome, Italy

Study question: Does the time required to reach blastocyst stage influence the implantation potential?

Summary answer: It seems that the time needed to reach the blastocyst stage is deeply linked to the embryo implantationpotential in an inversely proportional trend

What is known already: Embryo morphology has always been considered an important predictor of successful implantation andpregnancy. However, the Preimplantation Genetic Screening (PGS) technology proved that this parameterseems to have quite low predictive value on implantation potential. Few studies focused on the comparisonof pregnancy rates obtained with blastocysts vitrified on day 5 or day 6, demonstrating that the latter havea statistically significant lower value. Until now little is known if the clinical outcomes could be differenttransferring an euploid embryo obtained after 5, 6 or 7 days of culture.

Study design, size, duration: In this retrospective study, 781 cryopreserved euploid blastocysts obtained in 629 PGS cycles weretransferred in single frozen-mbryo transfers performed from April 2011 to October 2016. All blastocystswere biopsied and vitrified on day-5,- 6 or -7 of culture (BD5, BD6, BD7 groups); blastocysts were furtherdivided on the basis of their quality in A, B and C grades. Clinical pregnancy (CP), advanced pregnancy (over3 months) (AP) and abortion rates were compared between the groups.

Participants/materials, setting, methods: Mean female age was 35.7 ± 3.96 years. In order to classify the blastocysts on the basis of their morphology,the

expansion grade, the inner cell mass (ICM) and the trophoectoderm (TE) quality were analyzed. Grade-A included expandend blastocysy and good or very good ICM and TE quality; grade-B included notexpanded blastocysy and good or very good ICM and TE quality; grade-C included all expansion grades andpoor or very poor ICM and TE quality.

Main results and the role of chance: Out of the 746 analyzed blastocysts, 463, 287 and 31 were in BD5, BD6 and BD7 groups, respectively. InBD5, 122 (26.3%) grade-A, 259 (55.9%) grade-B and 82 (17.7%) grade-C blastocysts were obtained. In BD678 (27.2%) grade-A, 88 (30.7%) grade-B and 121 (42.2%) grade-C blastocysts were obtained. In BD7, 7(22.6%) grade-A, 1 (3.2%) grade-B and 23 (74.2%) grade-C blastocysts were obtained. In BD5 grade-A,grade-B and grade-C, 66 (54.1%) 154 (59.5%) and 36 (43.9%) CP, 61 (50%), 139 (53.7%) and 29 (35.4%) APand 5 (4.1%), 15 (5.8%) and 7 (8.5%) miscarriages were obtained, respectively. In BD6 grade-A, grade-B andgrade-C, 37 (47.4%), 49 (55.7%) and 50 (41.3%) CP, 33 (42.3%), 42 (47.7%) and 42 (34.7%) AP and 4 (5.1%),7 (7.9%) and 8 (6.6%) miscarriages were obtained, respectively. In BD7 grade-A, grade-B and grade-C, 2(28.6%), 1 (100%) and 6 (28.6%) CP, 2 (28.6%), 1 (100%) and 3 (13.0%) AP and 0 (0%), 0 (0%) and 4 (17.4%)miscarriages were obtained, respectively. Both CP and AP resulted higher in BD5 compared to BD6 (p = 0.03and p = 0.02, respectively) and to BD7 (p = 0.005 and p = 0.001, respectively);CP and AP resulted higher in BD6compared to BD7 (p = 0.05 and p = 0.02, respectively).

Limitations, reasons for caution: The main limitation of morphology assessment is that it is an operator-dependent static system.Furthermore, some blastocysts were already formed on the day antecedent the biopsy without reachenough expansion to perform safely the technique, therefore being cultured one day more andconsequently counted in the subsequent group.

Wider implications of the findings: Our data show a strong correlation between the day needed to reach blastocyst stage and implantationpotential. Trasferring an early (day-5) euploid blastocyst is most clinically advantageous than a blastocystobtained later (day-6 or day-7) and it should be considered when more blastocysts are available for thetransfer.

Trial registration number: Not applicable.

P-222   Adding a low-quality embryo to a high-quality embryo in embryo transfer does not improve pregnancy rates and increases multiple gestation rates

C.G. Vergouw[1]**, R.P. Berkhout**[2]**, M. Van Wely**[2]**, A.A. De Melker**[2]**, R. Schats**[1]**, S. Repping**[2]**, G. Hamer**[2]**, S. Mastenbroek**[2]**, C.B. Lambalk**[1]

[1]*VU University Medical Center, Obstetrics and Gynecology, Amsterdam, The Netherlands*
[2]*Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands*

Study question: Does the addition of a low-quality embryo in fresh day 3 embryo transfer affect ongoing pregnancy and multiple pregnancy rates in women undergoing IVF/ICSI?

Summary answer: The addition of a low-quality embryo in fresh day 3 embryo transfer does not increase ongoing pregnancy rates but increases multiple gestation rates.

What is known already: In recent years, double embryo transfer (DET) and single embryo transfer (SET) have become the most common embryo transfer strategies in IVF/ICSI. When analyzed per first transfer only, pregnancy rates after DET increase considerably compared to SET, but also multiple gestation rates increase. These conclusions are based on randomized controlled trials (RCTs) in which patients with two or more high-quality embryos were included. It is unknown whether the addition of a low-quality embryo affects ongoing pregnancy and multiple gestation rates. Given the relatively large group of patients with one or no high-quality embryo, this is an important question to address.

Study design, size, duration: Multicenter retrospective cohort study of 5050 patients receiving 7252 fresh embryo transfers on day 3 after fertilization in IVF/ICSI cycles from 2012 to 2015 in two academic hospitals in Amsterdam, The Netherlands.

Participants/materials, setting, methods: Cases were women that received fresh day 3 SET or DET with any combination of high-quality embryos

(7–9 blastomeres, < 20% fragmentation) or low-quality embryos (all other embryos). Outcomes were ongoing pregnancy rate (OPR), miscarriage rate and multiple gestation rate. We used a generalized estimating equations model adjusting for age, number of oocytes and center of treatment.

Main results and the role of chance: In our database, DET with two high-quality embryos resulted in a higher OPR (OR 1.42, 95% CI 1.17–1.73), while DET with one high- and one low-quality embryo resulted in a lower OPR (OR 0.67, 95% CI 0.49–0.93) compared to SET with one high-quality embryo. However, SET in patients that had only one high-quality embryo available resulted in a lower OPR compared to SET in patients that developed multiple high-quality embryos (OR 0.51, 95% CI 0.38–0.69). After adjusting for this con-founder we found that the difference between DET with one high- and one low-quality embryo and SET with one high-quality embryo was no longer statis-tically significant (OR 0.72, 95% CI 0.49–1.07). If only low-quality embryos were available, DET did also not increase the OPR as compared to SET with one low-quality embryo (OR 0.86, 95% CI 0.57–1.31). Multiple gestation rates were higher in all DET groups compared to both SET groups (all comparisons p < 0.0001). Meanwhile, the miscarriage rate was lower when one low-quality embryo (OR 0.52, 95% CI 0.41–0.67) or two low-quality embryos (OR 0.59, 95% CI 0.39–0.90) were transferred compared to transfer of one high-quality embryo.

Limitations, reasons for caution: Limitations to this study include the retrospective design and potential unascertained confounding factors.

Wider implications of the findings: Our study suggests that, in contrast to RCTs with high-quality embryos, in patients with one or no high-quality embryo, the addition of a low-quality embryo in embryo transfer does not improve pregnancy rates but increases multiple gestation rates. Future pro-spective studies should include embryo quality when comparing SET and DET.

Trial registration number: not applicable.

P-223   Hyaluronan enriched embryo transfer media improves Reproductive outcomes in frozen thawed cycles for couples with repeated implantation failure

C. Charulata[1]**, K. Mantravadi**[2]**, D.G. Rao**[3]

[1]*Oasis institute of reproductive medicine, Embryology, Hyderabad, India*
[2]*Oasis center for reproductive medicine, Embryology, Hyderabad, India*
[3]*Oasis center for reproductive medicine, IVF, Hyderabad, India*

Study question: Objective: To examine the effect of hyaluronan enriched embryo transfer media on reproductive outcomes in couples with failed implantations

Summary answer: Hyaluronan enriched transfer media seems to favor bet-ter ongoing pregnancy rates with reduced first trimester miscarriages in couples with history of failed implantations.

What is known already: Successful implantation requires a competent blastocyst interacting with receptive endometrial lining, followed by invasion of trophoblast. Hyaluronan, a glycosaminoglycan increases in the female repro-ductive tract at the time of implantation and helps developing 'sticky' matrix on endometrial wall, there it is postulated that media enriched with Hyaluronan may improve the implantation. We assessed the role of Hyaluronan in failed implanation group.

Study design, size, duration: Design: Retrospective study

Patients: Couples with recurrent implantation failures after two attempts of blastocyst transfers done in 2015 & 2016 were included in this study (n = 44). They were offered hyaluronan enriched embryo transfer media for their subse-quent embryo transfer. These group of women were compared against a con-trol group (n = 100) who had history of failed implantations and went ahead for subsequent transfer without hyaluronan enriched media.

Participants/materials, setting, methods: Interventions: Both groups had frozen embryos transfers at blastocyst stage. All patients had double embryo transfer. Embryos were transferred with or without hyaluronan enriched media. Reproductive outcomes in both the groups were compared

Main results and the role of chance: Results: Study group (n = 44) had a Clinical pregnancy rate was 65.9% [29/44], miscarriage rate of 4.54% (2/44)

and an ongoing pregnancy rate of 61.36% (27/44). In control group (n = 100) clinical pregnancy rate was 62% [62/100], 19% miscarriage rate (19/100) and an ongoing pregnancy rate of 43% (43/100). Statistical significance was noted with miscarriage rates and ongoing pregnancy rates (p values - 0.02 and 0.04 respectively).

Limitations, reasons for caution: Smaller size of study group.

This study did not look at live birth rates as the results are still pending. It would be interesting to see if use of hyaluronan can improve take home baby rates.

Wider implications of the findings: Considering the reduced miscarriage rates in study group, it would be interesting to explore the role of hyaluronan enriched transfer media in RPL women.

Trial registration number: Not Applicable.

P-224 Morphological grade impact on clinical outcomes in single or double blastocyst transfers

C. Jacobs[1], K. Martins[1], F. Mendez[1], J. Fioravanti[2], E. Motta[3], T. Bonetti[4], P. Serafini[5], J.R. Alegretti[6]

[4]Huntington Medicina Reprodutiva / Universidade Federal de Sao Paulo, Scientific Director / Gynecology Endocrinology Discipline- Gynecology Department, Sao Paulo, Brazil
[5]Huntington Medicina Reprodutiva / Universidade de Sao Paulo, Clinical Director / Gynecology Discipline- Obstetrics and Gynecology Department, Sao Paulo, Brazil
[6]Huntington Medicina Reprodutiva, Embryology Director, Sao Paulo, Brazil

Study question: Are there advantages in transferring two blastocysts, being a top-quality and a poorer-quality one, compared to one top-quality blastocyst transfer?

Summary answer: Transferring a poorer quality embryo with a top-quality one does not increase the pregnancy rate, but leads to high multiple pregnancy rate.

What is known already: Multiple births and its consequences are major adverse effects in IVF treatments. Decreasing the number of embryos transferred (ET) is effective in minimizing those risks. However, transferring more embryos supposing it would increase the chances of pregnancy turns the double embryo transfer (DET) a common worldwide approach. The challenge of single embryo transfer (SET) is the selection of embryos with higher development and pregnancy potential. On the other hand, extended embryo culture until blastocyst stage, associated to morphological classification, has been considered effective to select top-quality (TQ) blastocysts for transfer, leading to higher implantation and pregnancy rates.

Study design, size, duration: This cross-sectional study included fresh IVF cycles with one or two blastocysts transferred, performed from 2014–2016. Cycles with donated oocytes, preimplantacional genetic diagnosis and cleavage embryos transfers were excluded. Three groups were analyzed according to number and quality of blastocyst transferred: 58 cycles with one TQ blastocyst transferred (Group TQ-SET); 176 cycles with two blastocyst transferred - one TQ and one poor-quality (Group Mixed-DET); and 223 cycles with two TQ blastocyst transferred (Group TQ-DET).

Participants/materials, setting, methods: Ovarian stimulation and oocyte retrieval were performed using standard protocols. All case were submitted to ICSI and extended embryos culture was placed as routine. The blastocysts were classified according to Gardner and those containing at least one grade A score, in trophectoderm or inner cell mass, were considered TQ. The fresh blastocyst transfers were done at day 5 following routine protocols, and clinical pregnancy was confirmed by the presence of gestational sac with fetal heartbeat.

Main results and the role of chance: The groups were compared to women age (TQ-SET: 34.6 ± 3.6, MIXED-DET: 34.3 ± 3.1, TQ-DET: 34.3 ± 3.4; p = 0.830), number of oocytes recovered (TQ-SET: 9.0 ± 5.4, MIXED-DET: 10.7 ± 5.2, TQ-DET: 12.5 ± 5.2; p < 0.001), fertilization rate

(TQ-SET: 78.5%, MIXED-DET: 80.2%, TQ-DET: 81.8; p = 0.287) and blastocyst formation rate (TQ-SET: 53.5%, MIXED-DET: 58.0%, TQ-DET: 64.6; p < 0.001). Despite the number of oocytes recovered and blastocyst formation rate had been higher in TQ-DET, all groups were considered clinically good ovarian responders and had satisfactory blastocyst formation with at least one TQ blastocyst for transfer. The implantation rates were slight lower in the MIXED-DET group (31.8%) compared to TQ-SET (44.8%; p = 0.079) and TQ-DET (40.5; p = 0.081), and the clinical pregnancy rates were similar between groups TQ-SET (44.8%) and MIXED-DET (49.4%; p = 0.542), but it was higher in the TQ-DET (59.6%) compared with both TQ-SET (p = 0.043) and MIXED-DET (p = 0.042). The multiple pregnancy rates were extremely lower in the TQ-SET (3.8%) compared to MIXED-DET (31.0%; p < 0.001) and TQ-DET (38.9%; p < 0.001). The groups MIXED-DET and TQ-DET were not statistically different for multiple pregnancy rates (p = 0.238).

Limitations, reasons for caution: Besides the group TQ-SET had a reduced sample size, part of patients had just one blastocyst available for transfer and had no choice about transferring one or two embryos. However, all embryos transferred in that group were TQ, which is considered good prognosis.

Wider implications of the findings: When at least one TQ-blastocyst is available, SET should be considered. The presence of a second poorer-quality blastocyst won't improve the clinical pregnancy rate, but will significantly increase multiple gestations. While adding a second TQ-blastocyst will result in slightly higher pregnancy chance, with almost 40% of multiples.

Trial registration number: not applied.

P-225 Pre-clinical validation of the meiotic spindle transfer technique in the mouse model

E. Mestres, I. Vanrell, M. Garcia-Jimenez, G. Calderon, N. Costa-Borges

Embryotools, R&D Center, Barcelona, Spain

Study question: What is the impact of the meiotic spindle transfer technique in the viability of the reconstructed oocytes and their further potential to develop after insemination?

Summary answer: The MST technique does not affect the potential of oocytes to develop up to blastocyst. MST can even ameliorate embryo development in sensitive mouse strains.

What is known already: Mitochondrial replacement techniques have been proposed as a strategy to avoid the inheritance of mutated mitochondrial DNA (mtDNA). Through MST, genomic DNA (structured as a meiotic spindle in MII oocytes) is transferred from an affected oocyte into a previously enucleated healthy one. A recent clinical application of this technique has resulted in the birth of the world's first child born using this technology. However, there are still safety concerns about the usage of this technique, and thus more research is needed to evaluate e.g. the levels of cytoplasmic carry-over during manipulation, as well as oocyte viability to develop after MST.

Study design, size, duration: In a first series of experiments, B6CBAF1 mouse oocytes (n = 214) were subjected to reciprocal MST and inseminated by ICSI. Potential cytoplasmic carryover was estimated by volumetric measurements of karyoplasts. Spindle morphology was evaluated by fluorescence analysis in oocytes after MST and controls.

In a second series of experiments, strains with diverged mitochondrial haplotypes, hybrid B6CBAF1 and NZB, were used to perform MST as a proof-of-concept for this technique (n = 302). After ICSI, embryo development was followed.

Participants/materials, setting, methods: Oocytes were collected from superovulated females (6–10 weeks old). MST was performed in manipulation medium supplemented with cytochalasin B (5 µg/ml). After enucleation, karyoplasts were exposed for 10 seconds to an inactivated sendai virus solution to promote membrane fusion, and immediately placed into the perivitelline space of a previously enucleated donor oocyte. Karyoplast-cytoplast fusion was assessed by 1-2 h, and ICSI performed using Piezo-Drill actuator. Blastocysts were analyzed by fluorescence to calculate their total cell number.

Main results and the role of chance: High survival (95.3%) and karyoplast-cytoplast fusion (98.0%) rates were observed after reciprocal MST among B6CBAF1 oocytes. Survival rates after ICSI were not statistically different

between reconstructed and control oocytes (91.0% and 95.4%, respectively; p = 0.368). Similarly, blastocyst formation rates were statistically equivalent between MST and control groups (89.0% and 87.1%, respectively; p = 0.800). However, blastocysts (n = 75) derived from reconstructed MST oocytes showed a slightly decreased total number of cells compared to controls (177 ± 28 and 202 ± 26, respectively; p = 0.0007). All analyzed oocytes in control and test group presented a morphologically normal spindle, defined as bipolar, barrel-shaped and with aligned chromosomes in the MII plate.

Embryo development was compared between B6CBAF1 and NZB control groups, after insemination with fresh sperms obtained from the cauda epididymis of B6CBAF1 males. Blastocyst formation rate in control NZB group (n = 76) was significantly lower (5%) when compared to control B6CBAF1 (n = 46) (72%; p < 0.0001). Interestingly, when the meiotic spindle was transferred from NZB oocytes into previously enucleated B6CBAF1 oocytes that were subsequently inseminated by ICSI (n = 106), blastocyst developmental rates significantly increased up to 35% (p < 0.0001). These results suggest that MST could help overcome cytoplasmic-related deficiencies, in this case represented by the NZB control group.

Limitations, reasons for caution: Levels of mtDNA carry-over during MST should be evaluated through molecular analysis. Control and MST blastocysts should be compared in their potential to establish ESCs and develop *in vivo*. To assess whether heteroplasmy levels remain low after MST, these will be compared between ESCs and MST-generated mice in further studies.

Wider implications of the findings: Here, we demonstrate that MST among sibling B6CBAF1 oocytes does not affect oocyte potential to develop *in vitro*. Actually, in the sensitive NZB strain, MST can improve blastocyst development. If proved true in humans, MST could help on overcoming not only mitochondrial-inherited diseases, but also infertility caused by ooplasmic defects.

Trial registration number: Not applicable.

P-226   Morphokinetics analysis and reproductive outcome after Assisted Oocyte Activation with Calcium Ionophore. Multicentric Retrospective Analysis

J. Aguilar Prieto[1], L. Alegre[2], Z. Larreategui[3], E. Muñoz[4], M. Perez[1], M. Meseguer[2]

[1]IVI Vigo, IVF Laboratory, Vigo, Spain
[2]IVI Valencia, IVF Laboratory, Valencia, Spain
[3]IVI Bilbao, IVF Laboratory, Bilbao, Spain
[4]IVI Vigo, Gineacology, Vigo, Spain

Study question: Does ICSI with Assisted oocyte activation (AOA) affect embryo morphokinetics and reproductive outcomes in patients with previous fertilization failure?

Summary answer: Sperm microinjection with Calcium ionophore (ICa) improves reproductive outcomes in patients after fertilization failure and also affects morphokinetics of the early stages of embryo development.

What is known already: AOA with ICa in patients with fertilization failure after ICSI, have shown good results, although the number of reported patients and oocytes studied remain low. On the other hand, the use of morphokinetics parameters for improve embryo selection using algorithms have been widely studied recently, and have offered greater implantation rates when applied in certain groups of patients.

Study design, size, duration: Multicentric retrospective study of 756 oocytes from 93 patients who underwent previous ICSI with fertilization failure (less than 20% normally fertilized oocytes) and severe male factor (ICa group) which were compared to 748 oocytes from 79 patients also with severe male factor (Control Group), without previous fertilization failure between January 2011 and October 2016 in three different clinics

Participants/materials, setting, methods: AOA was performed by injecting the oocytes with spermatozoa in a buffered media with Ica (Ionomicyn from *Streptomyces conglobatus*). Later, they were incubated for twenty minutes with fertilization media and ICa in a 37°C, 6%CO2 atmosphere. Embryo culture was performed in an incubator provided with time-lapse monitoring system under a 37°C, 6%CO2, 5% O2 atmosphere Fertilization, direct cleavage, pregnancy, implantation rates, abortion and embryo morphokinetics, were analysed.

X^2, and ANOVA tests were employed when applicable.

Main results and the role of chance: Statistically significant differences were found in normal fertilization rate, being higher in control group (51.2% vs. 64.7%). Additionally higher triploid proportion and degenerated oocytes were observed in Ica group. No differences among groups were found in the frequencies of direct cleavage events. Similar pregnancy, implantation and abortion were obtained between groups. Timings of cleavages were significantly lower (faster embryos) at the early stages up to 5 cells, from the third cycle and forward, embryos became similar in the development progress. It seems that ICa effect will be observable in early embryo events, and will be diluted later. This morphokinetics parameters should be taken in account for embryo selection. With the use of ICa, the chance of pregnancy, and implantation of patients with severe male factor previous fertilization failure, become similar to the those of patients with severe male factor without fertilization failure.

Limitations, reasons for caution: The embryos herein analysed in ICa were obtained from patients with severe male factor who had a previous complete fertilization failure, and were compared to embryos from severe male factor patients, what may suppose that the conclusions reached may not be applicable for patients with other ethyologies.

Wider implications of the findings: Our findings describe primarily the effect of Ica on embryo development under AOA with Ica and demonstrate the utility of this strategy after fertilization failure.

Trial registration number: 'not applicable'.

P-227   Mechanical vs laser collapse of blastocysts prior to vitrification

Z. Brame[1], H. Williams[1], S. Gadd[1], S. Bennett[1], E. Napier[1], D. Walker[2], N. Sharp[2]

[1]Bath Fertility Centre, Embryology, Bath, United Kingdom
[2]Bath Fertility Centre, Bath Fertility Centre, Bath, United Kingdom

Study question: Is there a difference in embryo survival and clinical outcome of frozen embryo transfer (FET) between blastocysts vitrified after either mechanical or laser collapse?

Summary answer: Despite a trend towards improved outcomes with the use of a laser, no significant differences were found when comparing mechanical vs laser collapse of blastocysts.

What is known already: Artificial collapse of blastocysts prior to vitrification has shown to improve embryo survival rates by reducing the risk of ice crystal formation as a result of fluid evacuation from the blastocoel. Laser collapse of blastocysts has been shown to significantly improve blastocyst survival rate, implantation rate (IR) and clinical pregnancy rate (CPR) compared to non-collapsed controls (Darwash E & Magdi Y, 2016). When comparing laser collapse to mechanical shrinkage of blastocysts, however, there has shown to be no difference in blastocyst survival rate, IR and CPR (Cao S *et al*, 2014).

Study design, size, duration: This was a retrospective analysis of FET treatment cycles undertaken from June 2014 to December 2016. Study Group 1 (n = 193) utilised mechanically collapsed blastocysts vitrified between May 2014 – August 2015. Study Group 2 (n = 137) utilised laser collapsed blastocysts vitrified between September 2015 – August 2016.

Participants/materials, setting, methods: All blastocysts were vitrified using the same methodology: Irvine Scientific VitKit with HSV straws. Mechanical collapse was carried out by inserting an ICSI injection pipette into the blastocoel cavity. Laser collapse was undertaken using the RI Saturn 5[TM] Laser System. Biochemical pregnancy rate (BPR), IR and CPR was determined for each study group and statistical significance was calculated using the Fisher's exact test.

Main results and the role of chance: There was no difference in the blastocyst survival rate between the two groups (95.0% and 96.9% for mechanical and laser collapse respectively). Although there appeared to be a trend towards better clinical outcomes with the laser group, these did not reach statistical significance (BPR/ET = 43.5% vs 53.3%; IR = 31.0% vs 40.1%; CPR/ET = 32.6% vs 42.3% for mechanical vs laser collapse respectively).

Limitations, reasons for caution: Data for group 1 crossed a broader time period and had a greater number of cycles than group 2. The different techniques for blastocyst collapse were not carried out concurrently.

Wider implications of the findings: This study shows that there is no detriment to using one method of artificial collapse over the other. However, use of

a laser is more time efficient and, as a result, the time blastocysts are required to remain outside the incubator environment is reduced, minimising additional stress to the embryo.

Trial registration number: not applicable.

P-228 Impact of low versus atmospheric oxygen tension on embryo development at cleavage and blastocyst stages: Intermediate results of a prospective randomized blinded study

P. Maurin[1], C. Herbemont[1], I. Cedrin-Durnerin[2], N. Sermondade[1], J. Boujenah[2], C. Sonigo[2], M. Grynberg[2], C. Sifer[1]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, Bondy, France
[2]Hôpital Jean Verdier, Médecine de la Reproduction, Bondy, France

Study question: Is embryo development influenced by oxygen tension applied during culture? If yes, are both cleavage and blastocyst stages vulnerable to oxidative stress?

Summary answer: Hypoxia during embryo culture improves embryo quality and development ability. However, late pre-implantation embryo development seems to be less vulnerable to oxidative stress.

What is known already: In mammals, uterine environment is at low oxygen concentration (2–8% O_2). Then, culturing human embryos under 2–8% O_2 is recommended by ESHRE revised guidelines for good practices in IVF labs. Hence, hypoxia (5% O_2) seems to improve embryo quality at cleavage and blastocyst stages, presumably by reducing damages of oxidative stress. Nevertheless, recent meta-analyses concluded with a very low evidence to a superiority of hypoxia on IVF/ICSI outcomes. Furthermore, a study on mouse embryos suggested an impact of oxidative stress only at cleavage stage. This hypothesis has still never been investigated in humans.

Study design, size, duration: From January to December 2016, 132 IVF/ICSI cycles were included in this prospective randomized blinded study. Each cycle was randomly allocated to: group A (culture from day-0 to day-6 under 20% O_2; n = 42 cycles), group B (culture from day-0 to day-6 under 5% O_2; n = 49 cycles) or group C (culture from day-0 to day-2 under 5% O_2, switched to 20% O_2 from day-2 to day-6; n = 41 cycles).

Participants/materials, setting, methods: Inclusion criteria were: IVF/ICSI using fresh/frozen ejaculate from the male partner; female age < 40 years; absence of hydrosalpinx; ≥8 cumulus-oocyte complexes retrieved. After randomization, oocytes were fertilized and cultured in similar benchtop incubators (G-210, K-Systems®, Denmark), either under 5 or 20% O_2. Fertilization rate, cleavage-stage quality (good-quality at day-2 defined as 3–5 blastomeres, < 20% cytoplasmic fragmentation), blastocyst quality (top-quality: ≥B4AA/AB/BA (Gardner and Schoolcraft's classification)) and implantation rate were compared between groups A, B and C.

Main results and the role of chance: We analyzed our preliminary data. Patients' and cycles characteristics were similar between each group. Culture under hypoxia resulted in significantly higher good-quality embryo rates at day-2 (71.5%) than under atmospheric conditions (63.6%; p = 0.03). Considering blastocyst development, culture under 20% O_2 (group A) yielded a significantly lower top-quality blastocyst rate per cleaved embryo at day 5 (7.6%), when compared with both groups B (18.8%; p < 0.05) and C (15.8%, p < 0.05). Similarly, cumulative top-quality blastocyst rate per embryo at day 5+6 was lower in group A (A: 8.4% vs. B: 19.8%, p < 0.05; and vs. C: 16.3%, p < 0.05). Interestingly, no difference was observed in terms of blastocyst quality between groups B and C (p = 0.30). Implantation rates were similar in groups A, B and C (39.7% vs. 36.3% vs. 31.3%, respectively; Global p value = 0.60).

Limitations, reasons for caution: Embryos were not analyzed using morphokinetic parameters, which could have made the interpretation less subjective. Besides, the study being still in progress, these results are preliminary and need to be confirmed and completed with clinical outcomes.

Wider implications of the findings: If confirmed, these results could encourage to systematically culture embryos under hypoxia during early development stages, before embryonic genome activation. However, late preimplantation stage appearing less vulnerable to oxidative stress, atmospheric oxygen tension could be applied from day-2 to day-6 without impairing blastocyst quality.

Trial registration number: ID-RCB: 2015-A02019-40

P-229 Transcriptomic changes derived from Assisted Reproductive Technologies (ART) can be decreased by reproductive fluids in the swine model

S. Canovas[1], E. Ivanova[2], S. Garcia-Martinez[1], R. Romar[1], S. Andrews[3], G. Kelsey[2], P. Coy[1]
