Abstracts

37th Virtual Annual Meeting of the
European Society of
Human Reproduction and Embryology,
26 June to 1 July 2021

The abstracts are available on-line to all Human Reproduction/Update/Molecular Human Reproduction subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals.org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference.

The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers.

Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results.

The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

O-001 Delay in IVF treatment up to 180 days does not affect pregnancy outcomes in women with diminished ovarian reserve

P. Romanski[1], P. Bortoletto[1], Z. Rosenwaks[1], G. Schattman[1]

[1]The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine/ Weill Cornell Medical Center, NewYork-Presbyterian Hospital/Weill Cornell Medical Center, New York, U.S.A.

Abstract text

In clinical practice, infertility treatment delays can occur due to medical, logistical, or financial reasons. Concerns over treatment delays were brought to the forefront in March 2020 when the SARS-CoV-2 pandemic prompted both the ESHRE and ASRM to recommend the suspension of new infertility treatment cycles. At the time, little was known about the risk of viral transmission on reproductive health and necessary medical resources urgently needed to be reallocated to the front lines of the pandemic. These society recommendations were met with resistance from some clinicians and patients that raised valid concerns about whether delaying IVF treatment for a few months could negatively affect pregnancy outcomes.

To help answer this question, we designed a retrospective cohort study to assess whether a delay up to 180 days in initiating IVF treatment affects pregnancy outcomes in infertile women with diminished ovarian reserve. This population was selected because their treatment outcomes were the most likely to affected by treatment delays due to the continuous decline in ovarian reserve over time. Infertile women treated at our IVF center were included if they had diminished ovarian reserve and started an ovarian stimulation cycle within 180 days of their initial consultation that resulted in an oocyte retrieval with planned fresh embryo transfer between 1 January 2012 and 31 December 2018. Diminished ovarian reserve was defined as an anti-Mŭllerian hormone (AMH) <1.1 ng/mL.

In total, 1,790 patients met inclusion criteria (1,115 immediate and 675 delayed treatment). Each patient had one included cycle and no subsequent data from additional frozen embryo transfer cycles were included. Since all cycle outcomes evaluated were from fresh embryo transfers, no genetically tested embryos were included. Patients were grouped by whether their cycle started 1-90 days after presentation (immediate) or 91-180 days (delayed). The primary outcome was live birth (≥24 weeks of gestation). A subgroup analysis of more severe forms of diminished ovarian reserve was performed to evaluate outcomes for patients with an AMH <0.5 and for patients >40 years old with an AMH <1.1 ng/mL (Bologna criteria for diminished ovarian reserve). Logistic regression analysis, adjusted *a priori* for patient age, was used to estimate the odds ratio (OR) with a 95% CI. All pregnancy outcomes were additionally adjusted for the number of embryos transferred.

The mean ± SD number of days from presentation to IVF start was 50.5 ± 21.9 (immediate) and 128.8 ± 25.9 (delayed). After embryo transfer, the live birth rate was similar between groups (immediate: 23.9%; delayed: 25.6%; OR 1.08, 95% CI 0.85-1.38). Additionally, a similar live birth rate was observed in a subgroup analysis of patients with an AMH <0.5 ng/mL (immediate: 18.8%; delayed: 19.1%; OR 0.99, 95% CI 0.65-1.51) and in patients >40 years old with an AMH <1.1 ng/mL (immediate: 12.3%; delayed: 14.7%; OR 1.21, 95% CI 0.77-1.91).

Overall, we observed that a delay in initiating IVF treatment up to 180 days does not affect the live birth rate for women with diminished ovarian reserve when compared to women who initiate IVF treatment within 90 days of presentation. This observation persisted for patients who in the highest-risk categories for poor response to ovarian stimulation. Providers and patients should be reassured that when a short-term treatment delay is deemed necessary for medical, logistical, or financial reasons, treatment outcomes will not be negatively affected.

O-002 Expanding the ovary's reproductive lifespan: Preservation and Rejuvenation

A. Pellicer[1]

[1]IVIRMA- Rome, Reproductive Medicine, Rome, Italy

Study question: The ovary has short lifespan. Genetic and pathologic alterations make it shorter. Moreover, many women delay fertility requiring expanded ovarian function. Can be realistically achieved?

Summary answer: The reproductive lifespan of the ovary can be expanded to a certain extent in physiologic and pathologic (premature ovarian insufficiency (POI)) conditions.

What is known already: In ovaries functioning in physiologic conditions, oocyte cryopreservation (OC) is an established method to expand the reproductive lifespan allowing women to postpone fertility without compromising oocyte's performance. In oncology, ovarian tissue cryopreservation/ ovarian tissue transplantation (OTC/OTT) and OC are widely employed. In POI patients, there are resting follicles in 1/3 of patients. Different techniques have been developed to "awake" these follicles. Some surgical procedures disrupt Hippo signaling to induce primordial follicle growth; , others intend to employ the growth factors contained in blood; some others use bone marrow-derived stem cells to reach similar goals.

Study design, size, duration: A literature search was done to identify the most recent and informative studies on the different techniques applied to increase the reproductive lifespan of the ovaries, including those clinically available, such as OC, and others still considered experimental, such as OCT/OTT, injection of platelets-enriched plasma (PRP), culture-free in vitro activation(CF-IVA), and autologous stem cell ovarian transplantation (ASCOT).

Participants/materials, setting, methods: Outcome of 641 healthy women performing OC and ART cycles. In oncology, OC in 80 women and OTC/OTT in 285 patients willing to conceive was analyzed. Both techniques were compared in the same setting in oncology : 1024 undergoing OC and 800 performing OCT. In POI, we analyzed the outcome of 304 women after PRP; 11 undergoing CF-IVA; and 28 ASCOT patients. The most relevant experimental techniques were also analyzed to understand future directions.

Main results and the role of chance: When it comes to expanding the reproductive function in physiologic conditions, mostly due to delay in childbearing, the follow-up of 641 women out of 1073 who underwent OC and subsequent embryo transfer (ET) has shown 68.8% cumulative live birth rates (C-LBR). Age matters because C-LBR decreased >50% after age 35 yrs. If only the endocrine function of the ovary is considered, OCT/OTT has consistently shown almost 86% efficacy.

In Oncology, OC provided 42.1% C-LBR in 80 individuals after cure, while the follow-up of 285 women from 5 different centers after OCT/OTT yield 26% LBR. Both OC and OTT were compared in the same setting and OC proved to be slightly better, with 32.6% LBR as compared to 22.8% in OCT/OTT.

Regarding POI, the use of intraovarian PRP injection in 304 women displayed 8% LBR; CF-IVA 36.3% LBR in 11 women; and ASCOT 10% LBR in 10 POI patients and 27.8% in 18 poor responders (PR).

Experimental data suggest that a combination of ASCOT and PRP must be the best alternative to activate dormant follicles in POI women.

Limitations, reasons for caution: None of the studies was a RCT, and many had not controls, most are descriptive. Regarding oncology patients OC is save and reassuring. The experience shows that OCT/OTT is also safe, although some Scientific Societies label OCT/OTT still as experimental. All the techniques employed in POI are experimental yet.

Wider implications of the findings: Expanding the reproductive lifespan of the ovary in health and disease (oncology and others) employing OC is a routine; OCT/OTT can be also applied to expand the endocrine function of the ovaries. The best and less invasive method to activate follicles in POI and PR still needs to be defined.

[8]University of Western Australia, Medical School- Division of Internal Medicine and Curtin University Faculty of Health Sciences, Perth, Australia ;
[9]University of Western Australia, Medical School- Division of Obstetrics and Gynaecology and Fertility Specialists of Western Australia, Perth, Australia

Study question: Is the cardiometabolic health of adolescents conceived through ART worse than that of their spontaneously-conceived counterparts?

Summary answer: The majority of cardiometabolic and vascular health parameters of ART-conceived adolescents are more favourable than those of their spontaneously-conceived counterparts of similar age.

What is known already: It has been proposed that ART induces epigenetic alterations during embryonic development which could lead to cardiometabolic disease later in life. However, individuals requiring ART may themselves be metabolically less healthy than the general population, which could lead to a genetically increased risk of cardiometabolic disorders in the offspring, rather than the ART procedure. The literature pertaining to cardiometabolic health of ART-conceived offspring is contradictory, but generally suggests unfavourable cardiometabolic health parameters. With over 8 million children and adults born through ART worldwide, it is imperative to investigate whether early signs of adverse cardiometabolic differences persist into adolescence and beyond.

Study design, size, duration: The Growing Up Healthy Study (GUHS) is a prospective study that recruited 303 ART-conceived adolescents, born 1991-2001 in Western Australia. Their health parameters, including cardiometabolic factors, were assessed and compared with spontaneously conceived counterparts of similar socioeconomic background and age from the Raine Study Generation 2 (Gen2). The 2868 Gen2 participants were born 1989-1992 and are representative of the Western Australian adolescent population. At age 16-17 (2013-2017), GUHS participants replicated assessments previously completed by Gen2.

Participants/materials, setting, methods: Cardiometabolic parameters were compared between 165 GUHS (male=50.9%) and 1690 Gen2 (male=49.8%) adolescents. Assessments consisted of a detailed questionnaire; health and demographic parameters, anthropometric assessments; height, weight, body-mass index (BMI), waist circumference and skinfold thickness, fasting serum biochemistry, arterial stiffness and blood pressure assessment using applanation tonometry, assessment of non-alcoholic fatty liver (NAFLD) and thickness of abdominal fat compartments using ultrasonography. Chi^2, Fisher's Exact and Mann-Whitney U tests, performed in SPSS V25, examined cohort differences.

Main results and the role of chance: GUHS adolescents appeared to be healthier from a cardiometabolic perspective than their Gen2 counterparts. They were leaner, with lower BMI (median: 21.23 vs. 22.06, P=0.004), lower waist circumference (median: 74.10 vs. 76.75 cm, P=0.031), and thinner skinfolds (triceps median: 12.1 vs. 14.0 mm, P=0.019, subscapular median: 10.6 vs. 11.9 mm, P<.001, mid-abdominal median: 16.0 vs. 19.9 mm, P<0.001, supraspinal median: 10.7 vs. 13.5 mm, P<0.001). No significant differences were detected in the following serum fasting parameters: glucose, insulin, HOMA-IR, LDL cholesterol, total cholesterol, cholesterol/HDL-ratio, triglycerides, CRP and ALT. HDL cholesterol levels were more favourable in GUHS (P<0.001). NAFLD was present in 10.9% of GUHS vs. 15.2% of Gen2 adolescents (P=0.174), with no difference in steatosis severity score (P=0.309). ART offspring had less subcutaneous adipose tissue (median: 8.0 vs. 14.0 mm, P<.001), more visceral adipose tissue (median: 40.0 vs. 32.0 mm, P<0.001), with no difference in pre-peritoneal adipose tissue (P=0.087). Measures of arterial stiffness were lower in GUHS. Pulse wave velocity: median 6.1 vs. 6.4 m/s, P<0.001 and heart rate corrected augmentation index: median -10.25 vs. -8.00, P=0.006. No significant differences in blood pressure or heart rate were detected. Stratification by sex did not greatly alter the results.

Limitations, reasons for caution: Despite the substantial study size and the unique study design, we were unable to differentiate between different types of ART (e.g. IVF vs. ICSI), draw definite conclusions or relate outcomes to cause of infertility. Given the observational character of this study, causation cannot be proven.

Wider implications of the findings: In this study we did not detect any adverse effect of ART on cardiometabolic health at adolescence, in contrast to some studies. Given the lack of consensus, future well-designed and appropriately-powered studies are necessary to investigate cardiometabolic health in ART adults.

Trial registration number: not applicable

O-073 Perinatal outcomes of infants conceived using partner versus donor sperm - An analysis of singleton and twin pregnancies from the UK national dataset

C. Allen[1], D. McLernon[1], S. Bhattacharya[1], A. Maheshwari[1]

[1]University of Aberdeen, Applied Health Sciences, Aberdeen, United Kingdom

Study question: Are perinatal outcomes different in pregnancies conceived using donor sperm compared with those with partner sperm?

Summary answer: The perinatal outcomes of singleton and twin pregnancies conceived with donor sperm are better when compared to those conceived with partner sperm

What is known already: There has been a substantial increase in the use of donor sperm in the last 15 years across the world. A recent systematic review and meta-analysis has suggested that there is an increased risk of hypertensive disorders of pregnancy and small for gestational age babies from ART treatment using donor sperm compared to partner`s sperm. This meta-analysis was limited due to poor quality of primary studies often with small sample sizes.

Study design, size, duration: This is a retrospective cohort study on 196,293 singleton and 46,275 twin pregnancies from the Human Fertilisation

and Embryology Authority (HFEA) anonymised dataset including all live births from 1991 to 2016. Outcomes were preterm birth (< 37 weeks); very preterm birth (<32 weeks); very low, low, high and very high birth weight (<1500g, <2500g, >4000g and >4500g respectively); congenital anomaly and healthy baby (term live birth with appropriate weight and no congenital anomaly).

Participants/materials, setting, methods: All pregnancies resulting in singleton or twin livebirth were included. Any cycle involving donor oocytes, PGD, gamete intra-fallopian transfer, ectopic pregnancy, miscarriage, stillbirth, or termination was excluded. Logistic regression and generalised estimating equations were used for analysis of singletons and twins, respectively. Odds ratios (aOR) with 95% confidence intervals (CI) for donor versus partner sperm were adjusted for maternal age, previous pregnancy, cause of infertility and year for all outcomes plus gestational age for birthweight.

Main results and the role of chance: Baseline characteristics for donor and partner sperm pregnancies were assessed for singleton and twin livebirths separately. In both analyses there were significant differences between donor and partner sperm pregnancies in terms of maternal age, previous pregnancy status and cause of infertility.

Analysis of singleton births demonstrated an increased odds (aOR, 95% CI) of having a healthy baby (1.09, 1.05 - 1.12) and reduced odds of congenital anomaly (0.34, 0.29 - 0.39), very preterm birth (0.66, 0.58-0.75), preterm birth (0.81, 0.76-0.86), low birthweight 0.89 (0.83 - 0.96) in singleton births using donor sperm compared with those using partner sperm. There was, however, an increased odds of high birthweight (1.10, 1.05 - 1.16) and very high birthweight (1.16, 1.05-1.29) with donor sperm pregnancies.

Analysis of twin births conceived with donor sperm also showed higher odds of having a healthy baby (1.07, 1.01 - 1.15) and lower odds of congenital anomaly (0.52, 0.39 - 0.68) compared with partner sperm. There were no statistically significant differences between the birthweight or birth gestation outcomes for twin pregnancies.

Sensitivity analysis of only cases with complete outcome data showed no significant differences when compared to the primary analysis.

Limitations, reasons for caution: This is a retrospective study of a single nation's routinely collected data. We could not adjust for confounders such as smoking, BMI and pregnancy complications such as pre-eclampsia, as they are not recorded in HFEA's dataset.

Wider implications of the findings: Patients and clinicians can be reassured that donor sperm pregnancies are not at higher risk of adverse perinatal outcomes. In fact, they are more likely to result in a healthy baby. Worldwide registries should consider including maternal data to enable a better assessment of outcomes.

Trial registration number: Not applicable

Study question: Does human embryo culture in different IVF culture media lead to DNA methylation alterations in IVF offspring?

Summary answer: Genome-wide analyses identified no significant DNA methylation differences between culture medium groups in IVF children (neonates or 9-year olds) from two culture media studies.

What is known already: During in vitro fertilisation (IVF) treatments, embryos undergo preimplantation development in an artificial environment, while concurrently undergoing epigenetic reprogramming. Adversity during this period, such as peri-conception calorie restriction, has been linked to persistent DNA methylation aberrations and increased risk of cardiometabolic disease. Early environmental adversity is suspected in IVF offspring as they are born with lower birthweights and show increased risk of cardiometabolic dysfunction in adulthood as compared to their naturally-conceived counterparts. This is further supported by the observation from two culture media trials (MEDIUM0 and MEDIUM1) that embryo culture in different culture media leads to differences in birthweight.

Study design, size, duration: We recruited singleton offspring from two IVF culture media trials. The MEDIUM0 study, a pseudo-randomized trial comparing G3 (Vitrolife) and K-SICM (Cook), was conducted from 2003-2006. At the 9-year follow-up, saliva was collected (cohort-A). The MEDIUM1 study, a multi-center randomized controlled trial comparing G5 (Vitrolife) and HTF (Lonza), was conducted from 2010-2012. Umbilical cord blood (UCB) was collected at birth (cohort-B).

Participants/materials, setting, methods: DNA methylation was analysed in 120 saliva samples (65 G3, 55 Cook) and 106 UCB samples (47 HTF, 59 G5) using the Infinium MethylationEPIC array (Illumina). Mixed effects linear models, correcting for (gestational) age, sex, sample composition and batch effects alongside maternal age, pregnancy complications and IVF centre for cohort-B, were implemented at single or aggregated sites. Methylation outliers were defined as values over three interquartile ranges below or above 25th and 75th percentiles respectively.

Main results and the role of chance: 111 of the 120 saliva samples (60 G3, 51 Cook) and 105 of the 106 UCB samples (47 HTF, 58 G5) passed our quality control criteria. We filtered sites on sex chromosomes, and based on quality, proximity to single-nucleotide polymorphisms, and proportion of missing values, leaving 650,000-700,000 of the 850,000 sites included on the EPIC array for our analyses. To account for heterogeneity in the cellular composition of our samples we estimated their cell compositions using a reference-based approach. First, we investigated individual CpG sites, finding no differentially methylated sites in either cohort after correction for multiple testing (false discovery rate adjusted p. value threshold <0.1). Sites were then aggregated into regions based on their allocations to genes, promoters and CpG islands. No differentially methylated regions were identified in either cohort. A targeted analysis of DNA methylation of imprinting genes showed no differentially methylated sites or regions. To examine the contribution of stochastic epigenetic alterations we quantified the number of methylation outliers per sample. Although this revealed a predominance of hypomethylation outliers, there was no difference in the total number or distribution of DNA methylation outliers between the two culture media groups of cohort-A and cohort-B.

Limitations, reasons for caution: This analysis is currently limited by the lack of comparison to a naturally-conceived control group. As such, we cannot yet conclude whether IVF embryo culture, in any medium, is associated with DNA methylation aberrations. Additionally, given the large number of comparisons, we may lack power to detect small differences.

Wider implications of the findings: Although there are disparities in birth weight and childhood growth after embryo culture in different media, we observed no DNA methylation alterations preserved postnatally. Whether DNA methylation of these individuals deviates from that of naturally-conceived individuals will be determined in the near future.

Study question: Do high birth weight or large for gestational age (LGS) increase the risk of serious disease later in life?
Summary answer: High birth weight and/or LGA were associated with elevated risks for certain child malignancies, breast cancer, psychiatric disorders, childhood hypertension and diabetes type 1.
What is known already: Previous studies have shown that children born after frozen embryo transfer (FET) have an increased risk of being born LGA or having a high birth weight. In recent years the practice of FET in Assisted Reproductive Technology (ART) has increased rapidly. The perinatal risks of being born LGA or with a high birth weight are well studied, however less is known about the impact on long-term health and morbidity.
Study design, size, duration: Pubmed, Scopus and Web of Science were searched until December 2020. 11 748 abstracts were screened, 172 publications were selected for systematic review and 63 for meta-analyses. The methodological quality in terms of risk of bias was assessed by pairs of reviewers. Robin-I (www.methods.cochrane.org) was used for assessing risk of bias in original articles. For systematic reviews AMSTAR was used. For certainty of evidence the GRADE system was used.
Participants/materials, setting, methods: Exposures were LGA and high birth weight. Long-term morbidity outcomes were cancer, metabolic disease, cardiovascular disease and psychiatric disorders. Cancer was focused on breast cancer, child malignancies in the central nervous system (CNS), hematological malignancies and Wilm´s tumor. Metabolic diseases included diabetes type 1 and type 2. Cardiovascular diseases were focused on hypertension and other cardiovascular disorders and psychiatric disorders on schizophrenia/psychosis and cognitive disorders.
Main results and the role of chance: Pooled Adjusted Odds Ratios (AOR) for outcome variables were compared for birth weights >4000 or >4500 g versus <4000 g. For cancer, meta-analyses showed AOR of 1.24 (95% 1.11-1.39) for development of breast cancer, AOR of 1.15 (95% CI 1.05-1.27) for development of CNS tumors, AOR of 1.29 (95% CI 1.20-1.39) for childhood leukemia and AOR 1.68 (95% CI 1.38-2.06) for Wilm´s tumor.

For metabolic disease a meta-analysis showed AOR of 1.15 (95%CI 1.05-1.26) for the association between high birth weight and type 1 diabetes.

For psychiatric diseases an association was found between high birth weight and/or LGA and schizophrenia and depression.

For cardiovascular disease, an association was found between high birth weight and hypertension in childhood with an inverse association in adulthood. No difference in the risk of coronary heart disease in adults born with high birth weight compared to normal birth

Limitations, reasons for caution: The main limitation is that all data are based on observational studies with their inborn risk of selection bias. Our conclusions are however, mainly based on meta-analyses and/or studies with low risk of bias.
Wider implications of the findings: Even though high birth weight and LGA are associated with an increased risk of serious diseases, both in childhood and in adulthood, the size of these effects seems modest. However, the identified risk associations should be taken into account in stimulation strategies and when considering fresh or frozen embryo transfer.
Trial registration number: Not applicable

O-076 Neurodevelopmental morbidity in children born after ART: a Nordic register study from the Committee of Nordic ART and Safety (CoNARTaS) group

K. Rönö[1], E. Rissanen[1], C. Bergh[2], U.B. Wennerholm[2], S. Opdahl[3], L.B. Romundstad[4], A.K. Henningsen[5], A. Pinborg[5], M. Gissler[6,7], A. Tiitinen[1]

[5]Copenhagen University Hospital- Rigshospitalet, The Fertility Clinic, Copenhagen, Denmark ;
[6]THL- Finnish Institute for Health and Welfare, Statistics and Registers Unit, Helsinki, Finland ;
[7]Karolinska Institutet, Department of Neurobiology- Care Sciences and Society, Stockholm, Sweden

Study question: Does the risk of neurodevelopmental disorders differ between singletons born after various assisted reproductive techniques (ART) and spontaneous conception (SC) until young adulthood?
Summary answer: ART children had a slightly increased rate of learning and motor functioning disorders, autism spectrum disorders (ASD), and ADHD and conduct disorders.
What is known already: Studies on the impact of ART on offspring have reported both increased risk and comparable incidences of neurodevelopmental disorders between ART and SC offspring. The most studied neurodevelopmental disorders with ART are autism spectrum disorders (ASD.) There is, however, no consensus on the risk of ASD for ART children. The risk for other neurodevelopmental disorders, like attention-deficit hyperactivity disorders (ADHD) or tic disorder among ART children, is also a debated issue, as studies are scarce.
Study design, size, duration: A Nordic register-based cohort study including all singleton live births (N = 5 076 444) after ART (n= 116 909) or SC (n = 4 959 535) between 1995 and 2014 in Denmark and Finland, 1995 and 2015 in Sweden; and 2005 and 2015 in Norway. Children with intellectual disability (ICD-10: F70-F79) are excluded. The children are followed up to young adulthood (the year 2014 in Denmark and Finland, and 2015 in Norway and Sweden).
Participants/materials, setting, methods: Offspring outcomes were defined as following ICD-10 diagnoses: learning and motor functioning disorders (F80-83), ASD (F84), ADHD and conduct disorders (F90-F92), and tic disorders/Tourette (F95). We calculated crude and adjusted hazard ratios (HR) for neurodevelopmental diagnoses using Cox regression. Adjustments were made for the country, maternal age at the delivery, parity, smoking, and maternal psychiatric morbidity.
Main results and the role of chance: The cumulative incidences of neurodevelopmental disorders in the cohort were 1.74% for F90-F92, 1.40% for F80-83, 0.66% for F84, and 0.22% for F95. In crude Cox-regression ART children had an increased likelihood during the follow-up of being diagnosed with F84 (HR 1.12 [95% CI 1.04-1.21]) and F95 (HR 1.21 [95% CI 1.06-1.38]), but not with F80-83 (HR 1.01 [95% CI 0.96-1.07]) or F90-92 (HR 0.82 [95% CI 0.77-0.86]). After adjustments the likelihood was increased for F80-83 (HR 1.20 [95% CI 1.13-1.27]), F84 (HR 1.12 [95% CI 1.03-1.24]), and F90-92 (HR 1.09 [95% CI 1.04-1.19]), but nor for F95 (HR 1.13 [95% CI 0.99-1.30]).

After adjustments, intracytoplasmic sperm injection children compared with in vitro fertilization children had similar likelihood during follow-up for F80-83 (1.06 [95% CI 0.89–1.25]), for F84 (HR 0.92 [95% CI 0.76–1.11]), for F90-92 (HR 0.96 [95% CI 0.83–1.12]), and for F95 (HR 1.16 [95% CI 0.83–1.63]).

After adjustments, frozen embryo transfer children compared with fresh embryo transfer children had similar likelihood during follow-up for F80-83 (HR 1.11 [95% CI 0.90–1.37]), F84 (HR 0.98 [95% CI 0.76–1.27]), F90-92 (HR 0.96 [95% CI 0.78–1.19]), and F95 (HR 0.83 [95% CI 0.51–1.35]).
Limitations, reasons for caution: There may be residual confounding by unknown or unmeasured confounders. We lack information on possible confounders like the reason and length of infertility, maternal substance use other than self-reported smoking status, paternal age, and parental somatic morbidity. Additional limitations are differences in registration practice and data availability between study countries.
Wider implications of the findings: This is the largest singleton cohort and the first multinational study on the risk for neurodevelopmental disorders among ART children. While the rate of some neurodevelopmental disorders was increased among ART children, the absolute risk was moderate. The type of ART did not associate with the incidence of neurodevelopmental disorders.
Trial registration number: ISRCTN11780826

O-077 Cancer risk in a nationwide cohort of children and young adults conceived by assisted reproductive technology in 1983-2012

M. Spaan[1,2,3], M. Goddijn[4], T. Roseboom[2,3], C. Lambalk[5], F. Van Leeuwen[1]

[1]Netherlands Cancer Institute, Department of Epidemiology, Amsterdam, The Netherlands ;
[2]Amsterdam UMC- University of Amsterdam, Department of Obstetrics and Gynaecology- Amsterdam Reproduction & Development research institute, Amsterdam, The Netherlands ;
[3]Amsterdam UMC- University of Amsterdam, Department of Clinical Epidemiology Biostatistics and Bioinformatics- Amsterdam Reproduction & Development research institute, Amsterdam, The Netherlands ;
[4]Amsterdam UMC- University of Amsterdam, Centre for Reproductive Medicine- Amsterdam Reproduction & Development research institute, Amsterdam, The Netherlands ;
[5]Amsterdam UMC- Vrije Universiteit Amsterdam, Department of Obstetrics & Gynecology- Amsterdam Reproduction & Development research institute, Amsterdam, The Netherlands

Study question: Are children conceived by assisted reproductive technology (ART) at increased cancer risk, compared with the general population and with non-ART conceived offspring from subfertile women?
Summary answer: Overall cancer risk was not increased in ART-conceived offspring compared with non-ART conceived offspring from subfertile women (median follow-up, 17 years).
What is known already: There is growing evidence that ART procedures could perturb epigenetic processes during the pre-implantation period. Although the results of most studies are reassuring for children born after in vitro fertilization (IVF), recent studies showed (non-)significantly increased cancer risks after intracytoplasmic sperm injection (ICSI) and frozen embryo transfer (FET). Since the proportion of children born after these techniques increased dramatically over the past decades, it is important from a public health perspective to investigate cancer risk after ICSI and FET in larger studies.
Study design, size, duration: Data were used from the OMEGA-cohort, a historical nationwide cohort with prospective follow-up in the Netherlands. Offspring of women who were treated in one of the 13 IVF clinics or 2 regional fertility centers between 1983-2012 were included. Of 98,165 live-born children, 53,154 were ART-conceived and 45,211 were non-ART conceived (conceived naturally with or without ovarian hyperstimulation) by subfertile women.
Participants/materials, setting, methods: Data on type of fertility treatment and maternal risk factors were available from medical records from the mothers and the Dutch Perinatal registry. Cancer incidence was ascertained through linkage with the Netherlands Cancer Registry. Cancer risk in ART-conceived children was compared with risk in children not conceived by ART from subfertile women (hazard ratios [HRs]) and with children from the general population (standardized incidence ratios [SIRs]).
Main results and the role of chance: The median age at end of follow-up was 17 years and was shorter in ART-conceived children (16.1 years) compared with non-ART children (19.1 years). In total, 382 cancers were observed, 166 in the ART group and 222 in the non-ART group. In preliminary analyses, overall cancer risk was not increased in ART-conceived children, neither compared with children not conceived by ART from subfertile women (HR:0.98, 95% confidence interval (CI)=0.79-1.22) nor compared with the general population (SIR:0.98, 95% CI=0.81-1.11). Risks were also not significantly increased in children conceived by ICSI or FET (HR:1.20, 95%CI=0.85-1.70; 1.25, 95%CI=0.68-2.43, respectively). From 18 years of age onwards, the HR of cancer in ART-conceived versus non-ART individuals was 1.22 (95%CI=0.86-1.74). There were no significantly increased site-specific cancer risks in ART-conceived children compared with non-ART children and the general population. Risk of lymphoblastic leukaemia was not increased in the ART group compared with the non-ART group (HR: 1.03, 95% CI=0.58-1.82).
Limitations, reasons for caution: Despite the large cohort and long-term follow-up the number of cancer cases was limited which hampered some subgroup analyses, especially for analyses according to specific cancer types and children born after FET.
Wider implications of the findings: The results from this study importantly contribute to the current knowledge about health risks in ART-offspring. Physicians may inform parents who consider ART about potential health risks for ART-conceived children. Furthermore, pediatric oncologists caring for ART-conceived children/adolescents with cancer need evidence-based information about the association between ART and cancer risk.

O-078 Predictive factors of autologous Oocyte Post-warming Survival rate

D. Montjean[1], V. Pauly[2,3], C. Geoffroy-Siraudin[1], M.J. Gervoise-Boyer[1], P. Boyer[1]

[1]Hôpital Saint-Joseph, Centre Ste Colette: Service de Médecine et Biologie de la Reproduction, Marseille, France ;
[2]Aix-Marseille Université- Faculté de médecine- Unité de recherche EA 3279, Département de Santé Publique et Maladies Chroniques, Marseille, France ;
[3]Assistance Publique Hôpitaux de Marseille, Service d'information médicale, Marseille, France

Study question: Are there any clinical or paraclinical predictive factors of Oocyte Post-warming Survival (OPS) rate?
Summary answer: Woman age, Body mass Index, estradiol level on triggering day and estradiol/oocyte ratio are critical predicting factors that should be considered before performing oocyte vitrification.
What is known already: Since the development and the validation of oocyte vitrification, we vitrify oocytes in different medical situations for patients who benefit ICSI. Although the OPS rate in our centre is satisfying, occasionally, it happens to be lower. OPS is dependent on quality of oocyte as demonstrated by the difference of OPS in oocyte donation/autologous cycles. The present study questions the existence of clinical and paraclinical factors predicting in OPS. In order to tackle this issue, we have assessed several parameters related to the woman and to her response to hormonal treatment known to influence oocyte quality in relation to OPS
Study design, size, duration: A retrospective observational study of 786 autologous oocyte vitrification cycles was performed from October 2011 to July 2018 in 5 situations: cycles where only a part of mature collected oocytes were vitrified [1] Partial oocyte vitrification program(n=605), [2] Patients opposed to embryo cryopreservation(n=2) and oocyte freeze-all cycles for the following reasons [3] Uncontrolled Ovarian hyperstimulation(=89), [4] Unfavorable uterine environment/receptivity(n=71) and [5] Absence of spermatozoa(n=20). 1175 warming cycles were analyzed to identify predictive factors for OPS.
Participants/materials, setting, methods: Oocytes were vitrified/warmed using Kitazato media and system. The ratio of OPS survival was measured between the number of intact oocytes and the number of warmed oocytes. The factors assessed as potential predictors of OPS were: woman age, body mass Index (BMI), Estradiol level on triggering day (E2), E2/ number of recovered oocytes (EOR), number of recovered oocytes and maturity ratio (number of mature oocytes/ number of recovered oocytes). Statistics were performed using SPSS software.
Main results and the role of chance: A total of 1175 studied warming cycles were performed and 5421 oocytes were warmed with a mean OPS rate of 84,6% (±22,6). OPS rates were comparable in all situations: [1] 3084/3688 (83,6%), [2] 6/6 (100%), [3] 931/1121 (83,1%), [4] 393/458 (85,8%), [5] 125/148 (84,5%). The mean woman age (33,2 years±4,9 *vs* 33,1 years ±4,3), mean woman BMI (23,1 kg/m2±3,9 *vs* 22,9 kg/m2±4,2), mean E2 (2587,7pg/ml±1140,5 *vs* 2513,2pg/ml±1098,7), mean EOR (207,5pg/ml±119,4 *vs* 196,0pg/ml ±119,4), mean number of total recovered oocytes (15,0±6,8 *vs* 14,7±6,8), mean maturity ratio (85,4%±13,7 *vs* 86,0%±14,2) showed no statistical difference in women with reduced OPS (≤85%) as compared to women with standard OPS (>85%). Subgroups analyses revealed significant higher occurrence of reduced OPS in advanced age women (>40years) (OR=2,4; [95%CI:1,3-4,4] p<0,05) as compared to women of other age categories: <30years (OR=0,5; [95%CI:0,2-0,9]), 30-35years (OR=0,4; [95%CI:0,2-0,7]), 36-40years

(OR=0,2; [95%CI: 0,3-0,5]). The combination of advanced age with abnormal BMI (<18,5 or >24,9kg/m2: OR=7,3[95%CI:1,6-34,0] p<0,01), or elevated E2 (>3000pg/ml: OR=3,3[95%CI:1,0-11,0] p<0,05) or atypical EOR (<140 or >250pg/ml: OR=3,7[1,1-12,2] p<0,05) amplified the risk of reduced OPS. Women with abnormal BMI combined with elevated E2 (OR=2,1[95%CI:1,1-3,9] p<0,05) or atypical EOR (OR=1,6[95%CI:1,0-2.6] p<0,05) were also at higher risk of reduced OPS.

Limitations, reasons for caution: Oocyte vitrification is a manual technique that depends on the skill of the operator. Inter-operator variability was not taken into account in our statistical analyses neither were data regarding ovarian stimulation protocols nor were infertility etiologies.

Wider implications of the findings: This work enabled to identify patient or treatment related factors that highly influence the outcome of oocyte vitrification/warming cycles. Our findings will likely help refining criteria for the selection of candidate patients for oocyte vitrification or to cancel bad prognosis cycles.

Trial registration number: NA

O-079 Could ovarian reserve be affected after SARS-CoV-2 infection?

M. Cruz Palomino[1], C. González-Ravina[2], A. Pacheco[3], A. Requena[1]

[1]IVI Madrid, Reproductive Medicine, Madrid, Spain ;
[2]IVI Sevilla, Andrology and General Lab, Sevilla, Spain ;
[3]IVI Madrid, Andrology and General lab, Madrid, Spain

Study question: Is there a variation in ovarian reserve in women who have passed the disease?

Summary answer: The fact of having passed SARS-CoV-2 does not affect the ovarian reserve status

What is known already: Despite the overwhelming magnitude of this pandemic and its worldwide prevalence, information regarding the effects of the novel coronavirus on human reproduction are currently limited. As the assisted reproductive technology programs resumed operations, it was important to gather information regarding the status of individuals infected with the novel coronavirus, and to assess gametes and reproductive outcomes for those who had SARS-CoV-2 virus. Since it was described the presence of receptors of the virus in the ovary, studies on the reproductive involvement of coronavirus infection are warranted, particularly within recovered patients

Study design, size, duration: During the period May-June 2020, women performing an Assisted Reproductive treatment in any of the 11 clinics belonging to the IVIRMA group in Spain and who had a positive IgG for SARS-CoV-2 were invited to participate in the study; this group of women had a previous AMH determination of no more than 6 months. The study was approved by an Institutional Review Board (2007-MADR-052-AR) and all women provided written informed consent.

Participants/materials, setting, methods: A new AMH determination was made (Elecsys® AMH, Roche Diagnostics) to detect possible variations in the hormone levels. Women were stratified in two groups, according their previous AMH levels: low responders (AMH<1 ng/ml) or normo-high responders (AMH ≥ 1 ng/ml) Statistical analyses were performed using the Statistical Package for Social Sciences 19.0 (IBM Corporation, Armonk, NY, USA).

Main results and the role of chance: After filtering by the inclusion criteria described above, we included 46 patients in this phase of the study; 16 women were diagnosed as having low ovarian reserve (AMH < 1 ng/ml), with an average age of 38.6 years, whereas 30 were classified as having normal ovarian reserve (AMH ≥ 1 ng/ml), with an average age of 34.7 years. Generally, the data show no variation in AMH levels before and after SARS-CoV-2 infection (1.73 ng/ml vs. 1.61 ng/ml, respectively). However, when we analyzed these differences according to the study groups, we observed that, in women with normal ovarian reserve, average AMH level before infection was 4.6 ng/ml, whereas after infection AMH decreased to 3.1 ng/ml. For women with low ovarian reserve, AMH was 0.8 ng/ml before infection and remained at a similar value after infection (AMH=0.7 ng/ml).

Limitations, reasons for caution: This is an observational study and thus possible confounders cannot be completely excluded. More data are needed to draw firm conclusions it will be critical to increase the sample size to check if the results observed in this work remains in the general population

Wider implications of the findings: The fact of having passed the disease does not affect the ovarian reserve status but the degree of the variation of AMH levels depending on the patient were low or high responder. Nevertheless, we could assume that the chances of success of the Assisted Reproductive treatment remain intact.

Trial registration number: Not apply

O-080 Activated AKT/mTOR signalling in peripheral blood of women with premature ovarian insufficiency and its correlation with variable FMR1 expression profiles

J. Rehnitz[1], B. Messmer[1], X.P. Nguyen[1], A. Germeyer[1], K. Hinderhofer[2], T. Strowitzki[1], E. Capp[1,3]

[1]University Women´s Hospital Heidelberg, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany ;
[2]Institute of Human Genetics- University Heidelberg, Laboratory of Molecular Genetics, Heidelberg, Germany ;
[3]Medicine School- Universidade Federal do Rio Grande do Sul, Department of Obstetrics and Gynecology, Porto Alegre, Brazil

Study question: How predictive are gene expression levels of AKT/mTOR-signalling-pathway genes in peripheral blood of patients with premature ovary insufficiency (POI) and is there a link to *FMR1*-expression?

Summary answer: *AKT1, TSC2, mTOR, S6K* and *FOXO3*-expression-levels are significantly upregulated in POI-patients and demonstrate a positive correlation with *FMR1*-expression-level in case of *mTOR-, S6K* and *FOXO3*.

What is known already: The AKT/mTOR-signalling-pathway is involved in a range of cellular functions. In female germline it regulates early follicular-activation and follicular-pool-maintenance. Over the past few years AKT-activation has been experimentally applied to induce follicular maturation in POI-patients. Additionally, first evidence of a linked *FMR1* – AKT/mTOR signaling in female germline have been reported.

FMR1 is a major control gene in folliculogenesis. Due to increased (CGG)-triplet-numbers (54<n<200) in its 5'-untranslated-region, named premutation, increased *FMR1*-expression-levels and reduced FMRP-production have been described, associated with POI in 20% of cases. A former study found premutation independent, large transcript-level-variances of *FMR1* in leukocyte RNA-samples of POI-patients.

Study design, size, duration: 74 POI patients and 56 fertile controls were prospectively enrolled in this study. Accordingly, expression levels of genes associated with the AKT/mTOR-signaling pathway and *FMR1* were analyzed and correlated on the mRNA level of their leukocytes.

Participants/materials, setting, methods: All patients provided written informed consent. mRNA was extracted from EDTA blood after lysis; quantitative expression analyses of *FMR1, AKT, mTOR, S6K, FOXO3, FOXO1* genes were performed with specific TaqMan-Assays. Statistical analyses was performed with SPSS; statistical significance was set to P<0.05.

Main results and the role of chance: Gene expression levels of *AKT1, TSC2, mTOR, S6K, FOXO3* are significant higher in POI patients compared to controls (P< 0.009 or less).

The rate of *FMR1*-expression is highly correlated with *mTOR-, S6K* and *FOXO3*-expression levels (P<0.001) in all patients, in addition. When grouped according to ovarian reserve this effect is more pronounced in POI than in control patients. Additionally, the correlation of *FMR1* with *FOXO3* remained significant only in the POI subgroup.

The upregulation of AKT/mTOR-signaling in POI may reflect a compensative mechanism in POI aiming the activation of the last remaining follicles.

The linkage of *FMR1* with AKT/mTOR-signalling in peripheral blood comparable to prior results from germline, support its putative impact on the pathogenesis of POI and other folliculogenesis related disorders, such as poor ovarian response.

Limitations, reasons for caution: Results are based on limited patient numbers. More patients, stratified for age and other risks factors, are needed to further elucidate this mechanism.

Wider implications of the findings: This is the first evidence that *FMR1* is linked to an AKT/mTOR activation in POI potentially involved in its pathogenesis. Such a marker in peripheral blood offers a perspective towards its usability as a predictive tool in the diagnostics and prognosis of POI, if results are consistent in further studies.

Trial registration number: not applicable

O-081 High variability of molecular isoforms of AMH in follicular fluid and granulosa cells from human small antral follicles

L.S. Mamsen[1], J.A. Bøtkjær[1], S.G. Kristensen[1], S.E. Pors[1], J.V. Jeppesen[2], A. Kumar[3], B. Kalra[3], E. Ernst[4], C.Y. Andersen[1]

[1]University Hospital of Copenhagen- Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark ;
[2]University Hospital of Copenhagen- Rigshospitalet, The Fertility Department, Copenhagen, Denmark ;
[3]Ansh Labs, Ansh Labs, Webster, U.S.A. ;
[4]Regional Hospital Randers, Department of Obstetrics and Gynaecology, Randers, Denmark

Study question: Is the composition of AMH isoforms different in follicular fluids (FF) and granulosa cells (GCs) from human small antral follicles?
Summary answer: There is a high viability of AMH isoforms in FFs and GCs. Even between same size follicles from the same women, the isoform composition differs.
What is known already: Anti Müllerian Hormone (AMH) is a member of the TGF-β superfamily produced by follicular granulosa cells (GCs) in women from late gestation to the end of reproductive live. AMH is suggested to inhibit aromatase (i.e. CYP19) expression and thereby decreasing the conversion of androgens to oestrogens in humans, especially in small antral follicles before dominance is achieved and thereby act as a gatekeeper of ovarian steroidogenesis. However, the exact function and processing of AMH in human follicles is still not clarified.
Study design, size, duration: This retrospective study measured AMH isoforms in human FF and GCs from small antral follicles using ELISA, Western blot, and immunofluorescence analysis. A total of 41 female adolescents and women aged 15 to 38 years (mean age: 29.7 years), who underwent ovarian tissue cryopreservation (OTC) at the University Hospital of Copenhagen, Rigshospitalet were included between year 2006 and 2020 included.
Participants/materials, setting, methods: Donated human ovarian medulla tissue were FFs and GCs were obtained in connection with OTC. The following isoforms were evaluated in FFs using ELISA analysis: full-length AMH precursor (proAMH), cleaved associated AMH ($AMH_{N,C}$), N-terminal pro-region (AMH_N), and active C-terminal (AMH_C) AMH. Antibodies specific for the N-terminal and the C-terminal AMH were used in both Western blot and immunofluorescence analysis of FFs and GCs.
Main results and the role of chance: A negative correlation between follicle diameter and the mentioned AMH forms were detected. Moreover, Western blot analysis detected various AMH forms in both FFs and GCs, which did not match the above-mentioned consensus forms suggesting an unknown proteolytic processing of AMH. The presence of these new molecular weight isoforms of AMH differs between individual follicles of identical size from the same woman.
Limitations, reasons for caution: The study group is limited and the significance of the variable AMH isoforms compositions between follicles cannot not be clarified from this data.
Wider implications of the findings: Collectively, these data suggest that intrafollicular processing of AMH is complex and variable, and thus, it may be difficult to develop an antibody based AMH assay that detect all AMH isoforms. Furthermore, the variability between follicles suggests that designing a proper standard will be difficult.
Trial registration number: not applicable

O-082 The ratio AMH/antral follicle count varies according to the etiologies of diminished ovarian reserve suggesting differences in follicular health

M. Grynberg[1], C. Lethielleux[2], V. Claire[2], I. Cedrin Durnerin[2], M. Peigné[2], S. Charlotte[3]

[1]Hôpital Antoine Béclère, Reproductive Medicine & Fertility Preservation, Clamart, France ;
[2]Hôpital Jean Verdier, Reproductive Medicine & Fertility Preservation, Bondy, France ;
[3]Hôpital Antoine Bélcère, Reproductive Medicine & Fertility Preservation, Clamart, France

Study question: Does diminished ovarian reserve (DOR) and its etiology impact the AMH/AFC ratio?
Summary answer: AMH/AFC ratio varies according to the etiology of DOR in young women, suggesting different impact on the follicular health, and further oocyte quality.
What is known already: Anti-Müllerian hormone and antral follicle count currently represent the two most accurate markers of the follicular ovarian status. Even though they may diagnose a reduction in the follicular stockpile, low values remain inefficient for predicting poor oocyte quality, in particular in young women. Since AMH is produced by the granulosa cells of follicles ranging from primary to small antral follicles, we hypothesized that the etiology of diminished ovarian reserve might differently impact the follicular health and their capacity of producing this peptide.
Study design, size, duration: From November 2018 to December 2021, we conducted a monocentric, retrospective study including a total of 484 infertile patients <37 years with DOR.
Participants/materials, setting, methods: All patients underwent measurement of AMH levels and AFC. DOR was diagnosed according to the Bologna criteria (AMH<1.1 ng/mL and AFC<7). AMH/AFC ratio was compared to values obtained in 154 tubal or male infertility patients matched for age and BMI, with AMH and AFC in the normal ranges. This ratio was studied according to the etiology of DOR: genetic (n=26), post-chemotherapy (n=102), idiopathic (n=215) or ovarian diseases (ovarian cyst or history of ovarian surgery, n=141).
Main results and the role of chance: Overall, median age of women with DOR was 30 (18-37) years. As expected, age and BMI were comparable in women with DOR and those having normal ovarian reserve tests. In addition, the AMH/AFC ratio failed to show any difference between these 2 groups (0.143 ± 0.22 vs. 0.166 ± 0.11, NS, respectively). Among women with DOR, the etiology was significantly associated with different AMH/AFC ratio. Indeed, patient with DOR of surgical origin (ovarian diseases group) displayed higher mean values (0.283 ± 0.32 ng/mL/ Foll) when compared with those included in genetic (0.079 ± 0.15 ng/mL/ Foll, p<0.01), idiopathic (0.103 ± 0.16 ng/mL/ Foll, p<0.03) or post-chemotherapy (0.084 ± 0.20 ng/mL/ Foll, p<0.01) groups. Moreover, genetic and post-chemotherapy DOR was also associated with lower AMH/AFC ratio in comparison with idiopathic DOR.
Limitations, reasons for caution: Despite interesting results, the retrospective nature of the present study may represent a limitation. Moreover, AMH/AFC ratio constitute an indirect method for assessing per follicle AMH production. We hypothesized that this ratio might reflect the follicular health. Its impact on natural conception and assisted reproductive technologies outcome is not known.
Wider implications of the findings: AMH/AFC ratio may represent an innovative tool aiming to indirectly assess follicular health and possibly oocyte quality in young women with DOR. The etiology of DOR differently impacts the follicular function as reflected by AMH/AFC ratio. Further data on live birth rates following natural or medically assisted pregnancies is needed.

SESSION 04: MORPHOLOGICAL EVALUATION FOR EUPLOIDY DETECTION

28 June 2021 Stream 3 10:00 - 11:30

O-083 Non-invasive, label-free optical analysis to detect aneuploidy within the inner cell mass of the preimplantation embryo

C.Y. Tan[1], S.B. Mahbub[2], C.A. Campugan[1], J. Campbell[2], A. Habibalahi[2], D.J.X. Chow[1], S. Mustafa[1], E.M. Goldys[2], K.R. Dunning[1]

[1]Robinson Research Institute- Adelaide Medical School- The University of Adelaide- Australia- Australian Research Council Centre of Excellence for Nanoscale Biophotonics- The University of Adelaide- SA- Australia, Faculty of Health and Medical Science-, ;
[2]University of New South Wales- Sydney- Australia- Australian Research Council Centre of Excellence for Nanoscale Biophotonics- University of New South Wales- Sydney Australia, The Graduate School of Biomedical Engineering, Sydney, Australia

Study question: Can we separate between control and reversine-treated cells within the inner cell mass (ICM) of the mouse preimplantation embryo by using label-free and non-invasive hyperspectral microscopy?
Summary answer: Hyperspectral microscopy is able to discern between control and reversine-treated cells using cellular autofluorescence in the complete absence of fluorescence tags.
What is known already: Embryo mosaicism (containing cells that are euploid (46 chromosomes) and aneuploid (deviation from the expected number of chromosomes)) affects up to 17.3% of human blastocyst embryos. Current diagnosis of aneuploidy in the IVF clinic involves a biopsy of trophectoderm (TE) cells or spent media followed by sequencing. In some blastocyst embryos these approaches will fail to diagnose of the proportion of aneuploid cells within the fetal lineage (ICM).
Study design, size, duration: The impact of aneuploidy on cellular metabolism was assessed by using cellular autofluoresence and hyperspectral microscopy (broad spectral profile). Two models were employed: (i) Primary human fibroblast cells with known karyotypes (4-6 independent replicates, euploid n= 467; aneuploid n= 969) and reversine induced aneuploidy in mouse embryos (5-8 independent replicates, 30-44 cells per group). Both models were subjected to hyperspectral imaging to quantify native cell fluorescence.
Participants/materials, setting, methods: The human model is comprised of euploid (male and female) and aneuploid (triploid and trisomies: 13, 18, 21, XXX, and XXY) primary human fibroblast cells. For the mouse model, we treated embryos with reversine, a reversible spindle assembly checkpoint inhibitor, during the 4- to 8-cell division. Individual blastomeres were dissociated from control and reversine treated 8-cell embryos. Blastomeres were either imaged directly or used to generate chimeric blastocysts with differing ratios of control:reversine-treated cells.
Main results and the role of chance: Following unsupervised linear unmixing, the relative abundance of metabolic cofactors was quantified: reduced nicotinamide adenine dinucleotide (NAD(P)H) and flavins with the subsequent calculation of the optical redox ratio (ORR: Flavins/[NAD(P)H + Flavins]). Primary human fibroblast cells displayed an increase in the relative abundance of NAD(P)H with a decrease in flavins, leading to a significant reduction in the ORR for aneuploid cells ($P < 0.05$). The mouse embryos displayed an identical trend as the human model between control and reversine-treated embryos. Mathematical algorithms were applied and able to distinguish between (i) euploid and aneuploid primary human fibroblast cells, (ii) control and reversine-treated mouse blastomeres and (iii) chimeric blastocysts with differing ratios of control and reversine-treated cells. The accuracy of these separations was supported by receiver operating characteristic curves with areas under the curve. We also showed that hyperspectral imaging of the preimplantation embryo does not impact on embryo developmental competence, pregnancy outcome and offspring health in a mouse model. We believe the role of chance is low as both human somatic cells and mouse embryos showed a consistent shift in cellular metabolism in response to human fibroblast cells that are aneuploid and reversine treated mouse embryos.
Limitations, reasons for caution: Further validation of our approach could include sequencing of the ICM of individual blastocysts to determine the proportion of aneuploid cells in ICM and correlate this with the metabolic profile obtained through hyperspectral imaging.
Wider implications of the findings: With hyperspectral imaging able to discriminate between (i) euploid and aneuploid human fibroblast cells and (ii) control and reversine-treated mouse embryos, this could be an accurate, non-invasive and label-free optical imaging approach to assess mosaicism within the ICM of mouse embryos, potentially leading to a new diagnostic tool for embryos**.**
Trial registration number: Not applicable

O-084 Computer vision can distinguish between euploid and aneuploid embryos. A novel artificial intelligence (AI) approach to measure cell division activity associated with chromosomal status.

L. Bori[1], M.Á. Valera[1], D. Gilboa[2], R. Maor[2], I. Kottel[2], J. Remohí[3], D. Seidman[4], M. Meseguer[5]

[1]IVIRMA Global, Research laboratory, Valencia, Spain ;
[2]AIVF, IVF Research and Development, Tel Aviv, Israel ;
[3]IVIRMA Global, Obstetrics and Gynaecology, Valencia, Spain ;
[4]Sheba Medical Center, IVF Unit, Ramat Gan, Israel ;
[5]IVIRMA Global, IVF laboratory, Valencia, Spain

Study question: Can we distinguish between top-grade euploid and aneuploid embryos by AI measurement of cell edges in time-lapse videos?
Summary answer: Aneuploid embryos can be distinguished from euploid embryos by AI determination of a longer time to blastulation and higher cell activity.
What is known already: Continuous monitoring of the embryo development has brought out morphokinetic parameters that are used to predict pre-implantation genetic testing (PGT) results. Previous publications showed that euploid embryos reach blastulation earlier than non-euploid embryos. However, time-lapse data are currently under-utilized in making predictions about embryo chromosomal content. AI and computer vision could take advantage of the massive amount of data embedded in the images of embryo development. This is the first attempt to distinguish between euploid and aneuploid embryos by computer vision in an objective and indirect way based on the measurement of cell edges as a proxy for cell activity.
Study design, size, duration: We performed a retrospective analysis of 1,314 time-lapse videos from embryos cultured to the blastocyst stage with PGT results. This single-center study involved two phases; a comparison of the start time of blastulation between euploid (n=544) and aneuploid embryos (n=797). In phase two, we designed a novel methodology to examine whether precise measurement of cell edges over time could reflect cell activity differences in blastulation.
Participants/materials, setting, methods: We assumed that the delay in blastulation is reflected by higher cell activity that could be determined accurately for the first time using computer vision and machine learning to measure the length of the edges (from t2 to t8). We compared computer vision based measurements of cell edges, reflecting cell number and size, in videos of 231 top-grade euploid (n=111) and aneuploid (n=120) embryos.
Main results and the role of chance: The mean and standard deviation of blastulation start time was 100.1±6.8 h for euploid embryos and 101.8±8.2 h for aneuploid embryos ($p<0.001$). Regarding the measurement of cell activity, a computer vision algorithm identified the edges and provided a certainty score for each edge, higher when the algorithm is more certain that this is a cell edge (as opposed to noise in the images). A threshold was set to distinguish cell edges from noise using this score. The following results for top-grade embryos are shown as the sum of the edge lengths (μm) average of 160 pictures per embryo (frames between t2 and t8). The total length of the cell edges increased from two cells (420±85 μm) to eight cells (861±237 μm), in line with the mitosis events. Both the average total edge measured (450±162 μm for euploid embryos and 489±215 μm for aneuploid embryos, $p<0.01$) and the average total of the difference between consecutive frames (135±47 μm for euploid embryos and 153±64 μm for aneuploid embryos, $p<0.01$) were higher for aneuploid embryos than for euploid embryos. A regression model to differentiate between the two classes achieved 73% sensitivity and 73% specificity on this dataset.
Limitations, reasons for caution: The main limitation of this study is the difficulty to correlate our findings to other measure of cell activity. A more robust AI function (using not only cell edges lengths) would be required for future analysis to measure the cell activity in cell division up to the blastocyst stage.
Wider implications of the findings: Our results show for the first time that an AI based system can precisely measure microscopic cell edges in the dividing embryo. Using this novel method, we could distinguish between euploid and aneuploid embryos. This non-invasive method could further enhance our knowledge of the developing embryo.
Trial registration number: Not Applicable

O-085 In-depth analysis of embryo development: Differences among monosomic, trisomic and chromosomally chaotic embryos compared to euploid embryos.

F. Meseguer Estornell[1], L. Bori[1], R. Maor[2], I. Kottel[2], D. Gilboa[2], D. Seidman[3], M. Meseguer[4]

[1]IVIRMA Global, Research Laboratory, Valencia, Spain ;
[2]AIVF, IVF Research and Development, Tel Aviv, Israel ;
[3]Sheba Medical Center, IVF Unit, Ramat Gan, Israel ;
[4]IVIRMA Global, IVF laboratory, Valencia, Spain

Study question: Is there any visible variation in the development of aneuploid embryos depending on the type of chromosome abnormality?
Summary answer: There were significant visible differences in the development of euploid, monosomic, trisomic and, especially, chaotic embryos.

What is known already: Aneuploidy rates are remarkably high in in vitro fertilized human embryos, with up to 50% of embryos diagnosed as aneuploid based on preimplantation genetic testing for aneuploidies (PGT-A). However, very little is known about the impact of specific aneuploidies during the early human embryo development. A recent publication showed that embryos with single chromosomal gain or loss reached the blastocyst stage later or earlier depending on the chromosome affected (Shahbazi et al., 2020). In our study, we wanted to detect observable differences in embryo behavior between embryos with different chromosomal abnormalities during the entire in vitro development.
Study design, size, duration: This was a retrospective study including 2,500 blastocysts with PGT-A results. Embryos were cultured in EmbryoScope systems until the fifth/sixth day of development (up to the time of trophectoderm biopsy). Automatic-annotations for division times and quality gradings were supervised routinely by senior embryologists using Guided Annotations Tool. Out of the total, 1,000 were euploid embryos used for reference and 1,500 were aneuploid embryos with one or more defects, including monosomic, trisomic and chromosomally chaotic embryos.
Participants/materials, setting, methods: Chromosome analysis was performed using next-generation sequence technology. Then, an in-depth analysis of time-lapse videos and supervised-automatic annotations was performed. We calculated the proportion of embryos, in each aneuploid category, that reached one specific event later than the expected value for euploid embryos plus one standard deviation. Later, we calculated the "relative risk" of an embryo of reaching the milestone late. We did the same for the time between milestones and for pairs of milestones.
Main results and the role of chance: Every aneuploid category was more likely to reach each specific embryo developmental event later than euploid embryos and the time gaps between developmental milestones were also statistically longer in aneuploid embryos ($p<0.0001$). The following results were the most interesting relative risks (RR) when we compared the proportion of embryos (in each aneuploid category) to the proportion of euploid embryos (RR for euploid=1). For reaching the division time to two cells (t2): 1.31 in monosomic embryos, 1.50 in trisomic embryos and 2.43 in chaotic embryos. For the division time to four cells (t4): 1.42 in monosomic embryos, 1.54 in trisomic embryos and 3.07 in chaotic embryos. For the division time to eight cells (t8) and the time of starting blastulation: 1.45 in monosomic embryos, 1.22 in trisomic embryos and 2.74 in chaotic embryos. Combined milestones were stronger indicators than each milestone by itself, the RR were: 1.63 in monosomic embryos, 1.81 in trisomic embryos and 3.35 in chaotic embryos for t2 and t4; 1.50 in monosomic embryos, 1.80 in trisomic embryos and 2.84 in chaotic embryos for t2 and t8; 1.46 in monosomic embryos, 1.90 in trisomic embryos and 3.43 in chaotic embryos for t4 and t8.
Limitations, reasons for caution: At this stage, we did not go down to specific chromosome abnormality as there were very few cases in each fully detailed category. Also, not all the embryos reached every developmental milestone.
Wider implications of the findings: Aneuploid embryos were significantly different from euploid embryos in the first five days of development. A large proportion of aneuploid embryos could be rejected because their developmental milestones falling outside the normal range. This could form part of an automated system for determining euploidy/aneuploidy from observation of embryos in vitro.
Trial registration number: 1902-VLC-018-MM

O-086 End-to-end deep learning for recognition of ploidy status using time-lapse videos

C.I. Lee[1], Y.R. Su[2], C.H. Chen[1], T.A. Chang[3], E.E.S. Kuo[2], W.T. Hsieh[2], C.C. Huang[1], M.S. Lee[1], M. Liu[2]

[1]Lee Women's Hospital, Division of Infertility, Taichung, Taiwan R.O.C. ; [2]Binflux Inc, R&D Department, Taipei, Taiwan R.O.C. ; [3]University of Texas Health Science Center, Department of Obstetrics and Gynecology, San Antonio, U.S.A.

Study question: Our Retrospective study is to investigate an end-to-end deep learning model in identifying ploidy status through raw time-lapse video.
Summary answer: Our deep learning model demonstrates a proof of concept and potential in recognizing the ploidy status.
What is known already: Since the time-lapse system has been introduced into the IVF lab, the relationship between morphogenetic and ploidy status has been often discussed. However, the result has not yet reached a united conclusion due to some limitations such as human labeling. Besides the statistical approach, deep learning models have been utilized for ploidy prediction. As such approaches are single image-based, the performance remains unpromising as previous statistical-based research. Therefore, in order to move further toward clinical application, better research design and approach are needed.
Study design, size, duration: A retrospective analysis of the time-lapse videos and chromosomal status from 690 biopsied blastocysts cultured in a time-lapse incubator (EmbryoScope+, Vitrolife) between January 2017 and August 2018 in the Lee Women's Hospital were assessed. The ploidy status of the blastocyst was derived from the PGT-A using high-resolution next-generation sequencing (hr-NGS). Embryo videos were obtained after normal fertilization through the intracytoplasmic sperm injection or conventional insemination.
Participants/materials, setting, methods: By randomly dividing the data into 80% and 20%, we developed our deep learning model based on Two-Stream Inflated 3D ConvNets(I3D) network. This model was trained by the 80% time-lapse videos and the PGT-A result. The remaining 20% has been tested by feeding the time-lapse video as input and the PGT-A prediction as output. Ploidy status was classified as Group 1 (aneuploidy) and Group 2 (euploidy and mosaicism).
Main results and the role of chance: Time-lapse videos were divided into 3-time partitions: day 1, day 1 to 3, and day 1 to 5. Deep learning models have been fed by RGB and optical flow. Combining 3 different time partitions with RGB, optical flow, and fused result from RGB and optical flow, we received nine sets of test results. According to the results, the longest time partition with the fusion method has the highest AUC result as 0.74, which appeared higher than the other eight experimental settings with a maximum increase of 0.17.
Limitations, reasons for caution: The present study is retrospective and future prospective research would help us to identify more key factors and improve this model. In addition, expanding sample size combined with cross-centered validation will also be considered in our future approach.
Wider implications of the findings: Group 1 and Group 2 approach provided deselection of aneuploidy embryos, while future deep learning approaches toward high mosaicism, low mosaicism, and euploidy will be needed, in order to provide a better clinical application.
Trial registration number: CS18082

O-087 Embryos with higher mitochondrial DNA ratios show better clinical outcomes in single euploid embryo transfer

D. Chen[1], C.W. Kao[1]

[1]Stork Ladies Clinic, ART, Hsinchu, Taiwan R.O.C.

Study question: To assess whether there is a relationship between mitochondrial DNA content and implantation result.
Summary answer: The embryos with a higher mitochondrial DNA ratio increase pregnancy rate and implantation rate in single euploid embryo transfer.
What is known already: Mitochondria is an important organelle that generates energy during embryonic development. Recent literature points out that mitochondrial content and function may be related to implantation success and embryo viability. Some studies have linked increased ratios of mitochondrial DNA to aneuploidy, advanced maternal age, and euploid blastocyst with implantation failure, while others have failed to demonstrate similar findings.
Study design, size, duration: This study is a retrospective cohort study from 2016 to 2019, including 1465 single embryo transfer cycles.
Participants/materials, setting, methods: The involved embryos were biopsied on Day 5 or 6 and the mitochondrial DNA ratio of 1465 embryos was examined undergoing PGS/NGS. The mitochondrial DNA ratios were normalized for technical batch-to-batch variation. The mitochondrial DNA ratio between the implantation group and non-implantation group was statistically analyzed. Data were analyzed by the student's t-test for continuous variables and Chi-square test for categorical variables.
Main results and the role of chance: The mitochondrial DNA ratio of embryos was no significant difference between different age spans ($p=0.772$) and ploidy ($p=0.224$). D5 biopsied embryos, however, contained a significantly higher mitochondrial DNA ratio than D6 biopsied embryos ($p<0.0001$). All of the single embryo transferred embryos were classified into two groups; implanted and non-implanted embryos. Results from 1465 transferred embryos show that the mitochondrial DNA ratio of implanted embryos was statistically significantly higher than non-implanted embryos ($p=0.0053$). Besides, the cut-off

values were established, dividing the transferred embryos into high and low mitochondrial DNA ratio groups. The pregnancy rate and implantation rate of the high mitochondrial DNA ratio group was higher than the low mitochondrial DNA ratio group: [Pregnancy rate] 74% vs. 63.5% (p=0.0209); [Implantation rate] 57.3% vs. 50.8% (p=0.1907).

Limitations, reasons for caution: The mitochondrial DNA ratios were analyzed by bioinformatics processing in Miseq reporter software (Illumina) files in the BAM and FASTQ format. Not sure if there is reproducibility in different sequencing platforms.

Wider implications of the findings: There still remains a lack of clarity regarding the relationship between mitochondrial function and transfer outcome. This retrospective study links an association between increased mtDNA content and increased implantation.

Trial registration number: not applicable

O-088 Performance of a commercial artificial intelligence software for embryo selection (Embryoscope/KIDScore™) on predicting biopsied and non-biopsied blastocyst clinical pregnancy according to score subgroups.

R. Erberelli[1], C.K. Jacobs[1], M. Nicolielo[1], E.L. Motta[2], J.R. Alegretti[1], A.R. Lorenzon[3]

[1]Huntington Medicina Reprodutiva, Embryology, São Paulo, Brazil ; [2]Huntington Medicina Reprodutiva/Federal University of São Paulo, Medical Director / Department of Gynecology- School of Medicine, São Paulo, Brazil ; [3]Huntington Medicina Reprodutiva, Research and Development, São Paulo, Brazil

Study question: How informative is the score grade of KIDScore version 3 for day 5 blastocyst for clinical pregnancy in biopsied and non-biopsied embryos?

Summary answer: Potential clinical pregnancy is predicable according to score grades (above 7.0), regardless the use of PGT-A, in blastocysts on day 5.

What is known already: Time-lapse technology has promoted, along with the use of artificial intelligence (A.I.), a new spectrum of tools to improve embryo selection. Several software and algorithms have been launched in ART field in the last years, with the perspective of providing a substantial boost in IVF outcomes. KIDScore is one of these new tools, developed based on morphology and morphokinetics of embryo development with known clinical outcome and validated with transfer of blastocyst on day 3 or 5. Yet, it is highly recommended an in-house validation of any A.I. tool before it started to be apply in clinical decisions.

Study design, size, duration: Retrospective cohort study in a single private IVF center. Positive or negative clinical pregnancy (fetal heartbeat and gestational sac presence/absence) record of patient's autologous and donated cycles using fresh and frozen oocytes, with or without PGT-A embryos transfers using the Embryocope® Plus incubator, that underwent single embryo transfers (total sET, n=415; euploid=228, non-biopsied=187) of blastocysts developed on day 5 were included. Biochemical pregnancy and miscarriage were excluded of this analysis.

Participants/materials, setting, methods: Negative and positive clinical pregnancy KIDScore™Day 5's were stratified in three subgroups, according to V3 score intervals: subgroup 1: range between 1.0-3.9 (n=29), subgroup 2: 4.0-6.9 (n=154) and subgroup 3: 7.0-9.9 (n=232). sET of euploid embryos (n=228) were also analyzed in the described subgroups (subgroup 1: n=17; subgroup 2: n=93 and subgroup 3: n=118, respectively). For the analysis, Mann-Whitney, Chi-square and Fisher tests were used for statistical analysis, values of p<0.05 were considered significant.

Main results and the role of chance: Maternal age between overall positive and negative pregnancies were similar (38,48±3,86 versus 38,75±3,83,p=0,3573). When comparing score subgroups, overall positive clinical pregnancy rates were significant different [subgroup 1: 20.7% (6/29); subgroup 2: 43.5% (67/154); subgroup 3: 63.8% (148/232),p<0.0001]. When analyzing subgroup 1 versus subgroup 2 there was also a difference in positive clinical pregnancy (p=0.023) and subgroup 3 also showed a higher rate in clinical pregnancy when compared to subgroup 1 and 2 together (scores from 1.0 to 6.9,p<0.0001). Analyzing only euploid embryos, the results on positive clinical pregnancy were also significant different between subgroups [subgroup 1: 35.3% (6/17); subgroup 2: 45.2% (42/93); subgroup 3: 61.0% (72/118),p=0,024, and subgroup 1+2 versus subgroup 3,p=0,0115]. Maternal age between positive and negative clinical pregnancies in PGT-A cycles were similar (37,81±1,61 versus 38,38±3,25,p=0,069). Analyzing only non-biopsied embryos, the results on positive clinical pregnancy were also significant different between subgroups [subgroup 1: 0.0% (0/12); subgroup 2: 41.0% (25/61); subgroup 3: 66.7% (76/114),p=0,0343, and subgroup 1 + 2 versus subgroup 3,p<0.0001]. Maternal age between positive and negative clinical pregnancies in non-biopsied cycles were also similar (39,40±4,75 versus 39,22±4,43,p=0,7816). Positive clinical pregnancy in subgroup 3 were similar in biopsied and non-biopsied subgroups (61% versus 66.7%,p=0.4133).

Limitations, reasons for caution: The retrospective nature and low data of subgroup 1 (1.0-3.9 score), since they naturally are the last option to be chosen for transfer.

Wider implications of the findings: Differences on positive clinical pregnancy between subgroups (mainly scores greater than 7.0) reinforce the use of A.I. as a complementary tool for embryo selection. Interestingly, positive clinical pregnancy in 7.0-9.9 subgroup were similar in euploid and non-biopsied embryos, strengthening another potential application of A.I. in transposing embryo aneuploidy barrier.

O-089 A Genome Wide Association Study in men with unexplained infertility identifies nine SNPs at the FSHB locus to be associated with Follicle Stimulating Hormone level

M. Schubert[1], L. Pérez Lanuza[2], M. Wöste[3], M. Dugas[3], Y. Rassam[1], S. Heilmann-Heimbach[4], F. Tüttelmann[5], S. Kliesch[1], J. Gromoll[6]

[1]Centre of Reproductive Medicine and Andrology CeRA- University Münster, Department of Clinical and Surgical Andrology, Münster, Germany ; [2]University Children´s Hospital Münster, Department of Pediatric Hematology and Oncology, Münster, Germany ; [3]University of Münster, Institute of Medical Informatics, Münster, Germany ; [4]University of Bonn- School of Medicine & University Hospital Bonn, Institute of Human Genetics, Bonn, Germany ; [5]University of Münster, Institute of Reproductive Genetics, Münster, Germany ; [6]Centre of Reproductive Medicine and Andrology CeRA- University of Münster, Institute of Reproductive and Regenerative Biology, Münster, Germany

Study question: Which single nucleotide polymorphisms (SNPs) are associated with Follicle stimulating hormone (FSH) levels in men with unexplained infertility and can affect FSH action and spermatogenesis?

Summary answer: We identified a genomic region at chromosome 11p.14.1, including nine SNPs, that are significantly associated with FSH levels in men with unexplained infertility.

What is known already: FSH action is essential for the initiation and maintenance of human spermatogenesis. One well-studied SNP, *FSHB* c.-211G>T (rs10835638), is associated with *FSHB* mRNA transcription and directly affects FSH serum levels, testicular volume and spermatogenesis. Carriers of a T-allele in this promoter are diagnosed with functional secondary hypogonadism with isolated FSH deficiency.

Other genetic variants, for example at the *FSHR* have been shown to slightly modulate FSH action, however the clinical impact in these variants seems to be low. The so far identified FSH-associated SNPs revealed an impact of up to 2.3 % on FSH serum level variance.

Study design, size, duration: A Genome wide association study (GWAS) was performed on a clinically well characterized cohort of 742 men with unexplained infertility (discovery study). Of the nine identified SNPs, validation was performed for rs11031005 and the already described rs10835638 in an independent cohort of 1123 men with unexplained infertility (validation study).

Participants/materials, setting, methods: Patients were retrospectively selected from our CeRA database Androbase® applying strict selection criteria; DNA was isolated from stored EDTA-blood samples. Informative genetic

variants were identified using Illumina PsychArray v1.3. Illumina®GenomeStudio v2.0, PLINK v1.90 and R 3.6.3 were used to perform quantitative association analysis based on normalized FSH values. The validation study was performed using TaqMan PCR for SNP detection and R 3.6.3 for quantitative association to analyze the impact of each SNP on FSH level.

Main results and the role of chance: Imputation of the GWAS data revealed 94 SNPs with suggestive significance ($p < 8.56e-06$) and nine SNPs (including rs10835638) with genome-wide significance ($p < 4.28e-07$). The nine SNPs are all located at the *FSHB* locus on Chromosome 11p.14.1 and are in high linkage disequilibrium (LD). The validation study of 1123 patients with unexplained infertility for the SNPs rs11003005 and rs10835638 revealed a significant association with FSH ($p = 4.71e-06$ and $p = 5.55e-07$) and FSH/LH ratio ($p = 2.08e-12$ and $p = 6.4e-12$).The nine significant SNPs accounted for 3.60 – 4.65 % variance in FSH serum level each in the entire discovery cohort. In an oligozoospermic subgroup (n=249) this effect was increased to 4.89 – 6.95 %.

This the first GWAS in men with unexplained infertility. This study shows that not one single SNP, but rather a genomic region has an impact on FSH serum level in men with unexplained male infertility. This effect is even more pronounced in the more severe phenotype of oligozoospermic men.

Limitations, reasons for caution: The study is restricted to men with unexplained infertility, which might cause a selection bias. Validation and functional evaluation of the eight newly identified SNPs in independent cohorts would emphasize the results more. The sample size of 742 limits detection of loci with smaller effect on FSH levels.

Wider implications of the findings: The determination of one of the nine SNPs can improve diagnostic precision in identifying men with secondary functional hypogonadism with isolated FSH deficiency. An oligozoospermic subgroup of these men would putatively benefit from FSH treatment and has to be proven in randomized controlled trials.

Trial registration number: German Research Foundation CRU326

O-090 Correcting a PLCζ mutation in the human germ line to overcome hereditary infertility

B. Bekaert[1], A. Boel[1], M. Popovic[1], P. Stamatiadis[1], S.M. Chuva de Sousa Lopes[2], P. De Sutter[1], B. Menten[3], D. Stoop[1], P. Coucke[3], B. Heindryckx[1]

[1]UGhent, Department of Human structure and repair, Ghent, Belgium ; [2]Leiden University, Department of Anatomy and Embryology, Leiden, The Netherlands ; [3]UGhent, Department of Biomolecular Medicine, Ghent, Belgium

Study question: Can clustered regularly interspaced short palindromic repeats (CRISPR)/Cas9 gene editing result in the correction of a single base pair substitution that causes male infertility?

Summary answer: CRISPR/Cas9 administration during intracytoplasmic sperm injection (ICSI) leads to correction attempts of mutant phospholipase C zeta (PLCζ), howeverc loss-of-heterozygosity (LOH).

What is known already: Failed fertilization after ICSI can be caused by mutations in the sperm-related oocyte factor PLCζ which can be overcome by assisted oocyte activation (AOA). In this way, children may inherit the infertility-causing mutation. Mutation transmission can be overcome through CRISPR/Cas9 delivery during ICSI. In previous studies using CRISPR/Cas9 in the human germline for mutation correction, loss-of-heterozygosity (LOH, loss of the allele of one of the parents) was observed. Two different explanations were given, namely partial or complete paternal chromosomal loss or the correction of the mutation by using the maternal wild-type allele instead of the exogeneous supplied repair template.

Study design, size, duration: We injected a gRNA-Cas9 protein complex to target the PLCζ mutant allele, a repair template harboring the desired nucleotide substitution and an additional synonymous variant to track template usage, together with patient's sperm. To overcome fertilization failure, AOA was applied during ICSI. After a culture period of maximal 6 days the embryos were collected. At day 3, some embryos were dissociated in individual blastomeres. The extracted DNA was analyzed through different genetic sequencing techniques.

Participants/materials, setting, methods: Donated sperm of a patient experiencing complete fertilization failure after routine ICSI, harboring a heterozygous base pair substitution in *PLCZ1* (c.136-1G>C), was utilized. Sperm was injected in donated *in vitro* matured oocytes or *in vivo* matured oocytes containing clusters of smooth endoplasmic reticulum. Next-generation sequencing was used to assess correction potential. Short tandem repeat (STR) and single nucleotide polymorphism (SNP) assays were used to determine whether the sperm contained the mutation and to evaluate LOH.

Main results and the role of chance: CRISPR/Cas9 injections had no significant impact ($p > 0.05$) on embryonic development. Due to the heterozygous nature of the mutation, 47% (27/58) of the embryos originated from mutated sperm injection. The CRISPR components showed a high specificity with absence of insertions/deletions in 97% of the embryos originating from wild-type sperm (n=31). Embryos originating from mutant sperm (n=27) fall into three categories:(1) 22% showed the untargeted mutant allele, (2) 52% showed additional mutagenesis and (3) 26% showed the wild-type allele, which could be explained by correction. Mosaicism, defined as various editing events, was present in 17% (1), 21% (2) and 71% (3) of the embryos. The low occurrence of the synonymous variant, incorporated in the repair template, suggests that the template is not used during correction attempts. In only 29% (2/7) and 14% (1/7) of the 'corrected embryos', respectively long (>18Mb) or medium width LOH (4Mb) was observed through STR analysis. SNP analysis in closer proximity showed in 71% (5/7) of the embryos LOH, even in the absence of LOH through STR, suggesting also the occurrence of short width LOH. These results will be studied in more detail before definitive conclusions can be made. Chromosomal LOH will be studied by ddRADseq.

Limitations, reasons for caution: The occurrence of mosaicism and LOH might complicate the use of traditional CRISPR/Cas9 in human embryos and should be studied in detail to draw definite conclusions on its potential future use. To this end, genomic data have been produced from both individual blastomeres and whole-embryos which will be further analyzed.

Wider implications of the findings: Our findings demonstrate caution to use CRISPR/Cas9 to correct mutations in the germ line. They seem to contradict other reports that show predominant lack of mosaicism and presence of long width LOH. A deeper evaluation will be undertaken to define the length and type of LOH in this study.

Trial registration number: Not Applicable

O-091 Semen microbiota in patients with astenozoospermia and healthy controls: cluster analysis of real-time PCR data

E. Panacheva[1,2], D. Pochernikov[3], E. Voroshilina[2,4]

[1]"Garmonia" Medical Center, Department of ART, Yekaterinburg, Russia C.I.S. ; [2]Ural State Medical University, Microbiology- Virology and Immunology, Yekaterinburg, Russia C.I.S. ; [3]Ivanovo State Medical Academy, Surgery and Urology, Ivanovo, Russia C.I.S. ; [4]"Garmonia" Medical Center, Laboratory Department, Yekaterinburg, Russia C.I.S.

Study question: What are the differences in the semen microbiota composition of patients with asthenozoospermia and normospermia according to cluster analysis of PCR data?

Summary answer: The detection rate of 4 stable semen microbiota clusters and the dominant bacteria groups varied in patients with asthenozoospermia and normospermia.

What is known already: Most of the research dedicated to analyzing normal and pathological semen microbiota is based on 16S rRNA gene specific Next generation sequencing (NGS). It has shown that microbiota is represented by polymicrobial communities (clusters) that consist of microorganisms from different genera and bacteria phyla. Despite it being highly informative, NGS has several weaknesses: complex sample preparation, difficult sample intake control, long analysis process, complicated results interpretation, high cost of equipment and reagents. These factors make it virtually impossible to use this approach in routine medical practice. Quantitative real-time PCR (RT-PCR) is far more suitable for this.

Study design, size, duration: Patients included in the study (n=301) came to the "Garmonia" Medical Center (Yekaterinburg, Russia) either seeking preconception care or for infertility treatment. Depending on the spermiogram results, they were divided into two groups. Group 1 (n=171) — asthenozoospermia, Group 2 (n=130) — normospermia.

Participants/materials, setting, methods: Semen microbiota was analyzed using RT-PCR kit Androflor (DNA-Technology, Russia). Cluster analysis was performed for 201 samples with the total bacterial load (TBL) of at least 10^3 GE/ml (asthenozoospermia=96, normospermia = 105). Cluster analysis was

conducted using the k-means++ algorithm, scikit-learn. The Silhouette index and the Davies–Bouldin index (DBI) were used to confirm the stability of clusters.
Main results and the role of chance: Both in the samples with normospermia and asthenozoospermia, four stable microbiota clusters were distinguished. Cluster I was characterized by the prevalence of obligate anaerobes, *Lactobacillus spp*. were prevalent in Cluster II, Gram-positive facultative anaerobes were prevalent in Cluster III, *Enterobacteriaceae/Enterococcus spp.* were prevalent in Cluster IV. Cluster I was detected the most often in both groups. However, in normospermia it was represented by various obligate anaerobes without pronounced quantitative predominance of any bacteria group. In samples with asthenozoospermia one of the bacteria groups were prevalent in Cluster I: *Bacteroides spp./Porphyromonas spp./Prevotella spp., Peptostreptococcus spp./Parvimonas spp.* or *Eubacterium spp.* In samples with asthenozoospermia Cluster II was characterized by the prevalence of *Lactobacillus spp*., while in samples with normospermia other bacteria groups were present along with lactobacilli, mainly obligate anaerobes. In samples with normospermia *Corynebacterium spp.* and *Streptococcus spp.,* typical of normal microbiota of male UGT, were prevalent in Cluster III. In samples with asthenozoospermia Cluster III were characterized by the prevalence of *Staphylococcus spp.* In samples with asthenozoospermia *Lactobacillus spp* was present in Cluster IV along with *Enterobacteriaceae/Enterococcus spp.*, which was not typical of the samples with normospermia.
Limitations, reasons for caution: Cluster analysis was not conducted for the samples with TBL lower than 10^3 GE/ml, since their results were incompatible with the data received for the negative control samples.
Wider implications of the findings: Further research could determine the detection rate of the described bacterial clusters in semen with other pathologies. Establishing the relationship between the characteristics of semen microbiota and infertility in men might allow the development of new algorithms for treating patients with reproductive disorders, depending on the composition of semen microbiota.

[3]Université de Paris- Institut Cochin, U1016- Inserm- cnrsS, Paris, France ;
[4]Université Grenoble Alpes- Institut pour l'avancée des Biosciences, Inserm- cnrs, Grenoble, France ;
[5]APHP.nord –Université de Paris- Hôpital Bichat, Service d'Histologie-Embryologie-Biologie de la Reproduction, Paris, France

Study question: What are the feasibility and outcome of ICSI in case of presumably genetic severe asthenozoospermia with Multiple Morphological Abnormalities of the Flagellum (MMAF phenotype)?
Summary answer: ICSI outcome for couples with MMAF phenotype does not differ from that of other couples requiring ICSI, regardless to the genetic etiology
What is known already: Severe asthenozoospermia, especially when associated with multiple morphological abnormalities of the sperm flagellum (MMAF phenotype), results in male infertility. Recent findings confirm that a genetic etiology is frequently responsible for this phenotype. In such situations, pregnancies can be obtained using ICSI. However, few studies have provided detailed analyses of the flagellar ultrastructural defects underlying this phenotype, of its genetic etiologies and of the results of ICSI in such cases of male infertility.
Study design, size, duration: We performed a retrospective study including 25 infertile men showing severe asthenozoospermia associated with a MMAF phenotype identified through standard semen analysis. These men were recruited from an academic center for Assisted Reproduction in Paris between 2009 and 2017. Transmission electron microscopy (TEM) and Whole Exome Sequencing (WES) were performed in order to precise the sperm ultra-structural phenotype and identify causal mutations, respectively. Twenty of the 25 patients benefited from assisted reproductive therapy by ICSI.
Participants/materials, setting, methods: MMAF patients were recruited based on reduced sperm progressive motility and increased frequencies of absent, short, coiled or irregular flagella, in comparison with fertile control men. A quantified analysis of the ultrastructural defects was performed for the MMAF patients and for fertile control men. ICSI results for the MMAF patients were compared to those of 528 ICSI attempts performed for non-MMAF individuals considering the sperm parameters and the distribution of ultrastructural axonemal anomalies.
Main results and the role of chance: Thorough categorization by TEM analysis of the flagellar anomalies found in these patients brought important precisions about the structural defects underlying asthenozoospermia and sperm tail abnormalities detectable through standard microscopy. In particular, absence of the central pair of axonemal microtubules was the predominant anomaly, observed significantly more frequently than in control men ($p<0.01$). Exome sequencing performed for 24 of the 25 patients (96%), identified in ten of them homozygous or compound heterozygous mutations that were described to be pathogenic (CFAP43, CFAP44, CFAP69, DNAH1, DNAH8, AK7, TTC29, MAATS1). A majority of those patients (55.5%,5/9) displayed the most severe ultra-structural defects of the axoneme. Forty ICSI attempts were performed for 20 MMAF patients. A hypo-osmotic swelling (HOS) test was required in 13 cycles (5 couples). Fertilization rate in MMAF group (65.7%) was not statistically different from the rate obtained for non-MMAF patients (66.0%) and did not differ according to the flagellar phenotype, nor to the use of HOS test, nor to the genotype. Clinical pregnancy rate per embryo transfer did not significantly differ between the MMAF group (23.3%) and the ICSI control group (37.1%). To date, 11 healthy babies were born among 20 MMAF patients.
Limitations, reasons for caution: The outcome of ICSI procedure was retrospectively assessed on a small sample and may be susceptible to recall bias. Moreover, TEM analysis was not available for some of the patients due to too low sperm concentration, and WES results are not yet available for all men included.
Wider implications of the findings: Couples requiring ICSI for presumably genetic severe asthenozoospermia should benefit precociously from appropriate phenotypic and genetic investigations. So far ICSI results appear similar to those observed in other ICSI indications. Identifying a genetic etiology and its mode of inheritance allows providing to these couples a most often reassuring genetic counseling.
Trial registration number: Not applicable

O-093 Male translocations in recurrent pregnancy loss: Natural conception versus PGD treatment: what is the right option?: A systematic review and meta-analysis.

D. Cardenas Armas[1], M. Duran-Retamal[1], R. Odia[1], S. Cawood[1], E. Drew[1], E. Yasmin[2], W. Saab[1], P. Serhal[1], S. Seshadri[1]

[1]The Centre for Reproductive and Genetic Health, The Centre for Reproductive and Genetic Health, London, United Kingdom ;
[2]University College Hospital UCLH, Reproductive Medicine, London, United Kingdom

Study question: Does PGD treatment in couples with a history of RPL due to male translocations improve the outcome, increasing LBR and reducing miscarriage rate and time taken to live birth?
Summary answer: Live birth rate is significantly increased, miscarriage rate is significantly reduced using PGD. Time taken to achieve live birth rate is shorter in PGD treatment.
What is known already: Reciprocal translocation are the most common structural rearrangement in infertile men. The specific chromosomes and breakpoints involved might play an important role, often expressed as abnormal semen parameters or repeated pregnancy loss (RPL). The genetic counselling of these men remains challenging. Previous studies and meta-analysis performed showed no difference in live birth rate when comparing natural conception versus PGD treatment. However, the difference in miscarriage rate and time to live birth between PGD and natural conception has not been reported before in the medical literature.

Study design, size, duration: A systematic review of the literature was conducted through MEDLINE, EMBASE, and the Cochrane database up until December 2020. A comprehensive search yield 287 articles, 25 of which were included for abstract reading, finally, six were included in the meta-analysis.

Participants/materials, setting, methods: The six selected articles, reported on Live birth rate (LBR), miscarriage rate and time to live birth (TTLB) for natural conception compared to PGD for the same cohort of patients. All of the included articles were of retrospective design. The primary outcome was the comparison in LBR and the second outcome was the analysis in miscarriage rate and TTLB in the PGD group versus natural conception.

Main results and the role of chance: A total of 1438 couples that conceived naturally, had a LBR of 22.46%, compared with 43,17% among 681 couples that underwent PGD (0.53 95% CI (0.43-0.65) p o< 0,00001). The six articles included in this meta-analysis had significant homogeneity (I^2=96%). Comparison of miscarriage rates, natural conception represented 1339 miscarriages out of 1836 pregnancies, in comparison with 44 miscarriages out of 558 pregnancies achieved through PGD. The OR showed a 10 fold increase risk of miscarriage when conceiving naturally in couples with a male translocation (10.18; 95% CI (2.88-36.04) p=0.0003).

Regarding TTLB, the difference was not statistically significant, however it did reflect that PGD patients will have a shorter TTLB (3.56 95% CI (-0.88-8.00) p=0.12). One of the studies included, took into account the waiting list to access PGD funding, prolonging therefore the TTLB in the PGD group.

Limitations, reasons for caution: The main limitation of this study is the low number of studies. TTLB should be interpreted with caution given that one of the articles included the time of the waiting lists. More studies could demonstrate a shorter time period for these couples to conceive and have a successful ongoing pregnancy.

Wider implications of the findings: First study to demonstrate the value of PGD in decreasing miscarriage rates in couples with RPL. Specially when counselling couples with history of RPL with male translocations. PGD should be offered in these couples to improve the outcome, and to diminish the physical, emotional and sequelae of RPL and TOP.

Trial registration number: not applicable

O-094 Utilization of ultrastructural analysis and genomics of spermatozoa to better characterize subtle forms of male factor infertility

K. Hancock[1], P. Xie[1], S. Cheung[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can sequencing the sperm genome provide insight into the various forms of male factor infertility caused by sperm organelle ultrastructural defects?

Summary answer: A comprehensive genomic assessment of spermatozoal DNA is able to identify genetic causes of ultrastructural defects visualized by transmission electron microscopy (TEM).

What is known already: To evaluate a man's reproductive potential, a conventional semen analysis through the assessment of concentration, motility, and morphology can indicate the proficiency of male gametes. Among those, conventional morphology assay can only provide indirect information on the different components of the sperm cell. The assessment of nanoscopic details such as chromatin, centriolar, mitochondrial, and axonemal components can only be observed by TEM. Indeed, TEM has been used to identify defects in the acrosome, chromatin compaction, and axonemal/periaxonemal structures. Furthermore, exome sequencing of spermatozoal DNA may identify novel causes and candidate genes for these ultrastructural defects.

Study design, size, duration: In the past 2 years, 20 men with history of fertilization failure or severe astheno-/terato-zoospermia were selected for TEM analysis of their spermatozoa, while 3 fertile men served as controls. Sperm head characteristics, intactness of fibrous sheath, and axonemal/periaxonemal structure were examined by diagnostic TEM. For consenting patients, NGS assessment was concurrently performed to identify mutations responsible for the structural abnormalities identified by TEM.

Participants/materials, setting, methods: TEM was performed on the ejaculates of 20 infertile patients and 3 fertile controls. Post-centrifugation cell pellets were resuspended, fixed, and dehydrated to be infiltrated and embedded onto the resin. Fixed specimens were sliced by ultramicrotome to 100-nm sections, then viewed by JEOL-1400 electron microscope at 300,000X magnification. At least 100 spermatozoa were evaluated by TEM. For consenting patients, DNA was extracted and amplified from at least 500 spermatozoa for concurrent NGS analysis.

Main results and the role of chance: Four types of sperm ultrastructural defects were observed, including globozoospermia, dysplasia of fibrous sheath (DFS), proximal centriole defect, and primary ciliary dyskinesia (PCD). One combined case of globozoospermia and DFS was identified. In globozoospermic patients (n=13), 97-100% of the spermatozoa displayed characteristic spherical heads with absence of acrosomes, dispersed chromatin, and perinuclear theca deformities. Centrosomal and axonemal structures were conserved. NGS identified gene deletions (DPY19L, PICK1, SPATA16) directly related to the globozoospermic phenotype. In patients with DFS (n=4), complete absence of flagellum was observed in 90-100% of spermatozoa. These defective gametes also displayed mitochondria disorganization, microtubular deformities, and cytoplasmic residues containing coiled flagellum with deformed capitulum within the plasma membrane. Contrary to the globozoospermia, acrosomes and nuclei appeared normal, indicating incomplete late spermiogenesis. Indeed, NGS confirmed gene deletions involved in flagellar development/function (AKAP4, SPAG16, CATSPER1). For the patient with proximal centriole defect (n=1), sperm nucleus, fibrous sheath, and flagellar structure were conserved. However, 90% of proximal centrioles assessed exhibited microtubular disorganization, confirmed by ODF2 mutation per NGS. In the PCD patient (n=1), chaotic flagellar microtubule arrangement and absence of outer dynein arms were prevalent in 90% of axonemal cross-sections examined, which was explained by a DNAH5 gene deletion.

Limitations, reasons for caution: While TEM can overcome the limitations of conventional semen analysis by providing direct visualization of the inner organelle arrangement of spermatozoa to accurately diagnose rare sperm pathologies, it is not routinely applied in clinics due to its high cost and technical specifications. Therefore, confirmatory NGS can provide additional diagnostic value.

Wider implications of the findings: Ultrastructural analysis with a concurrent genomic assessment characterized phenotypes and genotypes of rare sperm pathologies in infertile men. The utilization of TEM, corroborated by genomic assay, is therefore crucial for clinical and translational reproductive medicine to better characterize male factor infertility.

O-003 The puzzling unknowns of abnormal fertilization and first cleavage

C. Racowsky[1]

[1]Hopital Foch, Service de Gynecologie-Obstetrique, Suresnes, France

Abstract text

Fertilization is a critical event in development in that it provides the connection between the gametes and the earliest stages of embryogenesis. Yet, despite the central importance of this process in contributing to embryo developmental fate, clinical embryologists have historically assessed fertilization merely by the number of pronuclei and, if two are present, perhaps, by the presence of two polar bodies. Even though over 20 years ago, time lapse imaging was applied for defining early events of fertilization (Payne et al., 1997), it is only with contemporary time-lapse imaging systems in the last few years that detailed evaluation of spatial and temporal events of fertilization have been described (Iwata & Yasuyuki, 2016; Cottichio et al., 2018). These careful analyses allow us to describe typical and atypical events of fertilization and how they are each associated with timing of the first cleavage division and subsequent embryo development.

In this lecture, we will first describe the fundamental underpinnings of fertilization and highlight the normal events associated with this process. We will then discuss gross morphological abnormalities as visualized by light microscopy and highlight the unknowns associated with these events. Finally, we will focus on time-lapse imaging studies, which have revealed the remarkable spatial and temporal coordination of meiotic resumption, pronuclear dynamics, chromatin organization and cytoplasmic/cortical modifications that occur during fertilization and the implications of aberrations for the first cleavage division.

At the conclusion of this presentation, attendees should be able to: Review the normal events associated with fertilization and the first cleavage division.

1. Describe gross morphological aberrations of these two fundamental processes.
2. Discuss temporal and spatial abnormalities in the coordinated sequence of events that underly these processes.
3. State the potential application of these abnormalities as predictors of abnormal embryo development.
4. Summarize the puzzling unknowns that underly these abnormalities.

O-004 Self-correction in human preimplantation development: What do we know?

A. Campbell[1]

[1]*CARE Fertility Group, Embryology, Cheshire, United Kingdom*

Abstract text

Recent advances in preimplantation genetic testing for aneuploidy (PGT-A) and time-lapse imaging have improved our understanding of the early human embryo confirming the variable patterns of development and chromosomal status. Aneuploidy is common and increased sensitivity in PGT-A allows the non-binary reporting of euploid-aneuploid mosaicism. The PGT-A result is the inference of the biopsied embryo's ploidy status at a point in time, by assessment of a small percentage of cells, and, whilst concordance with the rest of the embryo is high; it is not absolute.

Many reports have demonstrated that, with the transfer of embryos with increasing severity and complexity of mosaicism, comes compromised implantation, reduced ongoing pregnancy rates and increased miscarriage rates. Segmental mosaic embryos have been reported to have slightly reduced implantation potential compared with euploid counterparts. However, complex mosaic embryos are widely reported to result in severely reduced implantation success, if transferred.

Outside of PGT-A treatment cycles, undoubtedly fertility clinics are unwittingly transferring mosaic and aneuploid embryos daily, with variable success. The transfer of embryos in which mosaicism has been detected, although associated with lower implantation and higher miscarriage rates than euploid embryos, can lead to normal pregnancies and healthy births. We know that the placenta can harbour chromosomal aberrations which are absent from the fetus, and there are few reports of births with demonstrably high levels of mosaicism through fetal development. This raises the question as to whether correction mechanisms exist. In other words, do conceptuses become chromosomally more normal as development progresses, and what are the mechanisms, if so?

PGT-A, time lapse, novel live cell imaging and *in vitro* model techniques have enabled a more detailed study of early embryo development and consideration of the phenomenon of self-correction. This has provided insights and hypotheses surrounding the mechanisms of development and of self-correction.

The relatively lower levels of chromosome abnormality in the blastocyst, compared with cleavage stage, are well documented and indicative of some form of correction. A recent investigation reported that a large proportion of embryos initially diagnosed as mosaic were later diagnosed as euploid when assessed at day 12 of development; providing evidence of the depletion of abnormal cells throughout the early post-implantation stages.

There are many time-lapse reports of anomalous 'direct' or multichotomous blastomere divisions being associated with aneuploidy, and leading to developmental arrest or reduced implantation potential and of temporal delays in aneuploid embryos compared with their euploid counterparts. It is possible, therefore, that errors and even attempts to repair them, in individual cells in the rapidly developing embryo; which involve complex biochemical systems, could delay karyo- and cytokinesis, resulting in these detectable delays. The embryonic mortality model suggests that there is selection against embryos based on their degree of aneuploidy, such that aneuploid cell lines are lost during implantation.

We know that irregularities in blastomere cleavage can generate chromosome segregation errors but these may sporadically be confined to cells excluded, or extruded, from the morula or from the blastocyst; a possible exhibition of the clonal depletion or embryo mortality model.

The trisomic/monosomic rescue model suggests that aneuploid cells can give rise to diploid cells (and possibly uniparental disomy) through mitotic chromosome losses or gains. We know that an abnormal number of pronuclei does not always produce an aneuploid blastocyst and that early embryos exhibiting multinucleation can result in healthy live births. Finally, the preferential allocation of aneuploid cells to the trophectoderm model is based on the hypothesis that euploid cells are preferentially retained in the ICM in order to achieve viability.

This presentation aims to consider what we know, and discuss the theories and available evidence for self-correction.

O-005 Mullerian anomalies overview

S. Prasad[1]

[1]*Matritava Advanced IVF & Training Centre, Reproductive Medicine, New Delhi, India*

Abstract text

Mullerian Duct Anomalies- An Overview

Prof. Sudha Prasad

President Indian Fertility Society, Director, Matritava Advanced IVF & Training Centre, New Delhi, India

Congenital anomalies of the mullerian duct system is one of the complex disorder encountered in gynecological practice. Mullerian ducts are paired embryological structures which undergo fusion and resorption in utero to form the uterus, fallopian tubes, cervix and upper two-thirds of the vagina. Disruption in the mullerian duct development throughout embryogenesis could result a large spectrum of inherent abnormalities identified as mullerian duct anomalies (MDAs).

There is a wide variation in the prevalence of MDAs across various studies, ranging from 1–10% in the general population to 2–8% among infertile women and 5–30% among women with a history of miscarriage. These discrepancies in the reported prevalence are mainly attributed to lack of a universal classification system.

Different varieties of malformations can occur when this system is not well developed. It ranges from absence of uterus, cervix or vagina, septum/duplication of vagina to of the uterus and vagina to minor uterine cavity abnormalities. Mullerian malformations are frequently associated with abnormalities of the renal and axial skeletal systems. Therefore, on initial examination of MDAs patients, these points should be kept in mind.

Most mullerian duct anomalies (MDAs) are associated with functioning ovaries and age-appropriate external genitalia. These abnormalities are often recognized after the onset of puberty. After the onset of puberty, young women often

present to the gynecologist with menstrual disorders. Late presentations include infertility and obstetric complications.

A meta-analysis of nine studies comprising 3805 women with congenital uterine anomalies reviewed the obstetric outcome. The study reported that canalization defects such as septate and partial septate uteri had reduce fertility and increase rates of miscarriage and preterm delivery. None of the unification defects (bicornuate, unicornuate and didelphic uteri) reduce fertility but some are related to miscarriage and prematurity. Arcuate uteri are specifically associated with second-trimester miscarriage. All uterine abnormalities increase the risk of fetal malformation during delivery[1].

A retrospective longitudinal study concluded that reproductive performance of the unicornuate and didelphys uteri was poor (20–30% chance of carrying a pregnancy to term), while that of the septate and bicornuate uteri (live birth rate of 62%) was better than expected. The arcuate uterus had no impact on reproductive performance of women[2].

Agenesis of uterus and vagina requires surgical techniques, such as the Vecchietti and McIndoe procedures, have enabled many women to have normal sexual relations. Uterine transplant has changed the perspective of all other surgical advances and assisted reproductive technologies to improve fertility and obstetric outcomes[3, 4,5].

O-006 Diagnosis debate – USG vs endoscopy

K. Jain[1], M. Jain[2]

[1]KJIVF AND LAPAROSCOPY CENTER- DELHI, REPRODUCTIVE MEDICINE, DELHI, India ;
[2]KJIVF and laparoscopy center - delhi, Reproductive medicine, Delhi, India

Abstract text

MULLERIAN ANOMAIES – DEBATE USG OR ENDOSCOPY

Mullerian duct anomalies are a complex spectrum of congenital anomalies resulting from defective fusion or canalization leading to different uterine anomalies. Early detection and proper diagnosis of uterine anomalies are paramount for proper management. Outflow obstruction defects like transvers septal defects or non canalised functional horn present early with complaint of pain while rest of patients present with amenorrhoea , infertility, repeated first-trimester abortion, fetal intrauterine growth restriction, and obstetric complications.The prevalence of uterine malformations is variable depending on the population studied , 0.4% , 4 % respectively in the general population and in infertile women while a high prevalence between 3 and 38% is reported in patients with repeated spontaneous miscarriages.

Imaging plays an important role in diagnosis and treatment planning in mullerian duct anomalies. There are different imaging and endoscopic modalities that can be used for the diagnosis and confirmation of uterine malformations. All modalities are having limitations and one need to select and combine various modalities depending on the clinical presentation of patient and pelvic examination. In younger patients or acute cases, trans abdominal ultrasonography (US) is the preferred method because it is readily available, inexpensive, and rapid and does not use ionizing radiation. However it may not give the complete picture because of poor demarcation especially in fatty patient and owing to complex nature of defects , Field-of-view restrictions with US, patient body habitus, and artefact from bowel gas. Pelvic magnetic resonance imaging (MRI) is an excellent tool in the diagnosis of Mullerian duct anomalies due to high soft tissue resolution. But it is more expensive and less available. 3D ultrasound may be a valid alternative to pelvic MRI as It is less expensive and better tolerated by patients however in doubtful cases of complex nature , hysteroscopy combined with laparoscopy may be considered to confirm the diagnosis. Another advantage of endoscopy is the opportunity to correct the defect in the same sitting in most of the cases.

Hysterosalpingography (HSG) and hysteroscopy are considered good modalities to assess the uterine cavity. Hysteroscopy provide the direct visualisation of the defect and considered as gold standard for cavity evaluation in doubtful cases of septate and bicornuate uterus and for simultaneous correction. However outer contour cannot be visualised so one need to use laparoscopy for complete evaluation which is a major drawback. Three-dimensional transvaginal sonography provides image quality like those provided by MRI and is being extensively used for diagnosis of all sorts of mullerian defects. it has got the advantage of realtime imaging which is helpful in distorted pelvic anatomy , visualisation of outer contour is possible ,which is considered very important to differentiate between bicornuate and septate uterus and unicornuate uterus with rudimentary horn. however it may not be possible in all cases to get a definitive diagnosis inspite of using a high end 3D machine specially in presence of artefacts , distorted contour and retroverted uterus. In such cases both modalities including MRI and endoscopy may be required to reach to a definitive diagnosis.

It can be concluded that primary imaging tool is still 2d ultrasound but 3D TVS should be included in all suspected anomalies along with complete careful pelvic examination to corroborate the findings of USG. In doubt ful or complex cases, MRI should be performed particularly for cervical and vaginal atresia and septum. endoscopy should be reserved for all doubtful cases for confirmation and for acute cases where a corrective surgery can also be planned to relieve the distress.

O-007 Do Mullerian anomalies need surgical correction

P. Trivedi[1]

[1]Dr. Trivedi"s Total Health Care Pvt Ltd, Mumbai, India

O-008 Improving outcomes in women with Mullerian anomalies

J. Malhotra[1], N. Malhotra[1], N. Malhotra[1]

[1]ART Rainbow IVF, infertility, Agra, India

Abstract text

Mullerian Anomalies are present in approximately 5% to 7% of the general population and the incidence is a little more in infertile and recurrent miscarriage women. Most of the recent studies have reported that the obstetric outcome is compromised in this group with greater risk of infertility, recurrent pregnancy loss, intrauterine growth retardation, preterm birth and many other obstetric complications, which may be individually related to the different types of Mullerian Anomalies. In this presentation, We are going to discuss on how the outcomes are different in the various Mullerian Anomalies depending upon the degree of the defects related to different complications with more profound defects. We will also discuss on how to optimize the pregnancy outcomes with various interventions and what the literature review supports.

O-095 Is the process to retract fabricated randomised clinical trials in reproductive medicine working sufficiently?

B.W. Mol[1]

[1]*Monash Medical Centre- Monash Health and Monash University, Obstetrics and Gynaecology, Melbourne, Australia*

Study question: How do journal editors and publishers respond on randomised clinical trials in reproductive medicine that have been identified as fabricated?
Summary answer: Despite clear proof of fabrication, only a small minority of fabricated RCTs is retracted within 12 months.
What is known already: Randomised controlled trials (RCTs) are recognised as scientific investigations that have the least potential for bias and are therefore widely used to direct clinical practice. The validity of data in RCTs matters to the accountability of medical practice and the wellbeing of patients. Detection of integrity problems and subsequent action is therefore of imminent importance. Across all fields of medicine, it takes on average 4 years for papers labelled with research misconduct to be retracted. While this is partially explained by the time needed to detect the misconduct, the process of investigation and retraction is also slow and bureaucratic.
Study design, size, duration: We studied the articles of 4 authors who have published 52 clearly fabricated RCTs in obstetrics/gynaecology. Data fabrication was clear from duplicate baseline and outcome tables in studies on different interventions done in different patients in different periods. The duplications could be from the author themselves, or from other articles. Our findings were published in the public domain for 3 of the 4 authors, with an article on the fourth author being submitted.
Participants/materials, setting, methods: After detection of the fabrication, we approached authors and their institutes for an explanation. As a satisfying explanation was not given, we notified the editors of the involved 14 journals in February 2020. The universities where two of the authors were awarded a PhD were informed in August 2020. Here we compare the journals' response to Committee on Publication Ethics (COPE)-guidelines, we report the percentage of retracted papers and other responses of editors and publishers.
Main results and the role of chance: Two articles had already been retracted prior to our notification. Twelve months after we had notified the editors, 4/50 (8%) (1 journal) of the articles had been retracted, 3 (6%) (2 journals) were formally investigating with notification on their website, 6/50 (8%) (3 journals) were informally investigating (without visible notification), 3/50 (6%) (1 journal) had made an expression concern and stated "caution that clinical practice or guidelines should not be based on this report" without formal retraction, and one (2%) had investigated original data and cleared it (although numerous data were identical to a study published 10 years earlier). For the other 33 articles (11 journals) no visible action had been taken. None of the journals provided feedback to the whistle-blower as required by COPE. The University of Utrecht and the Vrije Universiteit Brussel had not taken any action against the awarded fraudulent PhDs.
Among the reactions of editors were the statements "I have been in the business long enough; It exists in all specialties and in every country", "we receive 80 submissions a week, I am too busy to respond on this" and "we did still not get an answer about the result of the investigation by the local court".
Limitations, reasons for caution: This was a sample of four authors who had published 52 articles. There might be investigations ongoing that are not visible for the outside world.
Wider implications of the findings: Retraction of fabricated studies is seldom happening, and a majority of journals is not following COPE. This not only puts patients at risk, but it also lets whistle-blowers down and it jeopardises the trustworthiness of research. COPE-regulations consider the interests of authors and publishers, but not the interests of patients.
Trial registration number: Not applicable

O-096 The ethics of stem cell-based embryo-like structures: a focus group study on the attitudes of Dutch professionals and lay citizens

A. Pereira Daoud[1], **W. Dondorp**[1], **A. Bredenoord**[2], **G. De Wert**[1]

[1]*Maastricht University, Health- Ethics & Society, Maastricht, The Netherlands ;*
[2]*Utrecht University Medical Center, Medical Humanities, Utrecht, The Netherlands*

Study question: What are main themes guiding the attitudes of Dutch professionals and lay citizens with regard to the creation and research use of embryo-like structures?
Summary answer: The attitudes of Dutch citizens indicate feelings of trust and distrust, distinct 'embryo' conceptualizations, competing moral values and beliefs, and criteria for adequate regulatory safeguards.
What is known already: Researchers are hopeful that the creation and research use of so-called embryo-like structures (ELS), i.e., stem cell-based models that can mimic (parts of) early (human) embryogenesis, may provide a morally less controversial way of studying the period during which most human etiologies rise while also reducing and replacing the use of animals and/or human embryos in research. Scholars in the humanities and social sciences underline that public engagement and support will be essential in harvesting this presumed moral advantage. Studies on the public endorsement of and attitudes towards synthetic embryology remain nevertheless significantly scarce.
Study design, size, duration: For this qualitative study with a cross-sectional design, data were collected through four semi-structured focus group discussions (N = 33) between August and September 2020.
Participants/materials, setting, methods: The focus group interviews consisted of one pilot interview (n = 5), two interviews with lay citizens (n = 21), and one interview with professionals (n = 7). The pilot participants and lay citizens were invited based on sociodemographic characteristics of the Dutch public. Professionals were selected from the networks of the authors based on their experience and affinity with ethical and legal debates on emerging biotechnologies. The transcriptions were analyzed using inductive thematic analysis.
Main results and the role of chance: From our analysis emerged four themes: (1) *trust, distrust and ambivalence in synthetic embryology*, mainly due to concerns about scientific compliance with societal norms, also in view of a projected future ability of using ELS for reproductive ends; (2) *diversity of ELS-conceptualizations*, also in terms of their (non-)distinction from 'natural' human embryos; (3) *grounds for moral value and moral standing*, in which a possible potential to grow into a human being and perceived tinkering with nature were considered key issues of moral concern; and (4) *conditions for responsible embryo-like research*, with an emphasis on legally binding the use of ELS to non-reproductive research purposes. Interestingly, whereas questions on the developmental potential of ELS were critical for both the attitudes of professionals and those of lay citizens, lay citizens were much more concerned that synthetic embryology could fundamentally change human existence for the worse. In particular, lay citizens worried that synthetic embryology could lead to dystopian futures, for instance, because it stimulates a 'makeable human existence' or because of a presumed inability to monitor and control scientific progress. These findings may imply a correlation between fear of research and degrees of (un)familiarity with the governance systems of science.
Limitations, reasons for caution: Qualitative research methods provide rich and in-depth data for an ethical analysis of motivations and intuitions, but do not allow generalizations of the findings to broader publics.
Wider implications of the findings: The results may provide a useful starting point for further discussion and analysis of adequate regulatory parameters for the creation and research use of ELS. The findings also show that societal dialogue and public consultation can play a significant role in addressing concerns about emerging (bio)technologies.
Trial registration number: not applicable

O-097 The presentation of medical risks and incentives in egg donation: an analysis of Belgian, Spanish and UK fertility clinic websites

L. Jacxsens[1], **C. Coveney**[2], **L. Culley**[3], **C. Herbrand**[3], **S. Lafuente-Funes**[4], **V. Pavone**[5], **G. Pennings**[1], **C. Weis**[3], **N. Hudson**[3], **V. Provoost**[1]

[1]*UGent, Bioethics Institute Ghent, Ghent, Belgium ;*
[2]*Loughborough University, Social and Policy Studies- School of Social Sciences and Humanities, Loughborough, United Kingdom ;*
[3]*De Montfort University, Centre for Reproduction Research, Leicester, United Kingdom ;*
[4]*Goethe-Universität Frankfurt am Main, Institut für Soziologie, Frankfurt am Main, Germany ;*
[5]*Consejo Superior de Investigaciones Cientificas, Institute of Public Goods and Policies, Madrid, Spain*

Study question: How do fertility clinics' websites of the UK, Belgium and Spain present the medical risks of egg donation and incentives?
Summary answer: Spanish and UK websites typically included more incentives to recruit egg donors compared to the Belgian websites. OHSS was overall the most discussed risk.
What is known already: People commonly turn to the internet for initial information. Primary presentations of information of a subject co-determine how an individual interprets the topic and thus influence later decisions. Considering the growing demand and clinics' dependency on egg donors, some scholars have expressed concerns that clinics might (initially) misrepresent risks to recruit more egg donors. Offering appealing incentives may also encourage potential donors to dismiss possible risks and side-effects.
Therefore, it is important to see how incentives (both monetary and non-monetary rewards) and risks are presented on the websites of fertility clinics, the first source of information for egg donors.
Study design, size, duration: This study is part of the EDNA-project, a multi-phased comparative study (2017-2021), that aims to explore the social, political, economic and moral configuration of egg donation in the United Kingdom, Belgium and Spain. In this study, we only focused on the medical risks of egg donation and incentives presented on the fertility clinics' websites of the three countries.
Participants/materials, setting, methods: We analysed the websites of all Belgian fertility clinics (n=18), and a maximum variation sample in the UK (n=21) and Spain (n=23). The sampling was based on the geographical location of the clinic, size/number of cycles performed each year, the clinic's status (independent or part of a larger clinical group) and whether the clinic was public or privately funded in the UK. Frame analysis and content analysis were used for analysis in Nvivo12.
Main results and the role of chance: No misrepresentation of risks was found. There was an extensive variety in the representation of risks. There were differences *between the websites of the three countries* (e.g. the risks of having acne was only discussed on Spanish websites), but also remarkable differences *within the websites of a particular country* (of the 40 risks, 13 were one-off mentions, each found on a single website). A description of a risk was generally accompanied by a minimization or normalization of the risk, or a statement about the fertility clinic's excellent care for their egg donors. These three approaches were often combined.

Our analysis differentiated between incentives (i.e. external rewards) and emotional appeals. An appeal to emotions (e.g. empathy) can also motivate behavioural action (e.g. donation) but was not considered as an incentive since there is no external reward.

While Belgian websites used almost no incentives, Spanish and UK websites used gratitude and a rewarding experience as incentives. However, only Spanish websites used free medical tests as incentives, while UK websites were the only ones that used discounts received with egg sharing as an incentive. All countries' websites used emotional appeals by enticing feelings of empathy for the recipients.
Limitations, reasons for caution: Not all UK and Spanish fertility clinics' websites were analysed. However, our international team of researchers applied a maximum variation sampling strategy. This generated samples of clinics per country that were as diversified as possible.
Wider implications of the findings: The study shows that incentives are more often used on the UK and Spanish websites than on the Belgian websites. All three countries' websites used emotional appeals. It should be studied how effective these incentives and emotional appeals are, and if there is a correlation with the potential donors' risk-perceptions.
Trial registration number: not applicable

O-098 Embryo selection using Artificial Intelligence (AI): Epistemic and ethical considerations

M. Afnan[1], Y. Liu[2], V. Conitzer[3], C. Rudin[4], A. Mishra[5], J. Savulescu[6], M. Afnan[7]

[1]Imperial College London, Department of Medicine, LONDON, United Kingdom ; [2]Monash IVF Group- University of Western Australia- Edith Cowan University, Science City Monash IVF Group, Southport, Australia ; [3]Duke University, Computer Science- Economics- Philiosophy, Durham, U.S.A. ; [4]Duke University, Computer Science- Electrical Engineering- Statistical Science, Durham, U.S.A. ; [5]University of Oxford, Uehiro Centre for Practical Ethics, Oxford, United Kingdom ; [6]University of Oxford- Murdoch Children's Research Institute- Victoria- Australia, Uehiro Centre for Practical Ethics and Wellcome Centre for Ethics and Humanities Oxford, Oxford, United Kingdom ; [7]Qingdao United Family Hospital, Department of Obstetrics & Gynaecology, Qingdao, China

Study question: What are the epistemic and ethical considerations of clinically implementing Artificial Intelligence (AI) algorithms in embryo selection?
Summary answer: AI embryo selection algorithms used to date are "black-box" models with significant epistemic and ethical issues, and there are no trials assessing their clinical effectiveness.
What is known already: The innovation of time-lapse imaging offers the potential to generate vast quantities of data for embryo assessment. Computer Vision allows image data to be analysed using algorithms developed via machine learning which learn and adapt as they are exposed to more data. Most algorithms are developed using neural networks and are uninterpretable (or "black box"). Uninterpretable models are either too complicated to understand or proprietary, in which case comprehension is impossible for outsiders. In the IVF context, these outsiders include doctors, embryologists and patients, which raises ethical questions for its use in embryo selection.
Study design, size, duration: We performed a scoping review of articles evaluating AI for embryo selection in IVF. We considered the epistemic and ethical implications of current approaches.
Participants/materials, setting, methods: We searched Medline, Embase, ClinicalTrials.gov and the EU Clinical Trials Register for full text papers evaluating AI for embryo selection using the following key words: artificial intelligence* OR AI OR neural network* OR machine learning OR support vector machine OR automatic classification AND IVF OR in vitro fertilisation OR embryo*, as well as relevant MeSH and Emtree terms for Medline and Embase respectively.
Main results and the role of chance: We found no trials evaluating clinical effectiveness either published or registered. We found efficacy studies which looked at 2 types of outcomes – accuracy for predicting pregnancy or live birth and agreement with embryologist evaluation. Some algorithms were shown to broadly differentiate well between "good-" and "poor-" quality embryos but not between embryos of similar quality, which is the clinical need. Almost universally, the AI models were opaque ("black box") in that at least some part of the process was uninterpretable.

"Black box" models are problematic for epistemic and ethical reasons.

Epistemic concerns include information asymmetries between algorithm developers and doctors, embryologists and patients; the risk of biased prediction caused by known and/or unknown confounders during the training process; difficulties in real-time error checking due to limited interpretability; the economics of buying into commercial proprietary models, brittle to variation in the treatment process; and an overall difficulty troubleshooting.

Ethical pitfalls include the risk of misrepresenting patient values; concern for the health and well-being of future children; the risk of disvaluing disability; possible societal implications; and a responsibility gap, in the event of adverse events.
Limitations, reasons for caution: Our search was limited to the two main medical research databases. Although we checked article references for more publications, we were less likely to identify studies that were not indexed in Medline or Embase, especially if they were not cited in studies identified in our search.
Wider implications of the findings: It is premature to implement AI for embryo selection outside of a clinical trial. AI for embryo selection is potentially useful, but must be done carefully and transparently, as the epistemic and ethical issues are significant. We advocate for the use of interpretable AI models to overcome these issues.

[4]iGenomics SL, PGS Research - Parque Tecnologico, Valencia, Spain ;
[5]IVI, Madrid, Madrid, Spain ;
[6]Genoma Group srl, Molecular Genetics Laboratories, Rome, Italy ;
[7]ESHRE, Central Office, Grimbergen, Belgium

Abstract text

Study question: Which are the trends shown in data collection XXI of the European Society of Human Reproduction and Embryology (ESHRE) PGT Consortium compared with previous years?

Summary answer: Data collection XXI, year 2019, represents valuable data on PGT activity in (mainly) Europe and reports on the main trends observed, being the further expansion of comprehensive testing technology in PGT-SR and PGT-A.

What is known already: The ESHRE PGT Consortium was set up in 1997 and from that time has been collecting data on PGT and PGT-A. The PGT database comprises the world's largest collection of PGT / PGT-A data providing a valuable resource for data mining and for following trends in PGT practice. So far, up to the year 2015, data collections were carried out in a retrospective data way, from 2016 onwards a prospective data collection was in place.

Study design, size, duration: As the nature of PGT/ PGT-A treatments has changed significantly over the last years and IVF cycle management and genetic analysis techniques are getting more complex, ESHRE uses an online data collection system in which data are collected prospectively from oocyte retrieval to analysis, embryo transfer and pregnancy / live birth. Data are collected cycle by cycle on a voluntary basis.

Participants/materials, settings, method: For the 2019 data, individual centres (31) from 19 countries directly entered the data into the PGT database through software developed by ESHRE. Data were analysed at ESHRE headquarters and include all aspects of PGT/PGT-A cycles.

Main results and the role of chance: The Consortium has analysed the PGT analyses (n=2735) performed in 2019. The indications for PGT included inherited chromosomal abnormalities (n=253 analyses), monogenic disorders (n=1105 analyses), aneuploidy testing for infertility (n=1111 analyses) or combinations of the above (n=266 analyses). In addition, 662 clinical pregnancies and 216 deliveries have been analysed in detail. The methods used for biopsy were polar body (2%), cleavage stage biopsy (35%) and blastocyst biopsy (61%; comparable with data from 2018). The methodology used for diagnosis is what is evolving most over the last years, with data set XXI (2019) showing around 7% of FISH, 37% of PCR and 55% of WGA. Within WGA 90.6% of the analysis were done using NGS, in 4.4% cases SNP arrays were used and in 2.4% array-CGH was used. The overall clinical pregnancy rate is about 24% per analysis. The baby data show that it is difficult for most centres to have a detailed follow-up.

Limitations, reasons for caution: The findings apply to the 31 participating centres and may not represent worldwide trends in PGT. Data were collected prospectively, but details of the follow-up on PGT pregnancies and babies born were limited.

Wider implications of the findings: The ESHRE PGD Consortium continues its activities as an important forum for PGT practitioners to share data and exchange experiences. The information extracted from the data collections helps to monitor quality issues in PGT and survey the introduction and effectiveness of new PGT technologies and methods.

SESSION 10: LOOKING BEYOND THE XX FACTOR

28 June 2021 Stream 2 14:00 - 15:00

O-010 The significance of male factor and sperm damage to the offspring

J. Kirkman-Brown[1]

[1]The University of Birmingham, Centre for Human Reproductive Science, IMSR, Birmingham, United Kingdom

O-011 You are what your father ate- epigenetic implications

A. Soubry[1]

[1]KU Leuven, Dept. of Public Health and Primary Care\rFaculty of Medicine, Leuven, Belgium

Abstract text

Title: You are what your father ate: epigenetic implications.
Author: Adelheid Soubry
Abstract:
An unhealthy life style, obesity and excess of dietary fats or chronic consumption of processed foods create a harmful environment for sperm health. In the current presentation our most recent findings will be presented on male exposures related to an unhealthy life style and the effects measured on clinical sperm and/or embryo parameters in humans. Next, epigenetic implications will be shown from male obesity, "healthy" and "unhealthy" foods and other related determinants (such as advanced age) before conception. Our results lend support for the existence of epigenetic windows of susceptibility in life. If the acquired epigenetic signatures are passed down to the next generation(s) this may affect future health.

Our data are based on human studies, including the Newborn Epigenetics Study (NEST) cohort, The Influence of the Environment on Gametic Epigenetic Reprogramming (TIEGER) study and the Epigenetic Legacy of Paternal Obesity (ELPO) cohort.

In brief, we found that consumption of healthy food items, such as vegetables, fruits and nuts, is positively related to total motile sperm count (TMC), while consumption of fast foods (such as fries) is associated with lower TMC. Frequent consumption of fast foods (incl. pizza and fries) is associated with opposing effects on DNA methylation patterns at the DMRs of imprinted genes (such as *IGF2* and *MEG3-IG*), compared to dietary patterns rich in whole grains and vegetables. These results correspond to our findings in sperm from obese *versus* non-obese men, and are in line with our earlier findings in children from obese fathers. While this talk will be a compilation and comparison of our research findings, it will also serve as a base for guidance and counselling in infertility.

Our results fit our new concept of the Paternal Origins of Health and Disease (POHaD), where the role of the father has been suggested in disease development of his future offspring. If better understood, tailored dietary changes may positively shape the human sperm epigenetic profile and future programming of offspring health.

POSTER DISCUSSION

SESSION 11: REPRODUCTIVE EPIDEMIOLOGY, SOCIO-CULTURAL ASPECTS AND HEALTH ECONOMY POSTER DISCUSSIONS

28 June 2021 Stream 3 14:00 - 15:00

P-718 Paternal smoking in the preconception period is associated with an increased risk of spontaneous miscarriage in a dose-dependent manner: a systematic review and meta-analysis

N. Du Fossé[1], M.L. Van der Hoorn[1], N. Buisman[1], J. Van Lith[1], S. Le Cessie[2], L. Lashley[1]

[1]Leiden University Medical Center, Obstetrics and Gynaecology, Leiden, The Netherlands ;
[2]Leiden University Medical Center, Clinical Epidemiology/Biomedical Data Sciences, Leiden, The Netherlands

Study question: What is the association between paternal lifestyle factors in the preconception period and the risk of spontaneous miscarriage?
Summary answer: Preconception paternal cigarette smoking is associated with an increased risk of spontaneous miscarriage, while no associations were found with paternal alcohol consumption and obesity.
What is known already: Although maternal lifestyle risk factors for miscarriage are well-established, studies on potentially contributing paternal factors remain sparse. Recently, a significant association was found between advanced paternal age and spontaneous miscarriage. Biological evidence indicates that smoking, excessive alcohol consumption and obesity may lead to sperm oxidative DNA damage, being a known risk factor for miscarriage.
Study design, size, duration: Systematic review and meta-analysis.
Participants/materials, setting, methods: PubMed and Embase databases were searched in August 2020. Paternal factors examined were: cigarette smoking, alcohol consumption and Body Mass Index (BMI). A qualitative risk of bias assessment was performed for all included studies. Meta-analysis was performed if sufficient data was available from studies that controlled for maternal factors. PRISMA guidelines for systematic reviews were followed.
Main results and the role of chance: The systematic search included 3386 articles of which 11 articles met the inclusion criteria. In a meta-analysis of eight studies, paternal smoking of >10 cigarettes per day in the preconception period was found to be associated with an increased risk of spontaneous miscarriage, after adjustment for maternal smoking status (1-10 cigarettes per day: 1.01, 95% CI 0.97-1.06; 11-20 cigarettes per day: 1.12, 95% CI 1.08-1.16; >20 cigarettes per day: 1.23, 95% CI 1.17-1.29). Based on five available studies, no clear association was found between paternal alcohol consumption and spontaneous miscarriage. No studies were retrieved that evaluated the association between paternal BMI and spontaneous miscarriage.
Limitations, reasons for caution: Investigating the relation between paternal lifestyle factors and spontaneous miscarriage is challenging and prone to different forms of bias, especially in retrospective studies.
Wider implications of the findings: Awareness of the association between heavy paternal smoking in the preconception period and the risk of spontaneous miscarriage should be raised. More well-designed studies are needed to further investigate the effects of other paternal lifestyle factors on the risk of spontaneous miscarriage.
Trial registration number: not applicable

P-719 Self-declared infertility and child desire among women of reproductive age in the National Survey of Demography and Health, Brazil

S. Garcia[1], M. Koyama[2]

[1]Brazilian Center for Analysis and Planning - CEBRAP, Population and Society, São Paulo, Brazil ;
[2]Independent Consultant, Independent Consultant, São Paulo, Brazil

Study question: This article aims to characterize from a socio-demographic point of view, women of reproductive age who wish to have children, declared themselves infertile, and their search for treatments and outcomes.
Summary answer: It is essential to develop specific population surveys on infertility in Brazil to identify its magnitude and main economic and social components.
What is known already: Commonly neglected in developing countries where public policy is incipient, infertility brings social, economic and psychological consequences to couples. It is considered as a serious public health problem whose impact varies among different populations and acquires relevance for specific communities. In Brazil, there are no clinical or demographic data that point us to the magnitude of the problem, its social characteristics and impact. Taking into account the postponement of motherhood for after 30 years, there will probably be an increase in the number of women and couples who may resort to infertility treatments to fulfil the desire for procreation.
Study design, size, duration: The National Survey of Demography and Health of Women and Children (PNDS) is a cross-sectional study and a household complex probabilistic sampling. The sampling units were selected according to a stratified model of simple random conglomerates in two stages: lottery draw and household draw. The last survey was conducted between June 2006 and May 2007 in 14,617 households. In the selected households, interviews were conducted with 15,575 women of reproductive age.
Participants/materials, setting, methods: The participants consisted of 15.575 women between 15 and 49 years, representative of the five Brazilian macro-regions. The information was obtained through questionnaires, applied in person, raising information on fertility, fecundity, contraception, use of health services and socioeconomic profile. The interviewer's team was formed by approximately 100 people and 27 supervisors, all-female, divided into nine regional teams. The system used for data entry was the Census and Survey Processing System - CSPro.
Main results and the role of chance: The survey results indicate that of women who wish to have children, 9.2% declared themselves infertile; 50,8% of them sought health services for treatment; non-black women had higher percentages of demand compared to black women (62.4% versus 41.3%). Also, there were higher percentages of seeking help from women belonging to classes A (61.2%), B (83.3%) and C (60.9%) compared to those belonging to classes D (30.4%) and E (7.8%) On the other side, almost half of women did not seek help to get pregnant (49,1%); this percentage is higher among black women (58%). Moreover, women in classes D and E had the highest percentages of non-demand, 69.6% and 92.2%, respectively. The reasons cited for those who do not seek help, are "I think there is no solution" (54,7%); "I don't think I can get help" (17.3%), "financial reasons" (26.8%) or "I don't know where to get it" (1,2%). Among those who sought help, 48,5% are under treatment, 24,4 % said there is no solution; 15,8% are waiting for service and 11,3% have no money for treatment. Significance limit was established for values of $p < 0.05$. The analysis was performed in the programs Stata v.9 and/or SPSS v.14.
Limitations, reasons for caution: The limitations of the study are recognized. Firstly, opinions are restricted to the moment of the interview and, thus, the desire for children may change over time. Secondly, the statement of infertility is based on self-declaration, not on clinical diagnosis.
Wider implications of the findings: This is the first study based on PNDS 2006 data on infertility and demand for treatments in Brazil. It can contribute to providing insights, raising new questions and discovering relevant categories and dimensions of analysis to be taken into account in future studies and surveys.
Trial registration number: not applicable

P-736 Elevated levels of ambient air pollutants increase the primary sex ratio in human embryos

M. Maluf[1], M. Maluf Perin[2], P.O. Maluf Perin[3], P. Perin[1]

[1]CEERH - Specialized Center for Human Reproduction, Division of Reproductive Medicine, São Paulo, Brazil ;
[2]Fundação Lusíada Medical School, Not applicable, São Paulo, Brazil ;
[3]Fundação ABC Medical School, Not applicable, São Paulo, Brazil

Study question: Are there any associations between ambient outdoor air pollution and the primary sex ratio (PSR)?
Summary answer: Short-term exposure to increased PM_{10}, $PM_{2.5}$ and NO_2 levels were significantly associated with higher PSR.
What is known already: PSR estimates represent a backward extrapolation from data based on spontaneous or induced abortions, fetal deaths or live births and are usually male-biased. A recent study, analyzing 3- to 6-day-old embryos derived from assisted reproductive technology (ART) procedures, showed that the sex ratio at conception is unbiased (0.5). Epidemiologic studies of air pollution on secondary (birth) sex ratio showed that higher levels of particulate pollution were associated with increased rates of female birth. However, a direct association between urban levels of air pollutants and PSR has not been reported.
Study design, size, duration: A retrospective cohort study was carried out to assess the impact of long- or short-term exposure to six ambient outdoor air pollutants (particulate matter, $PM_{10\mu m}$ and $PM_{2.5\mu m}$; SO_2; CO; NO_2; O_3) on PSR (XY/XX) of couples undergoing their first IVF cycle for preimplantation genetic screening (N=337). Data was from fixed air quality monitoring stations across the city between January 2014 and December 2018. Embryos with sex chromosome abnormalities were excluded from the analysis.
Participants/materials, setting, methods: Average concentrations of the pollutants for the 90 (long-term exposure) and 15 days (short-term exposure) predating oocyte retrieval represented the exposures of interest. Pollutant levels were categorized into quartiles (Q_1 to Q_4) and exposure risk was divided into two periods in which average concentrations and confidence intervals for the pollutants were in the upper quartile (Q_4 period) or not (Q_1-Q_3 period). The

strength association between exposure risk and PSR was performed through analysis of covariance.

Main results and the role of chance: The estimated means of PM_{10}, $PM_{2.5}$, SO_2, NO_2, O_3 and CO for Q_1-Q_3/Q_4 periods were 27.7/39.3, 16.7/23.7, 2.5/3.9, 37.0/46.4, 32.2/45.3 µg/m3 and 0.64/0.87 ppm and 26.3/43.0, 16.0/26.3, 2.4/4.2, 36.5/47.8, 31.7/50.4 µg/m3 and 0.62/0.90 ppm for long- and short-term exposures, respectively. PM_{10}, $PM_{2.5}$ and NO_2 levels in the Q_4 period had significantly higher PSR (138.1, 134.0 and 137.6) when compared to Q_1-Q_3 period (94.4, 98.1 and 96.4) for the short-term exposure (*p=0.0193*; *p=0.0439*; *p=0.0180*, respectively). PM_{10}, $PM_{2.5}$, SO_2, NO_2 and CO levels in the Q_4 and Q_1-Q_3 periods for the long-term exposure showed no significant effect on PSR. Contrastingly, O_3 levels in the Q_4 period had significantly lower PSR (82.6) when compared to Q_1-Q_3 (115.9) for the long-term exposure (*p=0.0202*). A monotonic increase in PSR was observed with increased PM_{10} concentration in the Q_4 period for the short-term exposure (F-ratio: 4.4476; *p=0.0352*).

Limitations, reasons for caution: Some limitations of the study should be underlined, such as its retrospective nature, exposure assessment based on pollutant levels derived from a network average across city sites, and limited extrapolation of the results to the general population.

Wider implications of the findings: Our data suggest that short-term exposure to environmental factors could affect the primary sex ratio in polluted seasons or cities. A monotonic effect on PSR in the case of exposure to increasing PM_{10} levels was identified.

P-740 Socio-cultural and clinical implications of 'routine' AMH testing in India: Insights from an interview study with the healthcare professionals (HCPs)

P. Satalkar[1], V. Provoost[2]

[1]Ghent University, Bioethics Institute Ghent, Gent, Belgium ;
[2]Bioethics Institute Ghent, Department of Philosophy and Moral Sciences- Ghent University, Ghent, Belgium

Study question: How do Indian healthcare professionals describe their clinical experience with and perspectives on AMH testing in Indian women seeking fertility treatments including fertility preservation?

Summary answer: The HCPs cautioned against AMH testing as a screening tool in presumed fertile Indian women due to its anticipated impact on women's arranged-marriage prospects.

What is known already: AMH test is being increasingly used to assess women's ovarian reserve (OR) while planning fertility treatments or to guide decisions about fertility preservation (FP). There is weak evidence suggesting that serum AMH level and fertility treatment outcomes vary in different population groups. Surveys with women in reproductive age (e.g. the US, Ireland, the Netherlands) indicate that a majority wants to know their OR to aid reproductive decision making. As yet, both globally and in an Indian context, there are only few qualitative studies exploring the views of HCPs on the OR assessment in clinical practice and its socio-cultural implications.

Study design, size, duration: This paper reports the findings of an exploratory qualitative research aimed at understanding whether and how elective fertility preservation could influence reproductive autonomy of Indian women. Between June 2018 and April 2019, IVF specialists and obstetricians practicing in ten cities across five Indian states were interviewed in English (language commonly spoken) using a semi-structured interview guide. The discussion about OR assessment with AMH-testing was initiated by the participants indicating its significance in their clinical practice.

Participants/materials, setting, methods: The study sample included 17 male and 15 female HCPs, the majority (18/32) was practicing in Mumbai. Twenty-six of them were in private practice while six worked as OBGYNs in publicly funded teaching hospitals. Twenty-six participants were interviewed in their clinics and the remaining six using Skype or telephone. After several rounds of immersive reading, the interview sections on OR and AMH-test were analyzed inductively using Braun and Clarke's thematic analysis.

Main results and the role of chance: Several participants reported that many of their patients present with decreased OR (DOR) at a younger age and need higher dosages of hormones for ovulation induction compared to the dosages mentioned in international guidelines. They corroborated this experience with a few peer-reviewed articles indicating a six-years age difference in OR of Indian women undergoing IVF compared to Spanish women. A majority of participants advocated for the rational use of OR assessment in IVF patients but warned against its indiscriminate use or interpretation out of context due to concerns about overdiagnosis of ovarian factor infertility and overtreatment with IVF with donor eggs. Although the physicians who had performed elective FP perceived AMH test as a simple, affordable and empowering tool to guide FP decisions, most participants were critical of using AMH-test as a screening tool in young, presumed fertile women completing university education. They were concerned that a diagnosis of DOR as a result of such screening in this population in the Indian context will adversely impact women's chances of marriage and might further increase pressure on women to get married and complete their childbearing early even if they are not ready for it.

Limitations, reasons for caution: This is the first qualitative study assessing views of Indian HCPs on AMH testing. These results are indicative rather than a representation of views of Indian HCPs. Almost half of the contacted HCPs did not respond to interview requests; we do not know whether they had different views.

Wider implications of the findings: The insights on clinical implications of AMH testing in India are relevant to other societies beyond the Euro-American and Australian context where AMH testing will increase in the future. The socio-cultural implications of 'routine' AMH testing in India urges us to be aware of similar implications in other cultural contexts.

INVITED SESSION

SESSION 12: RECURRENT IMPLANTATION FAILURE: A MULTI DISCIPLINARY APPROACH

28 June 2021 Stream 4 14:00 - 15:00

O-012 Diagnostic strategies

N. Macklon[1]

[1]London Women's Clinic, London Women's Clinic, London, United Kingdom

Abstract text

Most discussions of the management of recurrent implantation failure (RIF) will start by expressing the criteria for 'diagnosis' of the condition. And here lies our first mistake. Defining RIF as a condition diagnosable in terms of a standard number of embryos transferred without achieving pregnancy suggests that is a medical diagnosis in itself, for which, like other diseases, an optimal treatment strategy exists. But the failure of our field to improve outcomes in patients who suffer RIF suggest that we have approaching the condition wrongly.

RIF is NOT medical disease diagnosed by applying simple clinical criteria. It is a personal experience suffered by patients and which can uncomfortably challenge their doctors. IN order to address the mistake we have made in our approach to RIF, we need to recognise that the condition needs to be recognized in a different way. In practical clinical terms, RIF can be considered to have occurred at the point when the patient(s) and their doctor conclude that further action is necessary beyond the standard work up and treatment approach for IVF.

Our failure to understand what constitutes RIF has also resulted in large and methodologically sound trials of interventions proposed to 'treat' RIF missing the target. Based as most have been on the premise that RIF is a disease for which the optimal treatment exists if we can just find it, these trials are largely destined to produce negative results, as those in whom the intervention was effective cannot be differentiated form those in whom it might have caused harm. The resulting 'zero sum' requires the study authors to write off the studied intervention as ' ineffective' potentially depriving certain patients of a useful treatment.

So how can we address the therapeutic impasse that we have created?

The answer is surely clear. When our standard best practices fail to result in pregnancy after IVF in a particular patient, we simply need to try to understand why. This requires the classic diagnostic approach: consider RIF a symptom; look for signs that might explain it and order investigations to pin down the cause(s).

So what diagnostic approaches should be applied? In many cases, the embryo factor will already have been subject to considerable scrutiny. When treatment continues to fail, the focus will therefore tend to turn at this point to the patients.

This is where the story begins to look more positive. In recent years it has become clear how active a role the endometrium plays in embryo implantation. As these novel endometrial factors have become elucidated, clinical tests of their function have begun to emerge. While many contributory factors merit investigation when RIF is considered to have arisen, this lecture will introduce the concept of the 'endometrial diagnostic toolkit' that promises to enable us to treat RIF on the basis of individual rationale rather than blind hope, and to test the efficacy of targeted rather than blind interventions.

28 June 2021 Stream 1 15:15 - 16:30

P-751 Immediate versus postponed frozen-thawed embryo transfer after IVF/ICSI: a systematic review and meta-analysis

S. Bergenheim[1], M. Saupstad[1], N. Pistoljevic[1], A. Nyboe Andersen[1], J. Lyng Forman[2], K. Løssl[1], A. Pinborg[1]

[1]Copenhagen University Hospital- Rigshospitalet, Fertility Department 4071, Copenhagen Ø, Denmark ;
[2]Copenhagen University Hospital- Rigshospitalet, Department of Public Health-Section of Biostatistics, Copenhagen K, Denmark

Study question: Can frozen embryo transfer (FET) be offered immediately after a stimulated IVF/ICSI cycle without compromising live birth rate (LBR)?
Summary answer: FET in the menstrual cycle immediately following the stimulated IVF/ICSI cycle was associated with a slightly higher LBR compared to standard postponed FET.
What is known already: It is standard clinical practice to postpone FET for at least one menstrual cycle following a failed fresh transfer or a freeze-all cycle. This practice is thought to minimize any possible residual negative effect of ovarian stimulation, with excessive steroid levels and multiple corpora lutea, on the resumption of a normal ovulatory cycle and receptivity of the endometrium. Even so, elective deferral of FET is an empirical strategy based on suggestions rather than solid scientific evidence and may unnecessarily delay time to pregnancy, causing frustration and decreased quality of life to couples.
Study design, size, duration: Systematic review and meta-analysis according to PRISMA guidelines. Original studies on subfertile women aged 18-46 with any indication for treatment with IVF/ICSI investigating the timing of FET after IVF/ICSI were included. Intervention was defined as FET in the menstrual cycle immediately following the stimulated IVF/ICSI cycle. Comparator was defined as FET in the second or subsequent menstrual cycle following IVF/ICSI. Risk of bias was assessed using Robins-I and quality of evidence using GRADE.
Participants/materials, setting, methods: PubMed (MEDLINE) and EMBASE databases were searched for MeSH and Emtree terms, as well as text words related to timing of FET, up to March 2020. There were no limitations regarding year of publication or duration of follow-up but to English language. The primary outcome was LBR. Secondary outcomes were implantation rate, pregnancy rate, clinical pregnancy rate (CPR), time-to-pregnancy, miscarriage rate (MR), cycle cancellation rate and patient wellbeing.
Main results and the role of chance: Out of 4124 search results, 15 studies were included in the review. Studies reporting adjusted odds ratios (aOR) for LBR, CPR and MR were included in meta-analyses. All studies (n=15) were retrospective cohort studies involving a total of 6,304 immediate FET cycles and 13,851 postponed FET cycles including 8,019 matched controls. Twelve studies of very low to moderate quality reported no difference in LBR with immediate versus postponed FET. Two studies of moderate quality reported a statistically significant increase in LBR with immediate FET and one small study of very low quality reported better LBR with postponed FET. Trends in rates of secondary outcomes followed trends in LBR regarding timing of FET. The meta-analyses showed a significant advantage of immediate FET (n=2,076) compared to postponed FET (n=3,833), with a pooled aOR of 1.20 (95% CI 1.01-1.44) for LBR and a pooled aOR of 1.22 (95% CI 1.07-1.39) for CPR.
Limitations, reasons for caution: Limitations include the retrospective design and heterogeneity of studies included, limiting comparison and pooling of data. With little transparency regarding cancellation rates, the risk of selection bias is apparent. Further, confounding by embryo quality is a limitation. Small sample sizes are a limitation to subgroup meta-analyses.
Wider implications of the findings: The standard clinical practice of postponing FET for at least one menstrual cycle following a failed fresh transfer or a freeze-all cycle may not be best clinical practice. Randomized controlled trials including data on cancellation rates are highly needed to provide high grade evidence regarding clinical practice and patient counseling.

P-766 Neurodevelopment in fetuses conceived by assisted reproductive technologies following fresh and frozen embryo transfer

M.L. Boutet[1], E. Eixarch[1,2,3], P. Ahumada-Droguett[1], F. Crovetto[1,2], M.S. Cívico[4], D. Manau[2,4], E. Gratacós[1,2,3], F. Crispi[1,2,3], G. Casals[4]

[1]BCNatal - Fetal Medicine Research Center Hospital Clínic and Hospital Sant Joan de Déu., Universitat de Barcelona, Barcelona, Spain ;
[2]Institut d'Investigacions Biomèdiques August Pi i Sunyer IDIBAPS, Barcelona, Barcelona, Spain ;
[3]Centre for Biomedical Research on Rare Diseases CIBER-ER, Barcelona, Barcelona, Spain ;
[4]Assisted Reproduction Unit- Hospital Clínic de Barcelona, Universitat de Barcelona, Barcelona, Spain

Study question: Do *in vitro* fertilization (IVF) offspring present different neurodevelopment assessed by fetal neurosonography and infant neurobehavioral tests as compared to those spontaneously conceived (SC)?
Summary answer: IVF offspring, especially those obtained after fresh embryo-transfer (ET), showed subtle structural differences in fetal neurosonography and poorer neurobehavioral scores at twelve months of age.
What is known already: The number of pregnancies following assisted reproductive technologies (ART) is currently increasing worldwide. Concerns about the neurodevelopment of subjects conceived by IVF have been rising and mostly studied in children and adolescents with inconsistent results. Many of the identified risk associations were only observed in subgroups or disappeared after adjustment for covariates, mainly multiple pregnancy and gestational age at birth. It is unknown whether fetal brain development and cortical folding differ prenatally in IVF fetuses as compared to SC.
Study design, size, duration: This is the first study examining fetal neurodevelopment by neurosonography in IVF fetuses.

A prospective cohort study of 210 singleton pregnancies recruited from 2017 to 2020, including 70 SC gestations, 70 conceived by IVF following frozen ET (FET) and 70 IVF after fresh ET.

Fetal neurosonography was performed in all pregnancies. Additionally, *Ages & Stages Questionnaires* (ASQ) were obtained at 12 months of corrected age.
Participants/materials, setting, methods: IVF pregnancies were recruited from a single Assisted Reproduction Center, ensuring homogeneity in IVF stimulation protocols, endometrial preparation, laboratory procedures and embryo culture conditions. SC pregnancies were randomly selected from low-risk fertile couples and paired to IVF by maternal age. Fetal neurosonography including transvaginal approach was performed at 32±2 weeks of gestation, measured offline by a single investigator and normalized by biparietal or occipitofrontal diameter. ASQ were obtained postnatally, at 12 months of corrected age.
Main results and the role of chance: Study groups were similar and comparable regarding maternal age, body mass index, study level and employment rate together with exposure to smoke, alcohol, aspirin and corticoids during pregnancy, gestational age (32±2 weeks) and estimated fetal weight (1700±400g) at neurosonography.

As compared to SC pregnancies, both IVF populations showed differences in cortical development with reduced parieto-occipital (fresh ET 12.5mm [SD 2.5] vs FET 13.4 [2.6] vs SC 13.4 [2.6]), cingulate (fresh ET 5.8 [IQR 4.2-7.4] vs FET 5.8 [4.1-7.5] vs SC 6.5 [4.8-7.8]) and calcarine (fresh ET 13.5 [IQR 10.1-16.1] vs FET 14.5 [12.1-15.8] vs SC 16.4 [14.3-17.9]) sulci depth together with lower Sylvian fissure grading. Cortical development changes were more pronounced in the fresh ET group as compared to FET. Corpus callosum length and insula depth were lower in FET and fresh ET groups, respectively. Neurosonographic changes remained statistically significant after adjustment by ethnicity, gender, gestational age and weight centile at scan.

IVF infants showed worse ASQ scores, especially in fresh ET for communication, personal-social, fine-motor and problem-solving skills. Gross-motor scores were significantly lower in FET as compared to SC and fresh ET. Differences were statistically significant after adjustment by maternal ethnicity, study level, employment status, breastfeeding, gender and corrected age.

Limitations, reasons for caution: The reported neurodevelopmental differences are subtle, with most neurosonographic findings lying within normal ranges.

Infertility factors contribution to the outcome cannot be unraveled from the ART procedure itself.

The milder features found in FET individuals cannot condition the technique´s choice and must be considered together with their global perinatal results.

Wider implications of the findings: Neurosonography is an appropriate tool to identify subtle brain differences between fetuses exposed and not exposed to ART. Prenatal features were consistent with postnatal neurobehavioral findings. These results support the relevance of a neurodevelopmental follow-up in IVF patients. Further studies are warranted to assess the long-term performance in these subjects.

Trial registration number: not applicable

P-767 Cumulative live birth rate after IVF - trend over time and the impact of blastocyst culture and vitrification

Z. Saket[1], K. Kallen[2], K. Lundin[1], Å. Magnusson[1], C. Bergh[1]

[1]Institute of Clinical Sciences- Sahlgrenska Academy, Department of Reproductive Medicine- Sahlgrenska University Hospital- SE-413 45 Göteborg- Sweden, Gothenburg, Sweden ;

[2]Intitution of Clinical Sciences- Lund University, Department of Obstetrics and Gynecology- Tornblad Institute, Lund, Sweden

Study question: Has cumulative live birth rate (CLBR) improved over time and which factors are associated with such an improvement?

Summary answer: During 2007-2017, CLBR per oocyte aspiration increased significantly (27.0 % to 36.3 %), in parallel with an increase in blastocyst transfer and cryopreservation by vitrification.

What is known already: While it has been shown that live birth rate (LBR) per embryo transfer (ET) is higher for fresh blastocyst than for fresh cleavage stage embryo transfer, CLBR per oocyte aspiration, including one fresh ET and all subsequent frozen embryo transfers (FET), does not seem to differ between the two culture strategies.

Study design, size, duration: STUDY DESIGN, SIZE, DURATION: National register study including all oocyte aspirations performed in Sweden 2007-2017, n=124 700. Donation cycles excluded.

Participants/materials, setting, methods: Data were retrieved from the Swedish National Registry of Assisted Reproduction (Q-IVF). CLBR was defined as the number of deliveries with at least one live birth resulting from one oocyte aspiration, including all fresh and/or frozen embryo transfers within one year. The delivery of a singleton, twin, or other multiples was registered as one delivery. Cryopreservation of cleavage stage embryos was performed by slow freezing and of blastocyst by vitrification.

Main results and the role of chance: Overall, the CLBR per oocyte aspiration increased significantly during the study period, from 27.0 % to 36.3 % (OR 1.039, 95% CI 1.035-1.043) and from 30.0 % to 43.3 % if at least one ET was performed (AOR 1.055, 95% CI 1.050-1.059). The increase in CLBR was independent of maternal age, number of oocytes retrieved and number of previous IVF live births. The CLBR for women <35 years and ≥ 35 years both increased significantly, following the same pattern. During the study period a substantially increasing number of blastocyst transfers were performed, both in fresh and in FET cycles. An important contributor included in the blastocyst strategy, may be the extended culture of the total cohort of embryos, also embryos earlier discarded at early cleavage stages, in order to reach the blastocyst stage. These embryos may contribute to the total number of available blastocysts and thereby increase the chance of a live birth within that oocyte aspiration cycle. Other important predicting factors for live birth, such as number of embryos transferred, could not explain the improvement, on the contrary the single embryo transfer (SET) rate increased with time.

Limitations, reasons for caution: The retrospective design implicates that other confounders of importance for CLBR can not be ruled out. In addition, some FET cycles might be performed later than one year post oocyte aspiration for the last year (2017) and are thus not included in this study.

Wider implications of the findings: The results suggest that blastocyst transfer, particularly when used in FET cycles and in combination with vitrification, is an important contributor to the improved live birth rates over time. This gives a possibility for fewer oocyte aspirations needed to achieve a live birth and a shortened time to live birth.

Trial registration number: -

P-777 Comparison of GnRH-a trigger and GnRH-a plus low-dose HCG trigger for high ovarian responders in IVF/ICSI: A retrospective study based on propensity score matching

Y. Li[1]

[1]Chengdu Jinjiang Hospital for Maternal and Child Health Care, Center for Reproductive Medicine, Chengdu, China

Study question: Does GnRH agonist trigger for high responders during IVF/ICSI cycles improve the number of good-quality embryos, the incidence of moderate-to-severe OHSS, and pregnancy outcome compared to GnRH-a plus low-dose HCG?

Summary answer: GnRH-a trigger alone can effectively reduce the incidence of moderate-to-severe OHSS in women with high ovarian responses without affecting embryo quality.

What is known already: Previous studies have shown conflicting results on the different trigger protocol in high responders in IVF/ICSI outcomes, and as for women with high ovarian response, there is little known about the effects of GnRH-a plus low-dose HCG versus GnRH-a alone on oocytes maturation, the rate of good quality embryos, the incidence of moderate-to-severe OHSS, and pregnancy outcome during IVF/ICSI cycles.

Study design, size, duration: A retrospective analysis was conducted on patients with high ovarian response who received IVF/ICSI treatment with a flexible GnRH antagonist regimen, at the Center of Reproductive Medicine, Chengdu Jinjiang Hospital for Maternal and Child Health Care, from January 1 2017 to December 31 2018. Using 1:1 propensity score matching, 513 cases entered each group (a total of 1,026 females).

Participants/materials, setting, methods: The high responders were included and assigned to groups A (0.2 mg triptorelin) and B (0.2 mg triptorelin plus 2000 IU HCG) for final oocyte maturation. Their basic clinical characteristics, information about controlled ovarian stimulation cycle, embryologic data, and pregnancy outcome in FET were retrospectively compared. The main outcome measures of the study were the rate of good-quality embryos, the number of available embryos, the incidence of moderate-to-severe OHSS, and the cumulative live-birth rate.

Main results and the role of chance: Using 1:1 propensity score matching, 513 females were included in each group. No significant differences in baseline clinical data were found between the two groups, including age at diagnosis, spouse's age, the duration of infertility, the infertility type, and the cause of infertility, BMI, anti-Müllerian hormone (AMH) levels, and the antral follicle count (AFC) ($p > 0.05$). None significant differences were found in the total doses of gonadotropin (Gn), the duration of ovarian stimulation, serum P and LH levels on the trigger day, the number of oocytes retrieved, the rate of 2PN embryos, and the rate of good-quality embryos ($p > 0.05$). The serum E2 level on the trigger day in group A was significantly higher than that in group B ($p < 0.001$). Women in group A had a lower incidence rate of moderate-to-severe OHSS than individuals in group B ($p < 0.001$). There was a non-significant difference in the cumulative live-birth rate between the two groups ($p > 0.05$).

Limitations, reasons for caution: As this is a retrospective study that uses data initially collected for other purposes, limitations may exist in the selection,

implementation, and measurement biases that cannot be avoided. However, our study underlies the need for further prospective, multi-center joint-controlled studies to validate these findings.
Wider implications of the findings: This study demonstrates that GnRH-a alone can reduce the incidence of moderate-to-severe OHSS without harming embyro quality in women with high ovarian response. These findings need further prospective validations in hyperresponsive populations by multi-center, large-sample, randomized controlled studies.
Trial registration number: N/A

P-783 Clinical, obstetric and perinatal outcomes after vitrified-warmed euploid blastocyst transfer are independent of cryo-storage duration.

R. Maggiulli[1], D. Cimadomo[1], L. Dovere[1], F. Innocenti[1], L. Albricci[1], D. Soscia[1], A. Giancani[1], F. Sanges[1], M.G. Amendola[1], L. Tacconi[1], G. Nastri[1], V. Morgante[1], A. Vaiarelli[1], F. Ubaldi[1], L. Rienzi[1]

[1]Clinica Valle Giulia, GeneraLife IVF, Rome, Italy

Study question: Is cryo-storage duration associated with the outcomes after vitrified-warmed euploid single blastocyst transfer?
Summary answer: Lower live-birth-rates from blastocysts cryo-stored for periods longer than 3-months are mostly imputable to the worse quality of the embryos being warmed across sequential transfers.
What is known already: Blastocyst vitrification is crucial in modern IVF. Given its widespread application, a constant comprehensive monitoring of its effect on reproductive outcomes is pivotal. For instance, the effect of cryo-storage duration on embryo implantation potential, gestational and perinatal outcomes is object of a still ongoing investigation. The evidence in this regard are contrasting especially with regard to similar or decreased live birth rates among blastocysts subject to long-term cryo-storage. When investigating the neonatal outcomes, instead, no impact of blastocyst cryo-storage duration has ever been reported to date. Yet, data on euploid blastocysts and adjusted for quality and full-blastulation day are needed.
Study design, size, duration: Retrospective observational study. We included 2688 vitrified-warmed euploid single blastocyst transfers. The primary outcome was the live-birth-rates (LBR) according to cryo-storage duration clustered as ≤60, 61-90, 91-180, 181-360, 361-720, 721-1080 and >1080-days. The secondary outcomes were the miscarriage rate, the rates of gestational and perinatal issues among the deliveries, and the mean gestational age and birthweight among the babies born. All data were adjusted for confounders through linear or logistic regression analyses.
Participants/materials, setting, methods: We included all vitrified-warmed transfers (range:1-8) conducted between May-2013 and March-2020 by 1884 patients (age:38±3yr) undergoing one blastocyst stage PGT-A cycle and obtaining ≥1 euploid embryo at our private clinic. Among putative confounders, only the number of sequential transfer from the same patient, blastocyst quality (Gardner's scheme) and full-blastulation day (5-7) significantly associated with the LBR through univariate regressions. No association was reported for sperm factor, maternal age, incubator, and culture media.
Main results and the role of chance: The LBR of euploid blastocysts cryo-stored for ≤60-days was 49.4% (N=319/646) versus 48.7% (N=292/599; OR:0.98,95%CI:0.78-1.21,p=0.82) between 61-90-days, 42.9% (N=291/679; OR:0.77,95%CI:0.62-0.96,p=0.02) between 91-180-days, 41.7% (N=169/405; OR:0.73,95%CI:0.57-0.94,p=0.02) between 181-360-days, 34.7% (N=50/144; OR:0.55,95%CI:0.37-0.79,p<0.01) between 361-720-days, 53.4% (N=63/118; OR:1.17,95%CI:0.79-1.74,p=0.42) between 721-1080-days, and 50.5% (N=49/97; OR:1.05,95%CI:0.68-1.60,p=0.83) for >1080-days. However, when these data were adjusted for blastocyst quality and full-blastulation day, all the multivariate-OR were not-significant. Indeed, the longer the cryo-storage period the worse the quality of the euploid blastocysts transferred (e.g. AA-blastocysts were 74% among embryos cryo-stored for ≤90-days, but always <70% for embryos cryo-stored for longer periods, p<0.01; similarly, day5-blastocysts were ~50% among embryos cryo-stored for ≤90-days, but always <50% for embryos cryo-stored for longer periods, p=0.02). The miscarriage-rate (overall 14%, ranging 7-18%) was not associated with cryo-storage duration already from univariate regressions. Also the gestational (overall 6%, ranging 0-8%) and perinatal issues rates (overall 3%, ranging 0-5%) were not associated with cryo-storage duration already from the univariate regressions. Neither the gestational age nor the birthweight showed significant associations with cryo-storage duration, as confirmed by linear regressions. In fact the rate of newborns whose weight was normal-for-gestational-age was similar across all cryo-storage duration groups (overall 81%, ranging 80-83%).
Limitations, reasons for caution: The prevalence of first transfers decreases from ≥95% for procedures conducted ≤90-days from vitrification to 71%, 39%, 22% and 4% for procedures conducted between 91-180, 181-360, 361-720 and >720-days, respectively. However, also the sequential number of transfer was not associated with the LBR when adjusted for blastocyst-quality and full-blastulation day.
Wider implications of the findings: Cryo-storage by vitrification is confirmed safe in the hands of experienced operators, and its duration does not impact any outcome. This information is valuable for freeze-all cycles, but also for women cryo-preserving surplus embryos for second pregnancies; in this regard, 6.8% of the patients in this study delivered ≥2 LBs.
Trial registration number: not applicable

[2]University Hospitals of geneva and the Faculty of medicine of the geneva University, Département de médecine - service d'angiologie et d'hémostase, Geneva, Switzerland ;
[3]University Hospitals of geneva and the Faculty of medicine of the geneva University, Centre de recherche clinique - service d'épidémiologie clinique, Geneva, Switzerland ;
[4]University Hospitals of Lausanne and the Faculty of medicine of the Lausanne University, DFMA-Ob/Gyn-reproductive medicine, Geneva, Switzerland

Study question: Does the evolution of prothrombotic biomarkers over time differ between antagonist and long agonist stimulation protocols for assisted reproductive techniques (ART) ?
Summary answer: The hypercoagulable state was higher and persistent in the agonist and antagonist with hCG triggering groups compared to the antagonist with GnRH agonist triggering group.
What is known already: Controlled ovarian stimulation (COS) for ART is associated with supra-physiological serum estradiol levels, a hypercoagulable state and an increased risk of venous thrombosis. Most thromboembolic events associated with COS occur in the context of ovarian hyperstimulation syndrome (OHSS). The use of hCG for final follicular maturation increases the risk of OHSS. In antagonist protocols, GnRH agonist triggering is known to prevent or reduce OHSS and is therefore widely used in women at risk. The impact of the different IVF protocols on pro-thrombotic biomarkers is unknown.
Study design, size, duration: In this prospective observational cohort study, infertile women undergoing COS for ART in 2017-2019 at the University Hospitals of Geneva and Lausanne (Switzerland) were included. We evaluated changes in key coagulation parameters (D-dimers, factor VIII, fibrinogen activity, protein S and protein C) and thrombin generation, our primary outcome, (using 5 pM of tissue factor) by calibrated automated thrombinography before stimulation (T1), on the day of ovulation triggering (T2) and seven days after triggering (T3).
Participants/materials, setting, methods: COS was started without hormonal pre-treatment. Protocols were prescribed according to the standards used in each centre taking into account the risk of OHSS (agonist protocol with hCG trigger in women without OHSS risk (Group 1); antagonist protocol in women at risk of OHSS with hCG trigger (Group 2;) or GnRH agonist trigger

(Group 3;); variation of endogenous thrombin potential (ETP) was measured and compared among groups using mixed effects linear regression model.

Main results and the role of chance: A total of 64 women were included: 24 were in group 1, 16 in group 2, and 24 in group 3. The mean age (SD) was 37.8 (2.8), 35.9(5.2) and 34(4.6) years in groups 1, 2 and 3 respectively. As expected, women in group 1 had a statistically lower level of anti-müllerian hormone (p=<0.001), a lower antral follicular count (p=<0.001) and lower number of MII oocytes and embryos obtained (p=<0.001). Mean serum estradiol levels were 1836 (1160), 1628 (815) and 3754 (2165) ng/L at T2, and 945 (471), 1061 (495) and 413 (729) ng/L at T3, in group 1 to 3, respectively. In multivariable regression analysis, the levels in group 3 were statistically higher at T2 and lower at T3 (overall time*group interaction: p<0.001).

The mean ETP was similar between all groups at T1, and increased in all groups at T2 (1442, 1426 and 1486 nM/min in groups 1, 2 and 3, respectively) (p=0.013). Overall, ETP evolution over time was statistically different between groups, with the lowest increase of ETP between T1 and T3 in group 3. Protein C and protein S levels were stable, while D-dimers, fibrinogen and factor VIII increased at T2 and T3 in all groups.

Limitations, reasons for caution: Stimulation protocols were prescribed according to the clinical profile and OHSS risks; groups therefore differ substantially in regards to age and ovarian reserve. Thromboembolic events are rare events after COS, we therefore evaluated biological markers of hypercoagulability and not clinical events.

Wider implications of the findings: Women with GnRH agonist triggering protocol did not increase mean ETP in the week after ovulation, while women with hCG triggering did. This different prothrombotic profile was independent of the variation of the other coagulation parameters investigated. This effect of ovulation triggering should be confirmed by further studies.

Trial registration number: NCT04188444

P-631 Embryo euploidy rates following follicular or luteal start ovarian stimulation. A prospective study with repeated ovarian stimulation ovarian stimulation cycles.

F. Martinez[1], E. Clua[1], M. Roca[1], S. Garcia[1], M. Parriego[1], N.P. Polyzos[1]

[1]Hospital Universitario Dexeus, Obstetrics- Gynecology and Reproduction Medicine, Barcelona, Spain

Study question: Is there any difference in embryo euploidy rates following luteal phase phase (LS) and follicular phase (FS) start ovarian stimulation.

Summary answer: The number of euploid blastocysts and embryo euploidy rate are comparable when comparing FS and LS.

What is known already: Random start ovarian stimulation (starting at any time of the cycle) has been traditionally used in women undergoing urgent fertility preservation for medical reason. Although there is accumulating evidence that in infertile women, LS can result in equivalent number of oocytes and embryos as compared with FS, no study has evaluated the effect of luteal phase start ovarian stimulation on embryo euploidy rates. The current study is the first prospective study designed to evaluate embryo euploidy rates in donors undergoing two identical consecutive ovarian stimulation protocols within a period of 6 months starting either in the (FS), or (LS).

Study design, size, duration: In a prospective study, conducted between May 2018 and January 2020, 40 oocyte donors underwent two consecutive ovarian stimulation protocols within a period of 6 months with an identical fixed GnRH antagonist protocol starting either in the early follicular (FS), or and luteal menstrual cycle phase (LS).

Participants/materials, setting, methods: All participants underwent two identical consecutive ovarian stimulation cycles with 150µg corifollitropin alfa followed by 200 IU rFSH in a fixed GnRH antagonist protocol either in the FS or LS. Six MII oocytes from the same oocyte donor, from each stimulation cycle, were allocated to the recipients and were inseminated with the same sperm sample (recipients partner sperm or donor sperm). Embryos were cultivated to blastocyst stage followed by preimplantation genetic testing for aneuploidies (PGT-A).

Main results and the role of chance: When comparing FP with LP, the duration of ovarian stimulation was significantly shorter (9.68± 2.09 vs 10.93± 1.55 days), 95% CI [-1.95; -0.55] and a higher total additional dose of daily recFSH was significantly lower (526.14± 338.94 IU vs 726.14± 366.27), 95% CI [-315,12; -84,88] when CPT was administered in the luteal phase. . There were no differences in the hormone values on the triggering day (Estradiol 2137.61±1198.25 pg/ml vs 2362.96±1472.89); 95% CI [-1160.45;709.76]. Overall no differences were observed in the number of oocytes (24.84± 11.200 vs 24.27± 9.08); 95% CI[-2,61; 3.75] and MII oocytes (21.41±10.19 vs 21.59± 8.81), 95%CI [-2.72; 2.35] retrieved between FP and LP cycles in the oocytes donors. Following oocyte allocation and fertilization to the recipients, a total of 245 blastocysts were biopsied (blastocyst formation rate 245/408, 60.05%), 117 in FP group and 128 in LP group. The overall blastocyst euploidy rate was 59.18% . There were no differences in the number of euploid embryos between FS (1.59±1.32) and LS (1.70±1.29), mean difference 0.11, 95%CI [-0.65; 0.46]. Finally, there were no differences in the percentage of euploid embryos per oocytes inseminated between FS [70/287 (24.4%)] and LP [75/278 (24.7%), mean difference -0.027, 95%CI [-0.11; 0.06].

Limitations, reasons for caution: The study was performed in oocyte derived from potentially fertile young oocyte donors thus caution is needed when extrapolating the results in oocytes derived from infertile women of older age.

Wider implications of the findings: Luteal phase stimulation does not alter embryo euploidy status as compared with follicular phase stimulation and thus it appears that it can be safely used not only in cases of urgent medical fertility preservation but also in patients undergoing ovarian stimulation for IVF/ICSI.

Trial registration number: Clinical Trials Gov (NCT03555942).

P-643 Pre-selected for an award: Is Euploid blastocyst number higher in luteal versus follicular phase? A case-control study of IVF outcomes of follicular versus luteal phase ovarian stimulation

B. Biscaro[1], A.R. Lorenzon[2], E.L. Motta[3], C. Gomes[4]

[1]Huntington Medicina Reprodutiva, Clinical Department, Santana de Par, Brazil ; [2]Huntington Medicina Reprodutiva, Research and Development, São Paulo, Brazil ; [3]Huntington Medicina Reprodutiva/Federal University of São Paulo, Medical Director/Department of Gynecology- School of Medicine, São Paulo, Brazil ; [4]Huntington Medicina Reprodutiva, Clinical Department, São Paulo, Brazil

Study question: Is there a difference between IVF outcomes in patients undergoing follicular versus luteal phase ovarian stimulation in different menstrual cycles?

Summary answer: Number of euploid blastocyst were higher in luteal phase ovarian stimulation IVF cycles. All other outcomes were similar between follicular and luteal phase IVF cycles.

What is known already: It has been published that human beings can have two or three follicular recruitment waves as observed in animals studies a long time ago. From these findings, several recent studies showed that two egg retrievals at the same menstrual cycle, named as Duo Stim, optimize time and IVF outcomes in women with low ovarian reserve due to more eggs retrieved in a shorter period with consequently higher probability of having good embryos to transfer. However, there is no knowledge about diferences concerning IVF outcomes between folicular and luteal ovarian stimulation, performed at the same women in different menstrual cycles.

Study design, size, duration: Retrospective, case-control study in a single IVF center. One-hundred-two patients who had two IVF treatments – the first cycle initiating ovarian stimulation at follicular phase (FPS) and the second cycle initiating after a spontaneous ovulation at luteal phase (LPS) – in different menstrual cycles (until 6 months apart) between 2014 and 2020, were included. Statistical analysis was performed with Mann-Whitney test and was considered significant when p≤0.05. Data is represented as mean±SD.

Participants/materials, setting, methods: Patients underwent two IVF treatments in different menstrual cycles; the FPS IVF treatment was initiating at D2/D3 of menstrual cycle and the LPS treatment started three or four days after spontaneous ovulation, if at least 4 antral follicles were detected. Both IVF treatments were performed with and antagonist protocol and freeze all strategy. The majority of patients presents low ovarian reserve/Ovarian age as primary infertility factor (84.3%).

Main results and the role of chance: Patient's mean age was 39.30±3.15 years, BMI (22.66±3.16) and AMH levels (0.85±0.85 ng/mL). Comparison of hormonal levels at the beginning of ovarian stimulation showed differences for FPS vs LPS, as expected: E2 (39.69±31,10 pg/mL vs 177.33±214.26 pg/mL,

p< 0.0001) and P4 (0.76±2.47ng/mL vs 3,00±5.00 ng/mL,p< 0.0001). However, E2 and P4 at the day of oocyte maturation trigger were not different between FPS and LPS (1355.24±895.73 pg/mL vs 1133.14±973.01 ng/mL,p=0.0883 and 1.12±1.49 ng/mL vs 2.94±6.51,p=0.0972 respectively). There was no difference for total dose of gonadotrofins (FPS 2786.43±1102.39.01UI vs LPS 2824.12±1188.87UI, p=0,8578), FSH (FPS 9.50±4.98 vs LPS 11.90±12.99, p=0.7502) and AFC (FPS 7.13±4.25 vs LPS 6.42±4.65,p=0,0944). From 102 patients that started ovarian stimulation, 78 had 1 or more oocyte collect in FPS group and 75 in LPS group: OPU (FPS 4.78±4.93 vs LPS 4.65±5.54,p=0.7889), number of MII (FPS 3.21±3.52 vs LPS 3.40±4.53,p=0.7889). From those, 52 patients performed ICSI in both cycles; fertilization rate 64.9%±28.6% for FPS vs 62.1%±32.4% for LPS,p=0.7899) and blastocyst formation 2.15±2.15 for FPS vs 2.54±2.35,p=0.3496). Data from 25 patients who had embryo biopsy for PGT-A showed similar number of blastocyst biopsed (2.12±1.72 FPS vs 2.48±1.71 LPS,p=0.3101) and a statistically significant difference regarding number of euploid blastocyst (0,20±0,41 FPS vs 0,96±0,93 LPS,p=0,0008).

Limitations, reasons for caution: This is a retrospective study in a limited number of patients. Therefore, it is not possible to make a definitive conclusion that LPS proportionate higher number of euploid than FPS. More studies are necessary to investigate not only IVF outcomes but also the impact on pregnancy rates.

Wider implications of the findings: In our study, LPS protocol after spontaneous ovulation, presents similar IVF outcomes compared to routinely FPS protocol. Intriguingly, the number of euploid blastocyst was significant higher in LPS, which may be further investigated. In this way, LPS is another option of IVF treatment, and may optimize time and treatment results.

Trial registration number: Not Applicable

P-646 Pregnancy outcomes in women with panhypopituitarism - A population-based study.

I. Feferkorn[1], A. Badeghiesh[1], H. Baghlaf[2], M. Dahan[3]

[1]McGill University, Obstetrics and Gyencology, Montreal, Canada ; [2]University of Toronto, Obstetrics and Gynecology, Toronto, Canada ; [3]McGill University, McGill University Health Center Reproductive Center, Montreal- QC, Canada

Study question: What are the consequences of panhypopituitarism on pregnancy outcomes?

Summary answer: After controlling for confounding effects, women with panhypopituitarism have a higher prevalence of adverse obstetrical (including post-partum hemorrhage, hysterectomy and maternal death) and neonatal outcomes.

What is known already: Panhypopituitarism is a condition of inadequate or absent anterior pituitary hormone production. Pregnancy in women with panhypopituitarism is uncommon and there is only limited data (mainly case reports) regarding pregnancy outcomes in these women. Given the scarcity of data we sought to assess the association between panhypopituitarism and obstetrical and neonatal outcomes.

Study design, size, duration: A retrospective population-based study utilizing data from the Healthcare Cost and Utilization Project—Nationwide Inpatient Sample (HCUP-NIS). A dataset of all deliveries between 2004 and 2014 inclusively, was created. Within this group, all deliveries to women who had a diagnosis of panhypopituitarism during pregnancy were identified as part of the study group (n=179), and the remaining deliveries comprised the reference group (n=9,096,609).

Participants/materials, setting, methods: The HCUP-NIS is the largest inpatient sample database in the USA, and it is comprised of hospitalizations throughout the country. It provides information relating to 20% of US admissions and represents over 96% of the American population. Multivariate logistic regression analysis, controlling for confounding effects, was conducted to explore associations between panhypopituitarism and delivery and neonatal outcomes. According to Tri-Council Policy statement (2018), IRB approval was not required, given data was anonymous and publicly available.

Main results and the role of chance: Women with a diagnosis of panhypopituitarism were more likely to be older, to have a diagnosis of chronic hypertension, to have a diagnosis of pre-gestational diabetes mellitus and to be carrying twins or a higher order pregnancy (all p<0.0001), than the controls. A significantly higher risk of post-partum hemorrhage (adjusted odds ratio-aOR:3.52; 95%CI:2.18–5.69,p<0.0001), maternal infection (aOR:3.97; 95%CI:2.30–6.85,p<0.0001), pulmonary embolism (aOR:14.90; 95%CI:2.06–107.82,p<0.007), disseminated intravascular coagulation (aOR:20.29; 95%CI:10.60–38.85,p< 0.0001), maternal death (aOR:31.90; 95%CI:3.33–234.85,p=0.001) and congenital anomalies (aOR:4.55; 95CI:1.86–11.16,p=0.001), were found among the panhypopituitarism patients. Surprisingly, there was a lower incidence of caesarean delivery (aOR:0.69; 95%CI:0.50–0.96,p=0.026) in the panhypopituitarism patients than the controls. No significant difference was found in the rate of pregnancy induced hypertension (95%CI:0.78-1.97), gestational hypertension (95%CI:0.14-1.41), preeclampsia (95%CI:0.96-2.99), gestational diabetes (95%CI:0.30-1.01), preterm delivery (95%CI:0.74-1.91), preterm premature rupture of membranes (95%CI:0.17-2.82), operative vaginal delivery (95%CI: 0.23-1.19), small for gestational age neonates (95%CI:0.27-2.02) or intra-uterine fetal demise (95%CI:0.13-6.71).

Limitations, reasons for caution: The limitations of our study are its retrospective nature and the fact that it relies on an administrative database. The severity of specific hormonal deficiencies and the presence and magnitude of posterior pituitary hormone deficiencies could not be assessed, nor could compliance with hormone replacement.

Wider implications of the findings: Until now, no control studies of outcomes with panhypopituitaryism in pregnancy are available in the medical literature. Physicians should be aware of and try to prevent the above possible maternal and fetal complications related to this endocrinopathy. Future studies should evaluate the role of medication compliance with pregnancy outcomes.

Trial registration number: not applicable

P-681 Will the hCG trigger dose used for final oocyte maturation in IVF impact endogenous progesterone during the luteal phase? - A randomized controlled trial

L. Svenstrup[1], J. Fedder[1], S. Möller[2], D. Pedersen[1], K. Erb[1], C. Yding Andersen[3], P. Humaidan[4]

[1]Faculty of Health Sciences- Department of Clinical Research- University of Southern Denmark, Fertility Clinic- Unit of Gynecology and Obstetrics- Odense University Hospital- Sdr. Boulevard 29- 3th- 5000 Odense C- Denmark, Odense, Denmark ; [2]Faculty of Health Sciences- Department of Clinical Research- University of Southern Denmark, OPEN- Odense Patient Data Explorative Network- Odense University Hospital, Odense, Denmark ; [3]Faculty of Health and Medical Sciences- University of Copenhagen, Laboratory of Reproductive Biology- Section 5712-Juliane Marie Centre for Women- Children and Reproduction, Copenhagen, Denmark ; [4]Faculty of Health- Institute for Clinical Medicine- Aarhus- Aarhus University Hospital- Palle Juul-Jensens Blvd. 99- 8200 Aarhus N- Denmark, The Fertility Clinic- Skive Regional Hospital- - Resenvej 25- 1th- 7800 Skive- Denmark, Skive, Denmark

Study question: Is there an association between the hCG dose used for ovulation trigger and the endogenous progesterone production during the luteal phase?

Summary answer: Increased hCG dosing significantly increased the endogenous progesterone level during the luteal phase.

What is known already: During the luteal phase of an IVF treatment, the endogenous progesterone (P_4) production is negatively impacted due to reduced circulating endogenous LH, caused by negative feed-back of elevated steroids; thus, luteal phase support (LPS) with exogenous P_4 remains mandatory in IVF. Apart from inducing final oocyte maturation, the gold standard HCG trigger also functions as an early LPS, boosting P_4 production by the corpora lutea (CL). P_4 plays a pivotal role for embryo implantation and pregnancy, and an optimal P_4 level around peri-implantation seems to be essential for the reproductive outcomes of fresh and frozen/thaw embryo transfer cycles.

Study design, size, duration: A randomized controlled 4-arm study, including a total of 127 IVF patients, enrolled from January 2015 until September 2019 at the Fertility Clinic, Odense University Hospital, Denmark.

Participants/materials, setting, methods: IVF patients with ≤ 11 follicles ≥ 12 mm were randomized to four groups. Groups 1-3 were triggered with:

5.000 IU, 6.500 IU or 10.000 IU, hCG, respectively, receiving a LPS consisting of 17-α-hydroxy-progesterone (17α OH P4) to distinguish the endogenous P4 from the exogenous supplementation. Group 4 (control) was randomized to a 6.500 IU hCG trigger and standard LPS. A total of eight blood samples were drawn during the early luteal phase.

Main results and the role of chance: A total of 94 patients completed the study: 21, 22, 25 and 26 patients in each group, respectively. Baseline characteristics were similar, except for the endogenous LH level and cycle lengths. There were no significant differences between groups regarding ovarian stimulation, number of oocytes and embryos. The median number of follicles ≥ 12mm on the day of trigger was 8.5, resulting in 6.6 oocytes being retrieved. Significant differences in P_4 levels were seen at OPU+8 ($p<0.001$), OPU+10 ($p<0.001$) and OPU+14 ($p<0.001$), with positive correlations between P_4 level and hCG dose. Groups compared individually showed significant difference in P_4 between low and high trigger dose at OPU+4 group 1 and 3 ($p= 0.037$) and OPU+8 group 1 and 3 ($p=0.007$) and between all the three groups around implantation at OPU+6 group 1 and 2 ($p=0.011$), group 2 and 3 ($p=0.042$) and group 1 and 3 ($p< 0.001$). Higher P_4 levels around implantation were related to follicle count and to pregnancy. After logistic regression analyses there were still significant individual differences between the groups.

Limitations, reasons for caution: Although patients were randomized and strict inclusion and exclusion criteria were used, the RCT was un-blinded, including a relatively small number of patients. Moreover, for dosing purposes urinary hCG as well as recombinant hCG was used and pharmacokinetics differ. Finally, the P_4 level could be influenced by circadian fluctuations.

Wider implications of the findings: This is the first study to explore dose-responses in circulating P_4 after hCG trigger in IVF patients. Increasing the hCG trigger dose increased the endogenous P_4 around peri-implantation. Personalizing the hCG trigger dose could be a key point to secure the most optimal P_4 mid-luteal phase P_4 level.

Trial registration number: Eudract 2013-003304-39

POSTER DISCUSSION

SESSION 15: REPRODUCTIVE (EPI)GENETICS POSTER DISCUSSIONS

28 June 2021 Stream 3 15:15 - 16:30

P-523 Whole-chromosome aneuploidies revealed by transcriptome of trophectoderm biopsied from human pre-implantation blastocyst.

L. Song[1], X. Yanwen[1], C. Bing[1], X. Yan[1], Y. Xiu[2], Z. Canquan[1]

[1]The First Affiliated Hospital- Sun Yat-sen University, Reproductive center, Guangzhou, China ;
[2]Sun Yat-sen University, Zhongshan School of Medicine, Guangzhou, China

Study question: Whether mRNA transcriptome of biopsied trophectoderm (TE) in human pre-implantation blastocyst can predict embryo karyotype?

Summary answer: mRNA transcriptome of biopsied TE can precisely predict whole-chromosome aneuploidies but not mosaicism or segmental aneuploidies.

What is known already: Karyotype of human pre-implantation blastocyst is well recognized by PGT-A. However, genome can't demonstrate gene expression level which might infer the development potential of euploidy. Transcriptome of blastocyst by singe-cell RNA-seq has revealed the lineage segregation of human pre-implantation blastocyst. It is not known whether transcriptome of biopsied TE used in PGT-A can infer the karyotype of human pre-implantation blastocyst.

Study design, size, duration: A total of 74 TE samples were biopsied from 26 blastocysts which were donated from patients who underwent PGT at our Reproductive Medicine Center. All of these embryos have been previously diagnosed as aneuploidies (n=19) or euploidies (n=7) with monogenic disorder.

Participants/materials, setting, methods: The DNA and mRNA of all biopsied TEs were separated independently using a modified oligo-dT bead capture, followed by PGT-A of DNA and smart2-sequencing of mRNA (G&T-seq). Karyotype of biopsied TEs were confirmed with PGT-A performed in MiSeq system (Illumina) in our PGT laboratory with the use of next-generation sequencing. Data of transcriptome was analyzed using Rstudio and R package InferCNV to predict aneuploidies by referring to euploidies which were inferred with corresponding PGT-A results.

Main results and the role of chance: In human pre-implantation blastocyst, all whole-chromosome aneuploidies could be inferred by transcriptome of biopsied TE, which were consistent with PGT-A result. But chromosomal mosaicism or segmental aneuploidies were hard to be predicted precisely by transcriptome of TE.

Limitations, reasons for caution: The main limitation of this study lies in the inability to retrieve the exact copy number variations from mRNA transcription. Gene expression is in a great imbalance in such an early development of human pre-implantation blastocyst.

Wider implications of the findings: Our data suggest that mRNA transcriptome is enough for prediction of whole-chromosome aneuploidies. The method and value for predicting mosaicism and segmental aneuploidies by transcriptome should be further investigated.

Trial registration number: not applicable

P-525 Analysis of segregation patterns of trivalent structure and the effect on genome stability in Robertsonian translocation carriers

T. Dang[1], P. Xie[2,3], L. Hu[3,4,5], Y. Tan[4,5], G. Lin[3,4,5]

[1]Hunan Normal University, Hunan Guangxiu Hospital, Changsha, China ;
[2]Hunan Normal University School of Medicine, Genetics, Changsha, China ;
[3]National Engineering and Research Center of Human Stem Cell, Genetics, Changsha, China ;
[4]Central South University, Laboratory of Reproductive and Stem Cell Engineering-key lab National Health and Family Planning Commission, Changsha, China ;
[5]Clinical Research Center for Reproduction and Genetics in Hunan Province, Reproductive and Genetic Hospital of CITIC-Xiangya, Changsha, China

Study question: What are the factors that affect the separation pattern of Robertsonian translocation trivalent, and whether the structure of the trivalent affected the chromosome stability?

Summary answer: The meiotic segregation modes can be affected by the carrier's sex and special chromosome, and a trivalent structure can affect the stability of the genome.

What is known already: Robertson translocation occurs when two proximal acrocentric chromosomes fuse at the centromere and forms a trivalent structure during meiosis. This structure will affect the fertility of Robertsonian translocation carriers, and may destroy the stability of the genome by affecting the separation of other chromosomes, which is called Inter-Chromosomal Effect (ICE). Previous research have confirmed that the use of PGT in Robertsonian translocation carriers can effectively reduce abortion and increase live birth. But some studies dispute this conclusion and the existence of ICE. However, there is no large data study to verify these controversies.

Study design, size, duration: PGT results of 928 oocyte retrieval cycles in 763 couples(one of the couples is a Robertsonian translocation carrier) were analysied from December 2012 to June 2020. A total of 1492 couples who received PGT-A were collected as control group, and matched according to age and testing time stage. The study was approved by the ethics committee(LL-SC-SG-2006-008 and LL-SC-SG-2014-016).

Participants/materials, setting, methods: Cytogenetic analysis was performed using GTG standard method (trypsin and GiemsaG banding) to analyze the chromosomes of peripheral blood lymphocytes. Blastocysts obtained by standard IVF procedure were biopsied on the 5th or 6th morning after fertilization, and the trophoblast cells were amplified by PicoPLEX whole genome amplification kit (Rubicon Genology) or Repli-g Single Cell Kit(Qiagen). PGT-SR was performed using SNP array or NGS as previously described.

Main results and the role of chance: In this study, a total of 3423 blastocysts from 763 couples were analysed using SNP-array or NGS. Among them, the rate of alternate segregation of male Robertsonian translocation carriers was significantly higher than that in female carriers (82.26% vs 59.96%, $P < 0.001$), and meiotic segregation modes could be affected by the special chromosome

such as 13 in female(P=0.042) and 15 in male(P=0.045) involved. A trivalent structure can affect the stability of the genome during mitosis, which is associated with an increase in the propotion of chromosome mosaic compared with the PGT-A control group(1.18% vs 0.53%，P < 0.01). In addition, we found an interesting phenomenon: in the meiotic segregation of female Robertsonian translocation carriers associated with chromosomes 21 and 22, the chromosome 21 or 22 of the two chromosomes involved in translocation are more likely to be abnormal, and according to our results, the effect of chromosome 21 seems to be greater.

Limitations, reasons for caution: (1) Limitations of retrospective analysis; (2) The results are not fully representative of the general population; (3) PGT-A patients always had repeated implantation failure or recurrent aboration, which may cause deviation to the results.

Wider implications of the findings: This study analyzed the influencing factors of the separation patterns of trivalent, and verified the existence of ICE. This suggest that PGT-SR can have a better outcome in patients with Robertsonian translocation, especially in male carriers. These results will provide carrier couple with more appropriate genetic counseling.

Trial registration number: no

P-536 Pre-selected for an award: Validation of a Next Generation Sequencing (NGS) workflow integrating simultaneous analysis of ploidy, microdeletions and de novo monogenic diseases for expanded preimplantation genetic testing (PGT).

Study question: Can major *de novo* genetic and chromosomal abnormalities (i.e., ploidy, microdeletions) be effectively tested on a single embryo biopsy specimen using an integrated NGS approach?

Summary answer: The integrated NGS workflow provided high accuracy for multilevel chromosome and genetic abnormalities analysis based on single biopsies expanding PGT informativity to *de novo* conditions.

What is known already: Current NGS-based methodologies employed in PGT for aneuploidy (PGT-A) do not detect embryo ploidy level nor frequent pathogenic *de novo* microdeletions below resolution limits. Moreover, despite their considerable incidence and adverse pregnancy outcomes, *de novo* mutations causing severe dominant monogenic fetal structural defects (FSD) are not investigated during PGT. The development of a single biopsy specimen-based PGT-A sequencing strategy that integrates ploidy and *de novo* microdeletions/mutations assessment would significantly widen PGT-A diagnostic scope and technical capabilities. This comprehensive approach would provide additional valuable genetic information of unquestionable clinical utility to further refine embryo selection process among those showing euploid profiles.

Study design, size, duration: Chromosomal conditions were validated using 24 embryo rebiopsies and 5 cell lines with both known ploidy level and known microdeletions (-4p; -8q; -1p; -22q; -5p; -15q; -11q). Genotyping for monogenic conditions was validated using 5 genomic DNA samples (33pg/µl) carrying known pathogenic Single Nucleotide Variants (SNVs) in COL1A1, SOS1, PTPN11, TSC2 and FGFR2 genes. To assess technical performance across identified SNPs, genotyping accuracy was evaluated on 17 samples from 5 embryos and 2 cell lines.

Participants/materials, setting, methods: Thirty-two *de novo* dominant monogenic conditions with FSD and strong gene-disease relationship were tested using a multiplex PCR panel with sequencing for the genes' whole coding region. Eight common microdeletions (<10Mb) syndromes (Wolf-Hirshorn, Langer-Geidion, 1p36 deletion, De George, Cri-du-Chat, Prader-Willy/Angelman, Jacobsen) were tested using B-allelic frequency (BAF) of 356 highly polymorphic Single Nucleotide Polymorphisms (SNPs). These SNPs were also used for ploidy assessment. Library preparation and sequencing were performed on the IonTorrent S5 (ThermoFisher).

Main results and the role of chance: Blinded NGS data analysis confirmed the ploidy status in all (19) samples with known constitution (8 diploids, 7 polyploids, 4 haploids). Specifically, the proportion of heterozygote calls (BAF 40%-60%) was 60.9% (95%CI:47.6-72.8) for diploid samples and <1% for haploid samples(P<0.001). All polyploid samples showed a typical splitting of BAF among 3 experimental ranges (20-40%,40%-60%,60-80%): 34.1%,18.2% and 47.7%, respectively. For microdeletions, all interstitial SNPs genotyped showed a loss of heterozygosity (LOH) as expected. The analysis of positive controls consisting of 20 blastocyst rebiopsies and 3 cell lines (-4p: n=3; -8q: n=4; -1p: n=5; -22q: n=3; -5p: n=2; -15q: n=4; -11q: n=2), allowed to accurately characterize 6 out of the 7 microdeletions (18/23 samples). In particular, all interstitial SNPs genotyped showed a LOH, while diploid controls showed an overall heterozygosity of 30.9% (average number of hetSNP x deletion=9/28). Only the very small telomeric 1p36 region failed to properly amplify. For monogenic conditions, sequencing analysis of 5 positive gDNA controls confirmed the presence of 4 known SNVs, whilst only 1 did not achieve the minimum coverage for variant calling. Moreover, 4 additional *de novo* SNVs detected by sequencing analysis in the gene panel on 8 blastocyst rebiopsies were all confirmed by qPCR/Taqman assays.

Limitations, reasons for caution: Positive controls were not available for all genes and microdeletions included in the panel. Moreover, inefficient amplification has affected some target regions and further optimization will be required. However, analytical performance on technical and biological replicates were highly promising for the tested conditions both cell lines and trophectoderm biopsies.

Wider implications of the findings: This study demonstrates that the integration of genotyping and chromosomal analyses can be efficiently achieved in the same NGS workflow. This approach can be employed to expand PGT diagnostic scope to conditions undetectable in parents due to their *de novo* onset, or that are below the standard PGT-A resolution.

Trial registration number: N/A

P-549 What trophectoderm cells from mosaic embryos tell us about embryonic competence at the transcriptional level

A. Martin, M.Sc.[1], A. Mercader[1,2], F. Insua[2], L. Escrich[2], N. Grau[2], A. Tejera[2], A. Mifsud[2], A. Pellicer[1,3], M.J. De los Santos[1,2]

[1]IVI Foundation, Research and Innovation, Valencia, Spain ;
[2]IVI RMA Valencia, IVF Laboratory, Valencia, Spain ;
[3]IVI RMA Rome, Reproductive Medicine, Rome, Italy

Study question: Does transcriptome of remaining trophectoderm (TE) reflect the developmental potential of mosaic blastocysts after preimplantation genetic testing for aneuploidy (PGT-A)?

Summary answer: TE from low-degree mosaic (Low-mos) and high-degree mosaic (High-mos) blastocysts are transcriptionally equivalent, standing between euploid and aneuploid categories and displaying key deregulated developmental processes.

What is known already: Blastocysts classified as mosaic by PGT-A are associated with lower implantation and higher miscarriage rates than those classified as euploid, yet they still lead to healthy babies. Unveiling the true developmental identity of these embryos faces a dilemma: understanding to which extent they represent technical artefacts or whether they hold own potential to implant and give rise to normal pregnancies. Current RNA sequencing (RNA-seq) techniques allow for the determination of whole transcriptomic profiles even from single cells, which paves the way for the identification of new molecular keys of embryonic competence.

Study design, size, duration: Prospective study comparing RNA-seq data of remaining TE from blastocysts classified as euploid (n=4), Low-mos (n=5), High-mos (n=4) and aneuploid (n=6) by PGT-A. Participants were recruited between October 2018 and November 2019 at IVI-RMA Valencia.

Participants/materials, setting, methods: Chromosomal mosaicism was defined in the range 30%-<50% (Low-mos) and 50%-<70% (High-mos) using a next-generation sequencing (NGS) validated algorithm. Whole TE fractions were separately collected and processed for RNA-seq. Differentially expressed genes (DEGs) were calculated with DESeq2 package [Benjamini-Hochberg (BH)-adjusted p<0.01 & abs(log2FoldChange)>2 significant]. Fgsea algorithm was used for enrichment analysis on Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways and Gene Ontology (GO) terms (BH-adjusted p<0.01 significant).

Main results and the role of chance: For comparisons, TE from euploid blastocysts were used as control. At the gene level, 15 DEGs were found in Low-mos, 20 DEGs in High-mos, and 64 DEGs in aneuploid blastocysts. To address the functional implications of these differences, pathways significantly deregulated according to KEGG and GO categories were identified. TE from aneuploid blastocysts displayed significant downregulation in up to 115 KEGG and GO processes directly involved in processing and integrity maintenance of nuclear and mitochondrial genomes, a reflection of their aberrant chromosomal identity. In addition, TE from High-mos and Low-mos were transcriptionally equivalent (0 DEGs between both groups), with 23 overlapping KEGG and GO processes significantly downregulated compared with control. Importantly, main significantly-affected processes included mitotic sister chromatid segregation, NIK NF-kB activity, regulation of apoptosis, and pathways related to the biosynthesis and metabolism of proteins, fatty acids, carbohydrates and steroid hormones. These findings indicate that mosaic embryos comprise a unique developmental entity, which swims between the euploid and aneuploid waterfronts and may regulate survival by diverse mechanisms, including cell proliferation and apoptosis.

Limitations, reasons for caution: This is a descriptive, single-center study with limited sample size. TE fractions were obtained by micromanipulation, which may have led to potential cross-contamination with the inner cell mass.

Wider implications of the findings: Transcriptomic equivalence between Low-mos and High-mos TE fractions questions the biological significance of inferring mosaicism degrees from single biopsies. Deregulated processes in these embryos support their reduced developmental and live birth potential, pointing to mechanisms that may mediate survival in the presence of aneuploid cells, as shown in the mouse.

Trial registration number: Not applicable

P-556 Pre-selected for an award: NAT10-mediated N4-acetylcytidine in RNA regulates mouse oocyte maturation in vitro

Y. Xiang[1], C. Zhou[1], Q. Guo[1], X. Liang[1]

[1]The Sixth Affiliated Hospital- Sun Yat-Sen University, Center of Reproductive Medicine, Guangzhou- Guangdong, China

Study question: Does NAT10-mediated N4-acetylcytidine (ac4C) in RNA, a newly identified mRNA epigenetic modification, participate in modulating in vitro maturation(IVM) of oocytes?

Summary answer: NAT10-mediated ac4C modification is an important regulatory factor during oocyte maturation in vitro, by regulating genes associated with translation, mitochondrial functions and protein destabilization.

What is known already: Unlike somatic cells, transcription and translation are uncoupled during oocyte maturation and gene expression is mainly regulated by post-transcriptional modulation, including mRNA degradation, translation and posttranslational modification, which are complex and have not been fully investigated. RNA ac4C is a newly identified mRNA modification and a key determinant of post-transcriptional regulation, which has been shown to promote mRNA stability and translation, and NAT10 is the only known RNA acetyltransferase. Therefore, NAT10-mediated ac4C represents a possible epigenetic regulator in oocyte maturation.

Study design, size, duration: Oocytes at different stages from mice were collected to detect the changing levels of ac4C and NAT10 during maturation. NAT10 in GV-stage oocytes was knocked down before IVM, to confirm the regulatory role of NAT10-mediated ac4C in meiotic process, followed by further exploration of cellular mechanisms. Each experiment was repeated at least three times, and data were analyzed by chi-square test, one-way ANOVA or unpaired-sample t-test.

Participants/materials, setting, methods: The expression of ac4C and NAT10 was detected by immunohistochemistry. NAT10 was knocked down in GV-stage oocytes by RNA interference through electroporation. The efficacy of knockdown was confirmed by qPCR and immunohistochemistry targeting ac4C and NAT10, and the percentages of oocytes matured in vitro were compared among groups. High-throughput sequencing and RNA immunoprecipitation were performed to reveal the modulated genes. Proteins specifically binding to ac4C sites were identified by RNA pulldown and mass spectrometry.

Main results and the role of chance: We first retrieved publicly available data from GEO and found that transcripts with potential ac4C sites were enriched in genes downregulated during IVM (P<0.001). The biased distribution of ac4C implicated a possible regulatory role. Then immunohistochemistry revealed significantly decreasing trends of ac4C and NAT10 expression from immature to mature oocytes. With NAT10 knockdown, ac4C modification was reduced and meiotic progression was significantly retarded. Specifically, the rate of first body extrusion was significantly decreased with NAT10 knockdown (34.6%) compared to control oocytes without transfection (74.6%) and oocytes transfected with control siRNA (72.6%) (p<0.001), while rates of germinal vesicle breakdown were not affected (P=0.6531). High-throughput sequencing and RNA immunoprecipitation revealed that the modulated genes were enriched in biological processes known to be associated with oocyte maturation, including translation, mitochondrial translational elongation and termination, and protein destabilization. Also, we identified a series of proteins specifically binding to ac4C probes by RNA pulldown and mass spectrometry, through which ac4C modification may exert its function in post-transcriptional modulation.

Limitations, reasons for caution: This study was performed in vitro. The role of NAT10-mediated ac4C in vivo remains to be elucidated. Also, limited by current techniques, ac4C modification in oocytes cannot be detected. Our exploration of regulated genes and ac4C binding proteins were performed in somatic cell lines.

Wider implications of the findings: Post-transcriptional modulation is crucial in oocyte maturation. Our study using in-vitro systems for mouse oocyte identified NAT10-mediated ac4C as an important regulator in IVM. It provided a new insight into the epigenetic mechanisms of IVM, which may lead to improvement of clinical IVM systems.

POSTER DISCUSSION

SESSION 16: PSYCHOLOGY AND COUNSELLING POSTER DISCUSSIONS

28 June 2021 Stream 4 15:15 - 16:30

P-479 Are FET and IUI cycles less emotionally difficult for patients than IVF? Evidence from smartphone app based emotional tracking data

I. Robertson[1], J. Boivin[2], Y. Cheong[1]

[1]University of Southampton, Human Developement and Health, Southampton, United Kingdom ;

[2]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: Is the emotional experience different in FET and stimulated IUI cycles compared to IVF cycles?

Summary answer: Emotional tracking data demonstrated cautious optimism and lower harm emotions in IUI, but FET cycles are associated with higher harm emotions than fresh IVF.

What is known already: It is sometimes claimed on clinic websites and by advocates for elective freeze all that FET cycles are inherently less stressful. However, little research evaluates the emotional difference between fresh and frozen cycles and the assumed emotional ease of FET may reflect clinician interpretation/bias rather than patient's lived experiences. Many undertaking FET will have experienced disappointment in a fresh cycle and with increasing cycles comes increased cost.

IUI treatment is perceived as less physically and emotionally intense, but studies have shown increased depression levels after a failed IUI cycle and high drop-out.

Study design, size, duration: Retrospective single-centre analysis of anonymised emotional tracking data entered by 707 patients using MediEmo app alongside IVF, 104 during stimulated IUI and 65 during medicated FET from May 2017-September 2020.

MediEmo includes medication timeline/ notifications, coping tools and emotional tracking. Patients rate 2 questions daily in each emotion domain (challenge, threat, harm, e.g. 'I am feeling tense') on a 0-3 scale and indicate coping ability ('I am unable to cope with the stress I'm experiencing').

Participants/materials, setting, methods: Egg donor, recipient and fertility preservation cycles were excluded. Mean and standard deviation of scores in each mood domain entered per cycle day were calculated, centred on luteal day 0/ egg collection, from cycle day +/-14.

Between group analysis performed using one-way analysis of variance (ANOVA) is presented here. Time series analysis, graphical presentation of emotions by cycle day and analysis of cycles resulting in live birth or return for further treatment will be presented.

Main results and the role of chance: Analysis of emotional tracking data demonstrated patients experience higher levels of positive challenge emotions (confident/encouraged/hopeful/positive) during FET and IUI cycles than fresh IVF: mean(s.d) score FET 1.64(1.1), IUI 1.74(0.89), IVF 1.48(1.06) (ANOVA $p<0.00001$). The difference between FET and IUI challenge levels was not significant ($p=0.07$).

Threat emotions (worried/nervous/anxious/tense) are significantly lower in FET compared to IVF and IUI cycles: FET mean 0.67(0.91), IUI 0.97(0.90), IVF 0.87(0.91), (ANOVA $p<0.00001$). The difference between IVF and IUI threat levels was not significant ($p=0.06$).

However, the harm emotions (sad/discouraged/disappointed) experienced by patients are significantly higher in FET, mean 0.62(0.89) compared to IVF 0.50(0.81), which are higher than IUI cycles, 0.36(0.68), (ANOVA $p<0.00001$). There were no significant differences in numbers recording intolerable stress between the three groups (FET mean scores 0.24(0.66), IUI 0.21(0.58), IVF 0.21(0.59), (ANOVA $p=0.67$).

As this is retrospective observational data, there are differences between groups in addition to treatment modality, e.g. mean patient ages in the FET and IUI groups were older than those entering data during IVF; FET 34.2(4.09), IUI 33.9(5.2), IVF 32.6(4.47). However, age was not correlated with levels of challenge emotions, suggesting assumptions that patient emotions, e.g. hopefulness, are closely linked to objective prognosis may be flawed.

Limitations, reasons for caution: Emotional data was only available for those who chose to use MediEmo, entered emotional tracking data and who gave consent for use of data in research. As such, this analysis may not fully reflect all patients' experiences. However, these limitations apply to all groups and should not prevent useful comparison.

Wider implications of the findings: Patients have less contact with clinic staff during FET or IUI than fresh IVF cycles. Fertility staff need to ensure availability of support during all treatment cycles and be empathic, particularly for those embarking on FET, who may still be coming to terms with a failed fresh transfer cycle.

Trial registration number: Not applicable

P-490 Recurrent pregnancy loss acts as a posttraumatic stress event in both women and men

E. Kuhlmann[1], P. Voss[1], M. Schick[2], B. Ditzen[2], L. Langer[1], T. Strowitzki[1], T. Wischmann[2], R.J. Kuon[1]

[1]University Hospital, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany ;
[2]University Hospital, Institute of Medical Psychology- Center for Psychosocial Medicine, Heidelberg, Germany

Study question: What are the psychological impacts of recurrent pregnancy loss (RPL) on men and women and their interdependencies?

Summary answer: Women show higher psychological risks than men, except for lack of social support. Avoidance behaviour of men correlates with higher posttraumatic stress of their partner.

What is known already: About 1-3% of all couples trying to conceive are affected by RPL. The loss of the unborn child can be the most traumatic experience in a woman's life and is associated with significant psychological distress besides the instant grief. RPL can also be stressful for the partner, even though being at a lower risk for psychiatric morbidities. The man's gender role expects him to support and not to show weakness which may result in a suppression of his feelings and a disenfranchised grief.

Study design, size, duration: Cross-sectional study. All women and men referred to the special unit for RPL between March 2019 and October 2020 were asked to participate voluntarily with a total sample size of 105 couples and 17 women. Exclusion criteria were less than two pregnancy losses, inadequate knowledge of the German language and incomplete data.

Participants/materials, setting, methods: Couples were invited to fill out a questionnaire package estimating their psychological risks (e.g. posttraumatic stress disorder, anxiety, depression, perceived social support) and coping strategies with established instruments. Clinical history was obtained from medical records. Couple data were analysed with the Actor Partner Interdependence Model, taking the couple as the unit of analysis.

Main results and the role of chance: The response rate was 82.3%. The following psychological risks were measured among women versus men: posttraumatic stress disorder (PTSD): 13.7% versus 3.9% ($p=0.017$); anxiety: 50.4% versus 17.3% ($p<0.001$), depression: 48.1% versus 14.4% ($p<0.001$), lack of social support: 32.5% versus 32.7% (N.S.). A risk in at least one category showed 68.9% of women versus 44.8% of men ($p<0.001$), with those at higher risk indicating a lower satisfaction with their partnership ($p<0.001$) and higher impairment of their sexual life ($p<0.001$). Neither total number of pregnancy losses nor time gap since last pregnancy loss showed relevant correlations with psychological risks. For women, number of curettages, controlled for the number of pregnancy losses, correlates with the severity of posttraumatic stress ($p<0.05$). Higher levels of anxiety, depression and a lack of social support in women correlated positively with posttraumatic stress in their partners. The coping strategy "trivialization and wishful thinking" as well as the subscale "avoidance" of the Impact-of-Event-Scale (self-report questionnaire measuring posttraumatic stress) of men was correlated with more severe posttraumatic stress in their female partners (both $p<0.05$).

Limitations, reasons for caution: The data show only correlations between the measured variables, as cross-sectional studies are not suitable to analyse causal relationships. The sample was obtained in a special unit for RPL at a university hospital, so the findings may not be generalizable to all couples with RPL.

Wider implications of the findings: Screening psychological risks in couples with RPL may be reasonable considering the high risks in both sexes and the extent of PTSD diagnoses in women, their interdependencies and the potential risk of chronification. Professionals should encourage affected couples to support each other and provide targeted information on mental health services.

Trial registration number: DRKS 00014965

P-503 Focus groups with health care professionals, patient advocates and patients to explore how the potential need for multiple cycles is managed during fertility treatment consultations

C. Harrison[1], J. Boivin[1], G. Sofia[1]

[1]Psychology, School of Psychology- Cardiff University, Cardiff, United Kingdom

Study question: How is possibility of failure and potential need for multiple cycles discussed with patients during the first or repeat IVF/ICSI treatment consultation?

Summary answer: Health Care Professionals plan treatment on a cycle-by-cycle basis because it is the normative way to plan treatment, but patients see advantages in multi-cycle planning

What is known already: Many patients need more than one round of IVF/ICSI stimulation to achieve their parenthood goals. A recent study has found around 60% of patients to be willing to plan for multiple cycles of treatment. However, it is not clear how patients are informed fully about the high possibility of treatment failure and the subsequent need for multiple cycles during their treatment planning consultations

Study design, size, duration: Qualitative focus groups with health care professionals (HCP) patient advocates (April 2020) and patients (July and August 2020, respectively). Patients were eligible if they had had a consultation to start a first/repeat stimulated IVF/ICSI cycle in the eight weeks prior to participation, were aged 18 or older (upper age limit of 42 years for women) and fluent in English. Eligible Health HCPs and patient advocates were those employed at a fertility clinic or charity, respectively

Participants/materials, setting, methods: HCP, patient advocate and patient focus group topic guides started with general questions about fertility consultations and progressed to discuss if and how the possibility of treatment failure and need for multiple cycles was introduced and discussed, and then preferences regarding planning IVF/ICSI on a multi-cycle rather than a single cycle basis. Focus groups were recorded, transcribed and analysed using framework analysis which allowed examination of shared, unique and incongruent thematic content across participant groups

Main results and the role of chance: Twelve HCPs, 2 patient advocates and 11 patients participated in seven semi-structured online focus group discussions. Framework analysis revealed 52 codes (e.g., possibility of failure tentatively introduced; discussion of multiple cycles dependent on clinical/patient benchmarks) abstracted into 17 higher-level categories (e.g., Failure is a sensitive topic to approach; IVF treatment failure is the norm). Synthesis of categories revealed four themes and one meta theme The meta theme showed planning treatment on a cycle-by-cycle basis was the norm. This meta-theme was supported by four themes: (1) 'culture of communication' that dictated benchmarks (e.g., clinic, national live birth rate) and definition of key concepts ('complete' cycle) that underpinned divergence between clinics; (2) 'HCP-patient dynamics' indexing degree of shared decision-making, advance preparation and involvement of partners in planning; (3) 'tempering optimism' that described tailoring, balancing and emotion management in giving personal chances of success; and (4) 'transitioning to multi-cycle planning' which identified worries of multi-cycle planning (e.g., need to learn from failure).

Limitations, reasons for caution: The majority of patients were women from private fertility clinics with no previous treatment experience recruited from social media websites, mainly associated with patient support groups. Similarly, the majority of HCPs were women from private fertility clinics. Informative comparisons across treatment stage, gender and funding source were therefore not possible

Wider implications of the findings: HCPs are hesitant towards multi-cycle planning. However, patients show openness, suggesting a cultural shift from the single cycle norm of planning IVF/ICSI may be possible. If adopted by clinics, HCPs patients and fertility organisations, multi-cycle planning could encourage patients to create informed treatment expectations and plans prior to treatment engagement

Trial registration number: MS200059_001

P-504 A randomised controlled trial comparing expectant management or intrauterine-insemination in couples with unexplained subfertility and a poor prognosis for natural conception: the impact on health-related-quality-of-life

F. Mol[1], J. Wessel[1], H.A. Verhoeve[2], J. Maas[3], J.P. De Bruin[4], L. Louwe[5], A. Cantineau[6], M. Mochtar[1], M. Van Wely[1]

[1]Amsterdam University Medical Centre, Centre for Reproductive Medicine-Women's Clinic, Amsterdam, The Netherlands ;
[2]OLVG, Obstetrics and Gynaecology, Amsterdam, The Netherlands ;
[3]Maxima Medical Centre, Obstetrics and Gynaecology, Veldhoven, The Netherlands ;
[4]Jeroen Bosch Hospital, Obstetrics and Gynaecology, Den Bosch, The Netherlands ;
[5]Leiden University Medical Centre, Obstetrics and Gynaecology, Leiden, The Netherlands ;
[6]University Medical Centre Groningen, Obstetrics and Gynaecology, Groningen, The Netherlands

Study question: Is health-related quality of life (HRQoL) in women with unexplained subfertility and a poor prognosis influenced by expectant management or intrauterine insemination with ovarian stimulation?

Summary answer: HRQoL did not differ, except for the relational domain which was lower after expectant management. Anxiety and depression disorders occurred frequently in both groups.

What is known already: In couples with unexplained subfertility and a poor prognosis, IUI with ovarian stimulation (IUI-OS) is a first line treatment. Not much is known about quality of live or depression and anxiety in these couples. The Fertility Quality of Life (FertiQoL) is reliable for assessment within relational and social domains, the Hospital Anxiety and Depression Scale (HADS) is a reliable tool to detect anxiety and depression disorders.

Study design, size, duration: We performed a multicentre RCT in couples with unexplained subfertility with a poor prognosis of conceiving naturally within one year. Women were allocated 1:1 to six months expectant management or to six months IUI-OS. HRQoL was assessed with standard self-administered psychometric measures with established reliability and validity: FertiQol and HADS. We intended to include 1091 couples but after almost 4 years, the study had to stop due to slow inclusion and therefore lack of funding.

Participants/materials, setting, methods: Between June 2017 and September 2020, we recruited 178 women of wich 92 were assigned expectant management and 86 IUI-OS. All women who participated and could read Dutch were eligible for the HRQoL measurements because HRQoL questionnaires in foreign languages were not yet available online. Women completed the questionnaires before randomisation, 3 and 6 months after randomisation. We used mixed model analyses to assess differences between treatment groups and the effect of time.

Main results and the role of chance: One hundred sixty-two women could read Dutch and were invited (162/178 (91%)). Analyzable data of the FertiQol questionnaire were available for 80% (130/162). Compared to women allocated to IUI-OS, women allocated to expectant management had a lower FertiQol score in the relational domain (mean difference -4.3 (95% CI -7.3 to -1.3) but not in the social domain (mean diff van -0.8 (95% CI -4.5 to 2.9).

Data of the HADS questionnaire were available of 156 women (96% (156/162)). Both groups had comparable scores in the Anxiety (mean difference -0.20; 95% CI 0.63; -0.99 to 0.6) and Depressions score (mean difference 0.002; 95% CI -0.67 to 0.67) at all three moments. At baseline, the incidence of an anxiety disorder (definition score 8 or higher) was 19% (30/156) and increased to 30% and 29% at 3 months and 6 months respectively. The incidence of a depression disorder (definition score 8 or higher) was 5% (7/156) and increased to 16% and 18% at 3 months and 6 months respectively. The incidences of anxiety or depression disorders did not differ significantly between expectant management and IUI.

Limitations, reasons for caution: Our randomized controlled trial did not reach the planned sample size. The results are only applicable to women with unexplained subfertility and a poor prognosis and not to all women with unexplained subfertility.

Wider implications of the findings: Although often assumed, IUI-OS does not improve HRQoL compared to expectant management in all domains. IUI might prevent loss of quality of the relationship, but the impact seems small. Future studies should look into the high incidence of anxiety and depression disorders in these women and how to support them.

Trial registration number: Trial register NL5455 (NTR5599)

P-513 Analysis of the extent of dropout-rates by extraction from cumulative live birth rates in IVF/ICSI: systematic review and meta-analysis

S. Vereeck[1], A. Sugihara[1], D. De Neubourg[1]

[1]Antwerp University Hospital, Centre for Reproductive Medicine, Edegem, Belgium

Study question: The purpose of this systematic review is to calculate dropout-rates of IVF/ICSI treatment by analysing the published cumulative live birth rates of IVF/ICSI treatment.

Summary answer: One out of three patients stop their treatment after their first IVF/ICSI cycle and dropout-rates tend to increase per consecutive cycle.

What is known already: Cumulative live birth rates (CLBRs) have created the possibility to present realistic probabilities of having a live birth after IVF/ICSI treatment. However, it is noted that a significant percentage of the patients stop their treatment before having a child ("dropout"). Possible reasons and predicting factors for dropout of treatment are already extensively investigated. However, only a few studies try to report about the incidence of dropout. Publications on CLBRs of large numbers of patients allow the extraction of dropout-rates. These rates will provide insight in the extent of the problem and could be used as a reference for interventional studies.

Study design, size, duration: Four databases (PubMed, The Cochrane Library, EMBASE, DoKS) were systematically searched from 1992 to December 2020. Search terms referred to "cumulative live birth" AND "ART/IVF/ICSI". No restrictions were made on the type or language of publication. Studies were included if they reported absolute numbers of patients and live births per

consecutive complete IVF/ICSI cycle or per consecutive embryo transfer cycle, starting from the first IVF/ICSI cycle for each patient.

Participants/materials, setting, methods: Dropout-rates per cycle were calculated in two manners: "intrinsic dropout-rate" with all patients that started the particular IVF/ICSI cycle in the denominator, and "potential dropout-rate" with all patients who did not achieve a live birth after IVF/ICSI (and potentially could have started a consecutive cycle) in the denominator. Dropout-rates were analysed for consecutive complete cycles and consecutive embryo transfer cycles, because these two manners are used in reporting CLBRs, often related to the reimbursement policy.

Main results and the role of chance: This review included 29 studies and almost 800,000 patients from different countries and registries.

Regarding the patients who started their first IVF/ICSI cycle, trying to conceive their first child by IVF/ICSI, intrinsic dropout-rate was 33% (weighted average) after the first complete cycle, meaning they did not return for their second oocyte retrieval cycle. After the first embryo transfer cycle, intrinsic dropout-rate was 27% (weighted average), meaning those patients did not return for their next frozen-thawed embryo transfer cycle or for the next oocyte retrieval cycle. Regarding the patients who did not achieve a live birth after the first complete cycle, potential dropout-rate was 48% (weighted average), and 37% (weighted average) after the first embryo transfer cycle.

Both potential and intrinsic dropout-rates for both consecutive complete and embryo transfer cycles tended to increase with cycle number.

One study on second IVF/ICSI conceived children showed a potential dropout-rate after the first complete cycle of 29%. From studies on women >40 years of age, the potential dropout-rate after the first complete cycle was 45% (weighted average) and from studies with the uses of testicular sperm extraction, the potential dropout-rate after the first complete cycle was 34% (weighted average).

Limitations, reasons for caution: Our analysis was hampered by the different ways of reporting on CLBRs (complete cycles versus embryo transfer cycles), informative censoring, patients changing clinics and spontaneous pregnancies. Dropout-rates were potentially overestimated given that spontaneous pregnancies were not taken into account.

Wider implications of the findings: The extent of dropout in IVF/ICSI treatment is substantial and has an important impact on its effectiveness. Therefore, it is a challenge for fertility centers to try to keep patients longer on board, by taking into account the patients' preferences and managing their expectations.

SESSION 17: THE OOCYTE - THE LEADING LADY IN FEMALE FERTILITY PRESERVATION

28 June 2021 Stream 1 17:00 - 18:00

O-014 How effective is oocyte cryopreservation?

A. Cobo[1]

[1]*IVIRMA-Valencia, IVF Laboratory-Cryopreservation Unit, Valencia, Spain*

Abstract text

The challenge of cryopreserve, store for prolonged period, and successfully implant the female gamete is nowadays feasible thanks to vitrification. The technology that was initially validated in oocyte recipients is currently applied to a vast population, including women at risk of losing their ovarian function due either to iatrogenic causes as occurs in cancer patients, or due to the natural depletion of the ovarian reserve as a result of age related fertility decline. That is the case of a growing population of women who wish to postpone childbearing and decide on oocyte vitrification as a means of fertility preservation (FP). At present, there is a growing body of evidence regarding the use of vitrified oocytes by many women under different indications, which makes it possible to evaluate the approach from different scenarios. So that vitrification can be evaluated in terms on survival rates, embryo development and the rate at which vitrified oocytes develop into live-born children in IVF cycles using vitrified oocytes which were initially stored due to different reasons. The effects of vitrification at the subcellular level and its impact on oocyte competence is of interest in the evaluation of the efficacy of the technology. Some studies have indicated that vitrification may affect ultrastructure, reactive oxygen species (ROS) generation, gene expression, and epigenetic status. However, it is still controversial whether oocyte vitrification could induce DNA damage in the oocytes and the resulting early embryos. Recent studies show that oocytes survival and clinical outcome after vitrification can be impaired by patients' age and the clinical indication or the reason for vitrification. These studies show that age at oocyte retrieval strongly affects the survival and reproductive prognosis. In our experience, oocyte survival, pregnancy and cumulative live birth rates are significantly higher when patients are aged 35 years or younger versus patients older than 35 years at oocyte retrieval. Therefore, elective-FP patients should be encouraged to decide at young ages to significantly increase their chances of success. There is also evidence that the reason for vitrification is associated to the success rates. Poorer reproductive outcome was reported in cancer patients, low responders and endometriosis patients when compared to healthy women in age matching groups. Moreover, there are certain individualities linked to specific populations, as occurs when endometriosis patients had cystectomy earlier than the oocyte retrieval for FP. These women achieved lower success rates as compared to non-operated age matching counterparts. In this case, the lower cumulative live birth rates observed in operated women are, most probably, due to the smaller number of oocytes available, as a consequence of the detrimental effect of the surgery on the ovarian reserve. In this regard, several reports show that the number of oocytes available per patient is another variable closely related to the outcome in all populations using vitrified oocytes after FP. Thus, a significant improvement in the cumulative live birth rates can be achieved by adding a few oocytes, especially in healthy young patients. Different populations using vitrified oocytes under several indications achieve differential results in terms of pregnancy rates, when calculated in overall. Nonetheless, when the calculations for the cumulative probability of achieving a baby are made according the number of oocytes used per patient belonging to the same group of age, the results become comparable between different populations, as shown by the comparison between elective freezers versus endometriosis patients. Undoubtedly, vitrification can be recognized as one of the latest brakethrough in the ART field, but certainly the next step forward would be the successfull automatization of the vitrification and warming processes to achieve fully consistency among different laboratories.

SESSION 18: PATIENT EMPOWERMENT DURING MAR PROCEDURES

28 June 2021 Stream 2 17:00 - 18:00

O-016 Hypnofertility for reducing stress and increasing fertility preparedness

M. Aluş Tokat[1]

[1]*Work adres, Dokuz Eylul University Nursing Faculty, Izmir, Turkey*

Abstract text

Using systematic, holistic and knowledge-based approaches for support the couples by nurses may be effective in reducing stress and increasing pregnancy outcomes, Hypnofertility is one of the methods that can help in reducing stress and increase fertility preparedness of couples. This program was first formed in 2013 by the HypnoBirthing Institute trainer, Sherry Gilbert. Its basic principle is that fertility is a natural function. The program is based on powerful and effective mind-body interaction. Mind consciously or unconsciously records all of our experiences and external messages. The purpose of this presentation is to present Hypnofertility method and to provide a systematic approach to reduce the stress of couples who receive fertility support. The mind functionally consists of

consciousness, subconscious and critical factors. Consciousness is the part that analyses, makes logic, and where reality takes place. It records short-term memory. In consciousness; personal boundaries, attitudes, beliefs, decisions, hope for the future, and thoughts. For people with fertility problems words such as infertile, unsuccessful, sterile, complete failure, complex, difficult, dysfunction, disorder, damage, deficiency, too late they hear often. The experiences and these negative messages can lead to the belief that the treatment and the person will fail; make the decision to stop treatment; despair about pregnancy; can lead to difficult, complex thoughts. The subconscious is the creative, emotional part that accepts without separating right or wrong like the computer, does not think rationally. It records long-term memory. It stores all positive/negative experiences from intrauterine life to adulthood. In our subconscious are emotions, behaviours, experiences and way of thinking. Emotions such as inefficient, inadequate, unhappy are often found in the subconscious of couples who live fertility problems. They adopt this way of thinking and experience stress as a behaviour. Finally, the critical factor is located between consciousness and subconscious. Our conscious state does not accept messages without judgment. On the contrary, our subconscious accepts all messages, positive or negative. Hypnofertility improves critical factor barrier. It activates and prevents negative messages from settling in the subconscious while allowing positive messages to be settled. How the consciousness can be affected? The language of consciousness are words. Affirmations are used to positively affect consciousness of couples. The affirmations should be personal, positive, precise, present, sensible and applicable. For example: Instead of saying "Your eggs are undeveloped, few and small", "Your eggs continue to develop, we need a little more time to collect them." The subconscious can be affected visualization, relaxation, and imagination. Creating a visual in the mind of a person and adding taste, smell and sound to it. For example; hanging pictures of couples who have children as a result of treatment in the clinic can help the couples to create the picture in their minds. In addition, the imagination technique allows the individual to mentally move away from the uncomfortable environment, relieve tension, and provide mental and physical relaxation. For example; by imagining blood flow to the uterus during and after embryo transfer, the person can activate the parasympathetic nervous system and relax, so can improve blood flow to the uterus. Relaxation is the relief of the person's body by breathing, visualization, mental space building and music can be used during it. Hypnofertility support program is non-invasive, cheap and easy to apply.. This program of care is a systematic, holistic and knowledge-based and it can reduce the stress, improve fertility preparedness, increase pregnancy outcomes, and increase the trust and confidence in the nurse. It is thought to be effective in changing perspective. Researcher nurses also can plan studies in order to evaluate its effectiveness on stress and pregnancy outcomes.

O-017 Appeased embryo transfer with hypnosis

D. Lelaidier[1]

[1]*centre PMA saint ROCH, hypnosis IVF center st Roch, Montpellier, France*

Abstract text

Objective,

We report in this presentation the use for couples undergoing infertility treatment of a new way of accompaniment. Hypnosis associated with learning of self-hypnosis is a solid support to valid an appeased uptake of an infertility program and lower the emotional charge associated with such treatments.

Main: enhance emotional comfort in couples undergoing infertility treatment.

Secondary: patients feelings after results of the attempt (whether failure or success), pregnancy rates.

Contains

During a first meeting family and historical back ground is analyzed as well as medical file and causes for infertility. Then a first specific session is proposed in relation with underlying problems using ericksonian hypnosis. For example sessions using amnesia can be used in patients having had traumatic experiences. Comfort and wellbeing suggestions are used after each hypnosis session.

Two other sessions can be proposed at office, one called "the two chests" first one to pack all past failures and second to collect present or past successes regarding all fields. These successes will be resourceful to refer to. The second session will be to enhance self-confidence using contes.

In order to enhance autonomy patients are given 4 audio sessions prerecorded to home practice.

Three of them are specific to intra uterine insemination or embryo transfer. One is called FIVETE to listen the day before medical procedure, one is called SIMPLE INDUCTION to start just before and throughout the procedure. One to do after procedure at home called DO NOTHING.

Patients are called few weeks after the attempt for debrief and results.

O-019 COVID – Impact on reproduction and reproductive practice

M. Cedars[1]

[1]*UCSF, Obstetrics- Gynecology and Reproductive Sciences, San Francisco- CA, U.S.A.*

Abstract text

A highly infectious novel coronavirus (now referred to as SARS-CoV-2) was first noted in December 2019 in Wuhan, Hubei Province, China, and by March 11, 2020, was declared a global pandemic by the WHO. The widespread community transmission of a virus, new to our species, continues to raise urgent questions about implications for pregnant women and those considering conception. Almost immediately, international committees, including ASRM and ESHRE, drew up guidelines to protect the public and our patients. Across the globe, clinics were closed, patients turned away and questions regarding spread of the virus, safety during early pregnancy and potential impact on fertility and pregnancy began to arise. Where are we now? What have we learned? And what more do we need to know to improve our ability to care for and counsel our patients?

Clinic Practice – While there was considerable controversy in the U.S., closing clinics was the correct course of action when an unknown virus had entered our countries and so little was known and resources (think NY, think Italy) were inadequate. The majority of clinics pivoted to more virtual visits and stopped transfers and retrievals. The duration of these changes varied across states and countries, with most clinics now functioning at full capacity for procedures but still utilizing virtual visits for many patients. We will discuss what we learned from this process, including impact on clinics and patients, as well as the greater community in which we all live.

Pregnancy – The physiology of pregnancy, including increased heart rate and oxygen consumption, decreased lung capacity and a shift away from cell-mediated immunity, all increased the risk for severe illness. Studies have now shown this increased risk for severe disease, mechanical ventilation and even death in pregnant women compared with their non-pregnant counterparts. Additionally, there is increased risk for pre-term labor and fetal death. Studies suggest infection earlier in pregnancy increases risk for complications. What about our patients? The first trimester is a highly critical period for fetal development. As a result, infectious and non-infectious exposures, occurring during the first trimester, are most likely to lead to severe effects on fetal development. Preliminary results no increased risk for pregnancy loss and no effect on nuchal translucency. However, some studies have shown the possibility of vertical transmission and increase in fetal inflammation. We will review the literature and update on current understanding of first trimester exposure and consequences for both mother and child.

Infertility – SARS-CoV-2 utilizes the angiotensin-converting enzyme 2 (ACE2) receptor for viral entry. The ACE2 receptor is present in both the male and female reproductive systems. Early case studies of severe cases of COVID-19

identified orchitis, while the presence in non-fatal disease remains controversial. Lowered sperm counts have been identified and some studies have found SARS-CoV-2 viral particles in the semen. ACE2 receptor is present in both the ovary and the endometrium, while infection is possible, there have been few studies specifically looking at these endpoints and no clear risk identified for women.

Vaccination – The rapid development and deployment of effective vaccination has brought hope to end the pandemic, even as new variants are arising. While vaccine hesitancy is common in many places, the mis-information regarding association between vaccines and infertility has hit our field particularly hard. Updating information to share with our patients, colleagues and friends will be critical to move forward and combat the pandemic.

O-099 TEAD4 regulates trophectoderm differentiation upstream of CDX2 in human preimplantation embryos

P. Stamatiadis[1], A. Boel[1], G. Cosemans[1], F. Van Nieuwerburgh[2], B. Menten[3], P. De Sutter[1], D. Stoop[1], S. M. Chuva de Sousa Lopes[4], F. Lluis[5]

[1]Ghent University, Department for Reproductive Medicine Ghent University Hospital, Gent, Belgium ;
[2]Ghent University, Laboratory of Pharmaceutical Biotechnology, Gent, Belgium ;
[3]Ghent University, Center for Medical Genetics- Department of Biomolecular Medicine, Gent, Belgium ;
[4]Leiden University Medical Centre, Department of Anatomy and Embryology, Leiden, The Netherlands ;
[5]KU Leuven, Department of Development and Regeneration, Leuven, Belgium

Study question: What is the main pathway regulating trophectoderm (TE) differentiation during pre-implantation development in mouse versus human embryos?

Summary answer: *TEAD4* is acting upstream of *CDX2* and is involved in TE differentiation, as TEAD4-null human embryos exhibit compromised TE lineage differentiation.

What is known already: TEAD4 is the earliest transcription factor during early embryo development, required for the expression of TE-associated genes leading to successful TE differentiation and subsequent blastocoel formation in mouse. Functional knock-out studies in mouse, inactivating *Tead4* by site-specific recombination have shown that *Tead4*-null embryos do not express TE specific genes, including Caudal-Type Homeobox Protein 2 (*Cdx2*) and GATA Binding Protein 3 (*Gata3*), but expression of inner cell mass (ICM)-specific genes, remains unaffected. Furthermore, ablation of *Tead4* compromises embryonic development and subsequent blastocoel formation in mouse. The role of *TEAD4*, during human pre-implantation development has not been functionally characterized yet.

Study design, size, duration: CRISPR-Cas9 was introduced in mouse zygotes and editing efficiency was evaluated by next-generation sequencing (NGS) on 4.5dpc embryos (n=55). Developmental kinetics were monitored in CRISPR-Cas9 targeted (n=83), sham-injected (n=26) and non-injected media-control (n=51) mouse embryos. Immunofluorescence analysis was performed in *Tead4* targeted (n=57) and non-injected media-control embryos (n=94). The same methodology was applied in human donated *in vitro* matured (IVM) metaphase-II (MII) oocytes, which were CRISPR-Cas9 targeted (n=74) during ICSI or used as media-Control (n=33).

Participants/materials, setting, methods: A gRNA-Cas9 mixture targeting exon 2 of *Tead4/TEAD4* was microinjected in respectively mouse 2PN (pronuclear) stage zygotes, or human IVM MII oocytes along with the sperm. Generated embryos were cultured *in vitro* for 4 days in mouse or 6.5 days in human. Embryonic development and morphology were assessed daily, followed by a detailed scoring at the late blastocyst stage. Successful targeting following CRISPR-Cas9 introduction was assessed by immunostaining and NGS analysis of the targeted locus.

Main results and the role of chance: In mouse, we confirmed previous findings, as the developmental capacity of *Tead4* targeted embryos was significantly reduced starting from the morula stage and blastocyst formation rates were 8.97% in the targeted group, compared to 87.23% in the control and 87.50% in the sham group, respectively. Immunofluorescence analysis of late morula and blastocyst stage embryos confirmed the absence of Tead4, Cdx2 and Gata3, resulting from the successful interruption of the *Tead4* locus (n=57). Exon 2 of *TEAD4* was successfully targeted in human. In total, 21 embryos from various developmental stages were successfully NGS analyzed and 90,48% (19 out of 21) of the embryos carried genetic modifications as a result of CRISPR-Cas9 genome editing and seven blastocysts were identified carrying exclusively frameshift mutations. In contrast to mouse, the developmental capacity of human targeted embryos (25%) did not differ significantly from the control group (23%). However, the blastocyst morphology and quality were compromised in the targeted group showing mostly grade C TE scores, containing very few cells. Immunofluorescence analysis of targeted blastocysts (n=6) confirmed successful editing by complete absence of TEAD4 and its downstream TE marker CDX2.

Limitations, reasons for caution: CRISPR-Cas9 germline genome editing results in multiple editing outcomes with variable phenotypic penetrance, the mosaic nature of which complicates the phenotypic analysis and developmental behaviour of the injected embryos.

Wider implications of the findings: Elucidation of the evolutionary conserved molecular mechanisms that regulate self-renewal of the trophoblast lineage can give us fundamental insights on early implantation failure.

O-100 The follicular fluid derived exosomes facilitate the differentiation of oocytes from human induced pluripotent stem cells through miR218 / PI3K / Akt molecular axis

Abstract withdrawn by the authors

O-101 Neospermatogenesis benefits from a three-dimensional culture system

S. Lawrence[1], M. Haddad[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Does a three-dimensional (3D) culture system increase the efficiency of male germline differentiation of mouse embryonic stem cells (mESC) over a bidimensional method?

Summary answer: Our 3D culture system based on direct spherification proves superior to the standard bidimensional plating in promoting neogametogenesis of mESC into post-meiotic male germ cells.

What is known already: Two-dimensional monolayer cell cultures are common in stem cell research. However, this method does not replicate a physiological 3D spatial relationship and may provide an inaccurate replication of *in vivo* environments. A 3D spherical structure allows us to mimic the seminiferous tubule, the site of *in vivo* spermatogenesis. By using spheroids as a scaffold to replicate cell culture systems, we can study spermatogenesis in a controlled setting. Direct spherification, a technique commonly used in molecular gastronomy, provides an opportunity to create spheroids that mimic *in vivo* events that materialize in the lab

Study design, size, duration: mESCs were initially cultured on a 6-well plate coated with fibroblasts and inserted into sodium alginate spheres. To coax differentiation, spheres (3 to 6 mm in diameter) were plunged directly into differentiation medium (DM) while the control mESC in 6-well dishes were layered with it. Cells obtained from both culture systems were tested by biomarkers for different germ cell stages

Participants/materials, setting, methods: Bidimensional mESC at 80% confluence were differentiated either on a plate or spherified for a 3D culture. Both systems underwent the same timeline of exposure to EpiLC medium with Activin A, bFGF and KSR for 3 days and PGCLC medium with BMP4, LIF, SCF and EGF for 7 days. Differentiated cells were retrieved from each method at day 3 and day 10 to assess for germ line differentiation markers, DAZL, VASA and BOULE

Main results and the role of chance: Under optic visualization through the sphere wall, cellular aggregation was seen on day 2 of culturing in EpiLC medium while this phenomenon was not observed on bidimensional plating. In the conventional method, cells expressed 7% DAZL (spermatogonium cell stage) and 1% VASA (pre-spermatid cell stage) whereas in direct spherification, cells expressed 20% DAZL ($P<0.001$) and 15% VASA positivity ($P<0.0001$).

To further compare the different methods in later stages of germ-line differentiation, the remaining spheres were cultured in PGCLC medium for 7 days. At day 10, isolated cells were assessed for VASA and DAZL again. In the conventional method, 23% of cells expressed positivity for VASA and 29% DAZL whereas direct spherification achieved a positivity rate of 43% for VASA ($P<0.005$) and 45% for DAZL ($P<0.005$). This increased expression in both VASA and DAZL signify the increased number of cells undergoing germline differentiation.

Additionally, BOULE was assessed for the presence of meiotic cells such as the spermatocyte. The conventional method yielded <1% BOULE positivity whereas in direct spherification, there was 10% positivity (*P<0.005*).

Direct spherifcation result shows that differentiation almost doubled in comparison to the conventional method, yielding more post-meiotic cells in the same amount of time

Limitations, reasons for caution: Despite a higher differentiation rate in direct spherification, these cells would still need to be tested for their fertilization potential. The ability to achieve fertilization, blastocysts and live pups would provide final proof and reliability of this method of neogametogenesis

Wider implications of the findings: Differentiating ESCs through direct spherification provides an alternative to studying intercellular relationships. This provides an opportunity to study spermatogenesis in more detail by replicating the microenvironment of the seminiferous tubule. Once embryo developmental competence of the *de novo* gamete is confirmed, this may open a new chapter in human reproduction

Trial registration number: N/A

O-102 Polymeric scaffold loaded with CD133+ BMDSCs for endometrial regeneration in Asherman's syndrome

N. Venkatesan[1], E. Fernandez Garcia[2], X. Santamaria Costa[2,3], C. Simon Valles[1,2,4]

[1]University of Valencia, Pediatrics- Obstetrics and Gynecology, Valencia, Spain ; [2]Igneomix Foundation, Research & Development, Paterna, Spain ; [3]Vall d´Hebron Institut de Recerca, Ginecologia, Barcelona, Spain ; [4]Harvard University, Obstetrics and Gynecology, Boston, U.S.A.

Study question: Can $CD133^+$ bone marrow-derived stem cells (BMDSCs) loaded in polyethylene glycol diacrylate (PEGda) and gelatin divide and decidualize?

Summary answer: Biocompatible porous PEGda and gelatin scaffold provides a three-dimensional environment for CD133+ cells to attach, divide, and decidualize *in vitro*.

What is known already: Intrauterine adhesions (IUA) develop due to acquired damages in the endometrium resulting in partial to complete endometrial dysfunction in the Asherman syndrome. Previous works from our group have demonstrated the engraftment of $CD133^+$ BMDSCs and its paracrine effect on endometrial proliferation, improved endometrial thickness and clinical outcome in murine and human models of Asherman syndrome (AS).

Study design, size, duration: Human CD133+ BMDSCs were obtained from refractory AS patients undergoing autologous cell therapy. Two different polymers PEGda and gelatin were analysed for their ability to form porous scaffold. CD133+ BMDSCs cell adhesion and division was analysed up to 14 days, and its differentiation upon 8-Br-cAMP was evaluated *in vitro* on day 5. *In vivo* biocompatibility was evaluated until week 5.

Participants/materials, setting, methods: Porous PEGda and gelatin scaffolds were synthesized by cryogelation. Porosity, interconnectivity, and its distribution were characterized by scanning electron microscopy (SEM) and micro-computed tomography. Cell adhesion, growth, and morphology were analysed by SEM and fluorescence microscopy while decidualization of the adhered cells were analysed by prolactin (PRL) and IGFBP1 secretion by ELISA and the mRNA expression levels by qPCR. Biocompatibility and degradation of the scaffolds were analysed by sub-cutaneous implantation in Sprague -Dawley rats.

Main results and the role of chance: The average pore size was higher in the case of gelatin (100 – 250 µm) compared to PEGda which had compact structure with through pores (25 – 150 µm) and thick walls. Cross-sectional analysis revealed, well interconnected pores in both polymers. There was no significant difference between the two polymers with respect to cell adhesion, and viability (> 80% in both the cases). There was a significant increase in the expression of mRNA levels of IGFBP1 with a fold change of 3 ± 2.25 (PEGda), and 10 ± 1.3 (gelatin) whereas for PRL it was 0.08 ± 0.82 (PEGda), and 0.39 ± 1.7 (gelatin) when treated with cAMP. Secretion of IGFBP1 (7.4 ± 4.5 pg/ml for PEGda and 8.5 ± 4 pg/ml for gelatin) and PRL (4.7 ± 1.8 pg/ml for PEGda and 5.6 ± 1.2 pg/ml for gelatin) also increased with the addition of cAMP. *In vivo*, PEGda degraded at a faster rate (~ 3 weeks) compared to gelatin (> 5 weeks) with no inflammatory reaction. Subcutaneous polymer degradation study was carried out to determine its degradation rate, its effect on inducing fibrosis, and to test its use as subcutaneous implant to aid in the regeneration of endometrium.

Limitations, reasons for caution: This is an *in vitro* study.

Wider implications of the findings: $CD133^+$ BMDSCs loaded inflatable PEGda and gelatin scaffold could be a potential alternative to deliver the cells locally for the repair of endometrial damage provoked by the iatrogenic destruction of the endometrial niche.

O-020 Aneuploidy and mosaicism in human embryos: How correct detection may improve IVF clinical outcomes

S. Munne[1], **E. Fragouli**[1]

[1]*Overture Life, Research & Development, Alcobendas Madrid, Spain*

Abstract text

Study question: Can new next-generation sequencing (NGS) based strategies for preimplantation genetic testing of aneuploidy (PGT-A) improve clinical outcomes after assisted reproductive technology (ART)?

Summary answer: Recent randomised controlled trials (RCTs) suggest that NGS-based PGT-A strategies can improve clinical outcomes for older women. The clinical management of mosaic embryos remains controversial.

What is known already: There are two types of chromosome abnormalities present in embryos, meiotic arising mostly during oogenesis, and mitotic arising after fertilisation. Meiotic aneuploidies are present in all of the embryonic cells and in their vast majority are lethal. Conversely, mitotic abnormalities are present in only part of the embryonic cells with the remaining cells having a different cytogenetic constitution. This phenomenon is known as mosaicism. The sensitivity of NGS meant that mosaic aneuploidy became readily detectable in trophectoderm (TE) samples during PGT-A. The viability and clinical management of mosaic embryos has led to debates and controversies in the reproductive medicine field.

Study design, size, duration: The study involved an assessment of the impact of mosaic chromosome abnormalities to embryonic viability and clinical outcomes after ART cycles using PGT-A via NGS. A large number of embryos generated in IVF clinics in Europe and the USA was examined.

Participants/materials, setting, methods: Embryos were generated by couples referred for PGT-A due to various indications. All embryos were cultured to the blastocyst stage, and underwent a TE biopsy, followed by vitrification. TE samples were shipped to 6 reference PGT laboratories and analysed via the use of the same NGS platform. Mosaic chromosome abnormalities were scored according to validated thresholds set by the reference laboratories. The clinical management of mosaic embryos took place according to published guidelines.

Main results and the role of chance: Comparison of clinical outcomes seen after the transfer of mosaic embryos with those seen after the transfer of euploid embryos led to the following findings:

1. A significantly lower ongoing pregnancy rate (37% for mosaic embryos vs. 77% for euploid embryos, $p < 0.001$).
2. A significantly higher miscarriage rate (25% for mosaic embryos vs. 7% for euploid embryos, $p < 0.001$).
3. A significantly lower ongoing pregnancy rate per oocyte retrieval (37% for mosaic embryos vs. 63% for euploid embryos, $p < 0.001$).

Mosaic embryos with <40% abnormal cells in the TE sample had an OIR of 50% compared to 27% for mosaics with 40–80% abnormal cells in the TE, and 9% for complex mosaic embryos. Karyotyping of ongoing pregnancies resulting after the transfer of mosaic embryos demonstrated a normal chromosome constitution of the resulting foetuses.

Limitations, reasons for caution- Cytogenetic classification was based on TE samples removed from blastocysts during PGT-A analysis. As only a fraction of the cells from each embryo are tested, inevitably some mosaic embryos will be incorrectly classified fully euploid or aneuploid. However, this misclassification is expected to have little impact on the results.

Wider implications of the findings- The transfer of NGS-classified mosaic embryos was associated with poorer clinical outcomes compared to euploid embryos. However, the ongoing pregnancies resulting from mosaic transfers were euploid. NGS's ability to identify embryos of reduced viability has the potential to improve IVF clinical outcomes.

O-022 Pro - FET: The future of IVF

C. Venetis[1]

[1]*University of New South Wales, UNSW Medicine, Sydney, Australia*

Abstract text

Assisted reproductive technology (ART) represents a relatively new but extremely dynamic field of medicine. Throughout its 40 year-old history, there has been a number of paradigm changes, all of which aimed to optimise the efficacy and safety of this technology. This presentation will cover all the scientific developments of the last few years that have now build the case for yet another paradigm change; the transition to predominantly frozen embryo transfers. Emerging knowledge on the effect of the supraphysiological levels of sex steroids, usually present during a stimulated cycle, on the probability of pregnancy combined with new strategies to completely eliminate the occurrence of ovarian hyperstimulation syndrome represent strong arguments in favour of frozen embryo transfer cycles. Dissociating ovarian stimulation from the embryo transfer, also allows for more intense stimulation, which can likely increase the cumulative live birth rate of a single aspiration and therefore reduce the need for future treatment. All these, combined with the encouraging evidence regarding the obstetric and neonatal outcomes of these pregnancies, render the option of the frozen-embryo transfer cycle quite compelling and a strong candidate as the future standard of care in IVF. This presentation will elaborate on these topics and provide guidance on the optimal strategy for frozen-thawed embryo transfer cycles so that the safety and efficacy of IVF are maximised.

O-024 Endoscopic management of the unexplained infertility, what does it add?

S. Gordts[1]

[1]*LIFE, Life Expert Centre, Leuven, Belgium*

Abstract text

Endoscopic management of the unexplained infertility, what does it add?

Stephan Gordts

stephan.gordts@lifeexpertcentre.be

Unexplained infertility "strictu sensu" is not a diagnosis, but a description of a status where no causal factor is identified in a couple trying to conceive for at least one year. The more parameters are assessed, the more likely to identify an etiology, the less likely becomes "unexplained" infertility. Limiting the fertility exploration to indirect visualization techniques like ultrasound, HSG or HycoSy involves the risk of missing existing pathologies.

Uterus

Uterine volumetric abnormalities can be detected by indirect techniques, but information is lacking on the visualization of the endometrium in case of chronic endometritis and the presence of endometrial defects and hypervascularization areas as seen in patients with adenomyosis.

Tubo-ovarian

Even with the increased accuracy of indirect visualization techniques, lesions of minimal endometriosis and tubo-ovarian adhesions are not detected (*Table*). Tubal normality constitutes not only normal tubal patency but also normal tubal function. The importance of subtle tubal lesions is underestimated. Hydatid of Morgagni are detected in 38.1% in patients with infertility versus only in 16,7% in fertile women (*Gupta et al. JMIG 2017*).Removal of these lesions resulted in a spontaneous pregnancy rate of 58.7% versus 20.6 in the non-treated group (*Rasheed et al. EJOG Repr. 2011*).

Endometriosis

In a series of 107 patients with unexplained infertility and 3 failed IVF cycles (*Agni Pantou et al. J. Clin. Med. 2019)*laparoscopy revealed the presence of endometriosis in 57.97%, peri-adnexal adhesions in 23.3% and was normal in 18.69%. Also, in a group of patients with 3 failed IVF cycles and unexplained infertility *(Xiaoming Yu et al.Medicine 2019)* laparoscopy showed endometriosis in 57.7%, tubal abnormalities in 31.1% and adhesions in 33.3%. Laparoscopic correction of these pathologies did not only result in a spontaneous pregnancy rate of 35% but resulted also in a higher pregnancy rate after IVF compared to the non-treated control group.

Unexplained infertility hides frequently undiagnosed endometriosis. Endometrial BCL6 levels, a proto-oncogene where overexpression is associated with increased cellular proliferation and progesterone resistance, are increased in patients with endometriosis. In case of elevated BCL6 in patients with unexplained infertility, laparoscopy confirmed the presence of endometriosis in 93.8% (*Evans-Hoeker et al. 2016*). Abnormal BCL6 expression in a population with unexplained infertility reduced the chance of having a successful IVF treatment in 74% of the population *(Almquist et al. Fertil Steril 2017)*.

Transvaginal Hydro Laparoscopy

Direct endoscopic visualization remains important but due to the invasiveness, diagnostic standard laparoscopy is frequently postponed or omitted in the exploration of the infertile patient. The technique of transvaginal hydro-laparoscopy allows in a minimal invasive way the inspection of the pelvis. In a consecutive series of 2288 patients without obvious pelvic pathology, findings were normal in 49.3%, endometriosis was diagnosed in 15.9% and tubal pathology in 14.5% of the patients *(Gordts et al. FVV 2021)*. The rate of failed access was 1% and the complication rate 0.74%. Causing a minimal ovarian trauma, treatment of these early endometriotic lesions resulted in a spontaneous pregnancy rate of 73.2%.

Conclusion: The inappropriate use of "unexplained infertility" by omitting the diagnostic endoscopy in the exploration of the infertile patient, can hide undiagnosed and treatable pathology, jeopardizing possibilities for patients for a spontaneous conception and can be responsible for reduced pregnancy rates after IVF.

O-025 Value of hysteroscopy

S. Haimovich[1]

[1]*Director of the Gynecology Ambulatory Surgery and Hysteroscopy Unit. Clinical Assistant Professor at the Rappaport Med School- Technion, Obstetrics and Gynecology at the Hillel Yaffe Medical Center, Hadera, Israel*

Abstract text

The 3 main characters in any ART are the uterus, the endometrium, and the embryo. With the rutinary use of 2D US and especially 3D US in infertile patients we are able to assess most of the uterine anomalies and intrauterine pathologies.

Until recently, the assessment of the endometrial cavity with hysteroscopy was reserved only for cases of IVF failure, as a complementary evaluation to ensure that nothing was missed during the ultrasound scan.

We also need to remember how hysteroscopy was performed in the past and, unfortunately, in some cases even today. In the old days, to assess the endometrial cavity, it was required to take the patient to the operating room and under general anesthesia, dilate the cervix to then introduce a large diameter hysteroscope only for diagnostic purposes.

The prevalent working model in ART today is in close collaboration between Fertility specialists, Ultrasound and Hysteroscopy units in order to improve patient's outcome.

In our center, a diagnostic hysteroscopy is performed as part of the diagnostic workup of the infertility patient. It is performed in office setting and without anesthesia, by the staff of the reproduction and infertility unit.

When we look at hysteroscopy as an in-office procedure and no longer as a procedure performed in operating room, we appreciate that it is something that all infertility patients can benefit from.

The right question to ask now would be "Is there a benefit in performing a hysteroscopy to all our patients?".

Ultrasound is not perfect, especially when evaluating the endometrium. The gold standard and the only modality that we have to assess the endometrium with direct visualization is hysteroscopy. Chronic endometritis, adhesions and adenomyosis are only a few examples of what can be assessed by direct vision of the endometrial cavity.

The advantages of a simple, inexpensive, office procedure such as hysteroscopy outweigh any other consideration against it.

During my talk all these points will be presented helping to understand why hysteroscopy is becoming an indispensable tool in every assisted fertility unit.

O-026 Advanced Glycation Endproducts: A new player in obesity related infertility

J. Hutchison[1,2], **T.T. Truong**[3], **T.A. Egell**[2], **L.A. Salamonsen**[1,2], **D.K. Gardner**[3], **J. Evans**[2]

[3]*University of Melbourne, School of BioSciences, Melbourne, Australia*

Abstract text

Globally, 39% of the adult population is overweight or obese, with the prevalence of obesity following an upward trajectory over the recent decades (WHO). Up to 30% of women of reproductive age in Western countries are obese before conception, and obese women experience higher rates of infertility and pregnancy complications than lean women; however, the mechanisms underpinning obesity-related infertility are poorly understood. Advanced Glycation Endproducts (AGEs) are a proinflammatory modification of proteins exposed to sugars, formed through the Maillard reaction. AGEs are elevated four-fold in the uterine fluid of obese, infertile women, compared to lean. AGEs equimolar to those in the obese microenvironment negatively impact the functions of endometrial epithelial and stromal cells, and adhesion and invasion of trophoblast cells, reducing the potential for successful maternal-fetal interactions (Antoniotti et al., 2018). This research further investigated preimplantation embryo development and endometrial cell functions in the presence of AGEs equimolar to those in obese uterine fluid.

Altered local environments in very early life can set offspring up for a lifetime of health or disease (DoHAD); thus, uterine AGEs may contribute to the prevalence of non-communicable disease in children of obese parents. Preimplantation mouse embryos were cultured *in vitro* with AGEs equimolar with uterine fluid concentrations from lean and obese women, and their development and implantation potential assessed. "Obese" AGEs did not impact the proportion of embryos reaching blastocyst stage by day 4, but significantly reduced the proportion of blastocysts hatching by day 5 ($P < 0.01$). AGEs equimolar with the obese uterine environment detrimentally impacted trophectoderm formation and function: reduced trophectoderm cell number ($P < 0.01$), reduced outgrowth on fibronectin (indicative of reduced implantation potential, ($P < 0.01$), but did not increase cell apoptosis (TUNEL assay). RAGE antagonism, but neither metformin nor antioxidants, improved trophectoderm cell number. Thus, obesity-associated AGEs link obesity and reduced fertility through poor placentation potential of embryos (Hutchison et al, 2020).

Endometrial epithelial cell function was examined in the presence of lean and obese concentrations of AGEs. Obese AGEs significantly reduced the rate of proliferation (xCelligence real time cell analysis) of the endometrial epithelial cell line ECC-1 versus lean AGEs ($P = 0.04$). Antioxidants successfully restored the rate of proliferation in the presence of obese AGEs ($P = 0.7$ versus lean AGEs). Subsequently, human endometrial epithelial organoid culture was utilised as a more physiologically relevant experimental paradigm. When cultured as organoids, primary endometrial epithelial cells were functionally responsive to obesity-associated AGEs, expressing both RAGE and TLR4. The morphology of organoids in culture was not impacted by the presence of obese AGEs versus lean; however, the proliferation of epithelial cells retrieved from organoid culture was altered by obese AGEs versus lean. Obese AGEs also increased the secretion of proinflammatory CXCL16 versus vehicle control ($P = 0.04$) while increased secretion of other proinflammatory cytokines and chemokines including TNFa approached significance in the presence of obese AGEs. As the inflammatory milieu is altered in the uterine fluid of infertile women, elevated AGEs may promote an infertile endometrial inflammatory environment.

AGEs link obesity and reduced fertility, being detrimental to preimplantation embryo development and endometrial cell function when present at concentrations equal to those in obese uterine fluid. Antioxidants and RAGE antagonism provide beneficial effects to cell function in the presence of obesity-associated AGEs. This research provides evidence supporting AGEs as a factor contributing to obesity related infertility, and as an emerging frontier for reproductive health. Clinically, reduction of uterine AGEs may improve fertility for obese couples wishing to conceive.

[6]Amsterdam University Medical Centers- Academic Medical Center, Department of Reproductive Medicine, Amsterdam, The Netherlands

Study question: How do infertility patients, endometriosis patients and health care providers rate the virtual care that was provided during the first lockdown of the COVID-19 pandemic?

Summary answer: Patients and health care providers rate telephone- and video consultations as good alternatives during the pandemic but it cannot replace future physical consultations.

What is known already: Virtual alternatives to regular care such as telephone and video consultations are gaining more attention as replacement for physical consultations and are ideal for use in a social distancing situation as the COVID-19 pandemic. However, infertility and endometriosis patients often rely on physical consultations for reassurance as well as for treatments such as artificial reproductive technology and surgery. Not being able to receive these reassurances and treatments may cause stress especially as infertility patients are known to experience a high sense of urgency to obtain treatment. For patients with endometriosis, regular follow-up visits are important for continuity of care.

Study design, size, duration: A cross-sectional cohort study was performed, including 555 patients and 101 health care providers in the field of infertility and endometriosis in the Netherlands. Online questionnaires were sent between May and October 2020.

Participants/materials, setting, methods: Patients with infertility and endometriosis patients from a university hospital and members of the respective national patients organizations, as well as health care providers in the fields of infertility and endometriosis were asked to participate. The questionnaires consisted of demographics, appraisal of telephonic and video consultations (TCs and VCs) and assessment of fertility related quality of life (FertiQoL) and patient-centeredness of endometriosis care (ENDOCARE).

Main results and the role of chance: The questionnaires were completed by 374 infertility patients, 181 endometriosis patients and 101 health care providers. 75.9% of the infertility patients, 64.8% of the endometriosis patients and 82.7% of the health care providers rated TCs as a good alternative for physical consultations during the COVID-19-pandemic. Only 21.3%, 14.8% and 21.3% rated TCs as a good replacement of physical consultations in general. 76.6% and 35.9% of the infertility and endometriosis patients reported to experience an increase in stress due to the altered care during the COVID-19 pandemic. 38.7% and 58.0% reported to have received sufficient information from their care givers. Infertility patients scored lower on the FertiQoL than the reference population, while the ENDOCARE results of endometriosis patients were comparable to the reference.

Limitations, reasons for caution: This study was limited to the Dutch population. As the organization of infertility care varies internationally, the results will not be directly applicable to other countries or health care systems.

Wider implications of the findings: Virtual care options are a good alternative for infertility and endometriosis patients in situations where physical consultations are not possible. Self-reported stress is especially high in infertility patients during the COVID-19-pandemic. Health care providers should provide more information to patients in order to increase their ability to cope with stress.

[13]IVI Alicante, Medical Department, Alicante, Spain

Study question: What is the SARS-CoV-2 positivity rate following the Spanish Fertility Society (SEF) / Association for the Study of Reproductive Biology (ASEBIR) screening recommendations?
Summary answer: The SARS-CoV-2 positivity rate in the centers following the SEF/ASEBIR screening recommendations was 0.316% after the first survey and 0.364% after the second one
What is known already: Due to the Sars-Cov-2 pandemic, all the Medical Assisted Reproduction (MAR) centers in Spain had to interrupt their activity most of the time during the first pandemic wave. On April 27th activity was restarted, and SEF and ASEBIR jointly elaborated a guide describing their SARS-CoV-2 screening recommendations for MAR centers. This document aims to achieve a safe environment for patients and staff. It includes the possibility of screening patients through a targeted clinical interview and the use of reverse-transcriptase polymerase chain reaction (RT-PCR). The aim of this study is to quantify the SARS-CoV-2 positivity rate based on these recommendations.
Study design, size, duration: National multicenter cross-sectional study. Information was gathered from centers using an anonymous survey asking for aggregated data about the number of positive cases among screened patients, sent twice. The first survey covered the period April 27th - June 30th. Second survey covered July 1st - August 31st. Response rates among centres were 9% (29/319) and 6% (20/319), respectively. This study includes 2,695 and 4,068 screenings performed in the first and the second survey, respectively.
Participants/materials, setting, methods: The SEF/ASEBIR recommendations describe two screening strategies. Strategy (a) consists in a targeted clinical interview (TCI) evaluating clinical symptoms and exposure risk, first before starting the cycle, and before egg-retrieval, intrauterine insemination (IUI), and/or embryo transfer (ET). Suspicious cases could be confirmed by further RT-PCR testing. Strategy (b) consists in conducting the same first TCI, and a systematic RT-PCR testing before the medical procedure in all patients. All patients in both strategies have a TCI.
Main results and the role of chance: In the 1st survey, 1,177 screenings and 919 RT-PCR (78.07%) were performed before the egg-retrieval. One patient with a negative TCI and positive RT-PCR was detected, and the cycle was cancelled. 1,518 screenings and 1,161 RT-PCRs (76.48%) were performed before the ET / IUI. Two patients with a positive TCI were detected, one did not perform a RT-PCR, while the other resulted in a positive RT-PCR. Both cycles were cancelled. Besides, 5 patients with negative TCI performed a RT-PCR with a positive result; all 5 were cancelled. Overall, the SARS-CoV-2 positivity rate was 8/2533 (0.316%), of which 7/2533 (0.276%) were identified by RT-PCR testing.

The 2nd survey included 1,376 screenings and 1,009 RT-PCR (73.32%) performed before the egg-retrieval. Four patients with negative TCI and further positive RT-PCR were detected, and their cycle was cancelled. 2,692 screenings and 2,134 RT-PCR (79.27%) were performed before ET / IUI. Two patients had a positive TCI, one with a negative, the other with a positive RT-PCR testing; both cycles were cancelled. Besides, 8 patients with negative TCI, but positive RT-PCR testing, were detected and their cycles cancelled. Overall, the SARS-CoV-2 positivity rate was 14/3846 (0.364%), of which 13/3846 (0.338%) after positive RT-PCR testing.
Limitations, reasons for caution: The criteria for performing the RT-PCR testing were not the same in all MAR Centres or even in the same centre at different times. Due to the low response rate of the study, we should not extend these results to all the MAR Centres in Spain.
Wider implications of the findings: The results of the surveys suggest that the SEF / ASEBIR recommendations could be a good screening strategy for SARS-Cov-2 at MAR Centres. Further survey collected at different times of the pandemic are warranted, including new strategies for screening as antigen tests or vaccination status.
Trial registration number: Not applicable

O-105 High prevalence of obesity and polycystic ovary syndrome in an online community seeking assistance with fertility

B. Ring[1], B. Wilson[2], S. Chen[3], A. Crisci[2]

[1]MedAnswers, Research- Development and Analysis, Foster City, U.S.A. ;
[2]MedAnswers, Research- Development and Analysis, San Pedro, U.S.A. ;
[3]Rutgers NJ Medical School, Department of Obstetrics- Gynecology & Reproductive Health, Newark, U.S.A.

Study question: What are the characteristics of a large online community of women trying to conceive and what are the factors that predict infertility in this group?
Summary answer: The cohort was not characterized by increased age, though age, obesity and PCOS strongly correlated with fertility. PCOS may be under-recognized within some ethnic groups.
What is known already: Obesity, polycystic ovary syndrome (PCOS), and age are among the primary predictors of infertility in women. However, most studies assessing reproductive health employ populations who have sought medical assistance for infertility or associated disorders, potentially leading to populations more likely to exhibit disorders such as PCOS or to be of increased age. Characterization of factors affecting fertility in a general population may highlight epidemiological influences that should be better addressed to aid women trying to conceive.
Study design, size, duration: This study employed users of the mobile application, FertilityAnswers, for people searching for answers to fertility problems. Users answered a short survey describing themselves, their fertility history and goals. Recruitment for this study began in March 2017 and ended in January 2021. 61814 participants downloaded the application during this period, and 56878 at least provided their age. The primary inclusion criteria were that study participants be US females over eighteen years of age.
Participants/materials, setting, methods: Regression models estimated beta coefficients and corresponding confidence intervals. Multivariable models determined independence of variables. To model PCOS, the available data in January 2020 was split randomly into discovery and validation subsets. Missing value imputation using random forests was performed in the discovery dataset. Minimal feature selection used a linear regression model penalized with a lasso and elastic net. The model was then validated on samples collected after the model was trained and tested.
Main results and the role of chance: Age was a significant predictor of fertility in this study (p<1x10-10). However, the distribution of age in the cohort was very similar to that of women at first birth in the United States, therefore we did not observe the majority of study participants to be of an age where in a typical clinical setting age-related concerns would be addressed (i.e., approaching 35 years). Using National Center for Health Statistics data, the mean age of 1,433,604 women at first birth in 2018 in the US was younger than the study population (restricted to those without children) by only one month. Obesity was of increased prevalence in this cohort, with 55% being obese, compared to 37% in an age-matched US population. Participants reported a variety of fertility-related disorders, with polycystic ovary syndrome (PCOS) being most

prevalent (19.0%), followed by endometriosis (6.0%). Prediction of PCOS, performed by modeling on training and test sets (10476 and 5312 participants) and then validating with an additional 21097 participants collected after the model creation, found that African-Americans and Latino members of this cohort had a lower self-reported rate of the disorder than was anticipated by the model, in contrast to those of Asian or European descent.

Limitations, reasons for caution: All health data was self-reported. Additionally, as this is the initial survey of this population, no a priori hypotheses were made as to the expected relationships to be observed. Instead, all associations were examined, and measurements of false discovery rate were estimated.

Wider implications of the findings: We found that women were seeking answers about infertility at ages coincident with that of their peers achieving first pregnancies. ART is often not a first-line treatment for women of this age, but there may be a disconnect between traditional clinical response to this group and their desire for assistance.

Trial registration number: not applicable

O-106 Non-donor IVF treatment cycles in the UK need to be re-evaluated against the 1.625 million oocytes retrieved

G. Bahadur[1], R. Homburg[2], A. Govind[1], S. Acharya[3], K. Jayaprakasan[4], P. Racich[5], J. Huirne[6], E. Jauniaux[7]

[6]University medical centers Amsterdam- location VUmc and AMC– The Netherlands.Uniiversity Medical Canter-, Research institute Reproduction and development– De Boelelaan 1081- 1081 HV Amsterdam-, 1007 MB Amsterdam, The Netherlands ;
[7]University College London, EGA Institute for Women's Health- Faculty of Population Health Science, London- WC1E 6HX, United Kingdom

Study question: Are IVF clinics collecting too many oocytes per retrieval procedure?

Summary answer: IVF cycles performed in the UK appear to be retrieving far too many oocytes, most of which may never be used and are probably discarded.

What is known already: For justifying IVF with low AMH, older women, poor responders, the Bologna and POSEIDON consensuses were developed. The positive linear correlation between cumulative live birth rates and numbers of oocytes collected is well established, thereby focussing intensely on stimulation regimes and the growth of FER cycles and oocyte freezing activities. The associated risk of OHSS is well-known. However, over-stimulation practices and numbers of oocytes retrieved within IVF remain unknown as is the impact on patients' health, emotional and financial welfare. This UK dataset uniquely reveals numbers of oocytes retrieved against IVF cycles undertaken, and which may well reflect global practices.

Study design, size, duration: This is a retrospective observational cohort study of oocyte retrieval procedures for non-donor IVF cycles in the UK between 2015 and 2018. Data were obtained from UK HFEA under the Freedom of Information Act 2000. For fresh oocytes, data were obtained for the number of cycles retrieving 1-5, 6-15, 16-25, 26-49, 50-59, and 60+ oocytes. The number of cycles that led to no oocytes was obtained as well as data on the utilisation of oocytes.

Participants/materials, setting, methods: The data from the HFEA covers up to 86 UK IVF clinics undertaking non-donor IVF. IVF clinics are legally obliged to provide IVF dataset as part of the licence requirement. The unbiased data was gathered independently by HFEA staff under the Freedom of Information Act 2000. Specifically, the number of treatment cycles with; 0, 1-5, 6-15,16-25, 26-49, 50-59, and 60+ oocytes retrieved for each year was requested. Additional limited data could be gained.

Main results and the role of chance: For 2015-2018 there were 172341 fresh oocyte retrieval cycles, where 10148 (5.9%) cycles from 9439 patients did not yield any oocytes. In this period, 42574 cycles (24.7%), 91797 cycles (53.3%), 23794 cycle (13.8%) and 3970 cycles (2.3%) yielded 1-5 oocytes, 6-15 oocytes, 16-25 oocytes, 26-49 oocytes respectively, while 58 cycle (0.033%) yielded over 50 oocytes. The data was accountable by 5-85 clinics and the outcomes and patterns remained uniform across the 4 years. The main desired oocyte yield of 6-15 oocytes occurred in 53.3% of IVF cycles distributed evenly across the clinics. However, 16.1% of cycles were associated with 16-49 oocytes retrieved per IVF cycle, while 58 (0.03%) cycles led to greater than 50 oocytes retrieved. The maximum number of oocytes collected was not provided by the HFEA due to technical reasons.
The total number of oocytes collected over 4-years numbered 1,624,912 oocytes from 147274 women yielding on average 11 oocytes per patient. These oocytes were fertilised to yield 931,265 embryos (57.3% converted). The fate of 42.7% oocytes remains unknown. Of the embryos created, 209,080 (22.4%) were transferred over 172,333 cycles, while 219,563 (23.6%) embryos frozen and the fate of 53.97% of embryos remained unaccounted for.

Limitations, reasons for caution: This retrospective analysis spans 4 years in which stimulation regimes, patient characteristics, or outcomes were unavailable. Only a qualitative analysis is possible with the HFEA dataset, but the corresponding data is unique and of public interest. The outcome of unaccounted oocytes appears a limitation in the regulatory body data set.

Wider implications of the findings: This unique observation on IVF clinics practices suggests that the high oocyte number per retrieval procedure needs re-evaluation. In particular, this needs to focus on the side-effects, including OHSS and procedure-related complications. In addition, the outcome and cost of unused frozen oocytes need to be established.

Trial registration number: not applicable

O-107 Searching for the optimal number of oocytes to reach a life birth following in vitro fertilization: a systematic review with meta-analysis

N. Sermondade[1], C. Sonigo[2], M. Pasquier[3], N. Yata-Ahdad[4], E. Fraison[5], M. Grynberg[2]

[1]Hopital TENON, Service de Biologie de la Reproduction - CECOS, PARIS, France ;
[2]Hopital Antoine Béclère, Médecine de la Reproduction et Préservation de la Fertilité, Clamart, France ;
[3]Centre Hospitalier Intercommunal de Créteil, Médecine de la Reproduction, Créteil, France ;
[4]Centre Hospitalier de Meaux, Médecine de la Reproduction, Meaux, France ;
[5]Hospices Civils de Lyon, Médecine de la Reproduction, Lyon, France

Study question: To investigate the relationship between the number of oocytes and both the live birth rate after fresh embryo transfer and the cumulative live birth rate.

Summary answer: Above a 15-oocyte threshold, live birth rate (LBR) following fresh transfer plateaus, whereas a continuous increase in cumulative live birth rate (CLBR) is observed.

What is known already: Several lines of evidence indicate that number of oocytes represents a key point for in vitro fertilization (IVF) success. However, consensus is lacking regarding the optimal number of oocytes for expecting a live birth. This is a key question because it might impact the way practitioners initiate and adjust COS regimens.

Study design, size, duration: A systematic review and meta-analysis was performed. MEDLINE, EMBASE, and Cochrane Library were searched for studies published between January 01, 2004, and August 31, 2019 using the search terms: "(intracytoplasmic sperm injection or icsi or ivf or in vitro fertilization or fertility preservation)" and "(oocyte and number)" and "(live birth)".

Participants/materials, setting, methods: Two independent reviewers carried out study selection, quality assessment using the adapted Newcastle-Ottawa Quality Assessment Scales, bias assessment using ROBIN-I tools, and data extraction according to Cochrane methods. Independent analyses were performed according to the outcome (LBR and CLBR). The mean-weighted threshold of optimal oocyte number was estimated from documented thresholds, followed by a one-stage meta-analysis on articles with documented or estimable relative risks.

Main results and the role of chance: After reviewing 843 records, 64 full-text articles were assessed for eligibility. A total of 36 studies were available for quantitative syntheses. Twenty-one and 18 studies were included in the meta-analyses evaluating the relationship between the number of retrieved oocytes and LBR or CLBR, respectively. Given the limited number of

investigations considering mature oocytes, association between the number of metaphase II oocytes and IVF outcomes could not be investigated. Concerning LBR, 7 (35.0%) studies reported a plateau effect, corresponding to a weighted mean of 14.4 oocytes. The pooled dose-response association between the number of oocytes and LBR showed a non-linear relationship, with a plateau beyond 15 oocytes. For CLBR, 4 (19.0%) studies showed a plateau effect, corresponding to a weighted mean of 19.3 oocytes. The meta-analysis of the relationship between the number of oocytes and CLBR found a non-linear relationship, with a continuous increase in CLBR, including for high oocyte yields.
Limitations, reasons for caution: Statistical models show a high degree of deviance, especially for high numbers of oocytes. Further investigations are needed to assess the generalization of those results to frozen mature oocytes, especially in a fertility preservation context, and to evaluate the impact of female age.
Wider implications of the findings: Above a 15-oocyte threshold, LBR following fresh transfer plateaus, suggesting that the freeze-all strategy should probably be performed. In contrast, the continuous increase in CLBR suggests that high numbers of oocytes could be offered to improve the chances of cumulative live births, after evaluating the benefit–risk balance.

[6]CEGyR, Embryology Laboratory, Caba, Argentina

Study question: What is the degree of acceptance of new family models using Assisted Reproductive Techniques and what is the childbearing perception among different generations in Argentina
Summary answer: The youngest accept different family conformations through fertility treatments more than olders. They also consider, in greater proportion, that happiness is not linked to childbearing
What is known already: (1). Human reproduction changed dramatically in the last 40 years, with the development of Assisted Reproductive Treatments (ART) (2). In accordance with the new family models, gender diversity, self-acceptance and social openness, unacceptable until recently, are today a new reality. Since 2013, in Argentina, fertility treatments are regulated under National Law No. 26.862, allowing full access to ART regardless of marital status or sexual orientation. (3). However, there is still a legal vacuum around uterine surrogacy, which hinders treatment particularly in male homosexual couples.
Study design, size, duration:
This is a cross-disciplinary descriptive study based on data obtained from an online self-administered survey. We surveyed a sample of 1800 people from the general population during June 2020.
Participants/materials, setting, methods: A structured and self-administered survey was carried out through OPINAIA (research consultant). Participants answered voluntarily an anonymous online questionnaire. We stratified our population in 4 groups according to different generations that represent the Argentinean population: Centennials (18-25 years), Millennials (26-35 years), Gen X (36-49 years), Baby Boomers (more than 50 years), respectively. We also stratified our sample by gender, socioeconomic level, and geographic location.
Main results and the role of chance: The data obtained in our survey showed that 92% of our population expressed an agreement to the use of ART for heterosexual couples, 76% for single women, 65% for single men, 62% for female couples and 59% as to male couples. However, when stratifying by generations, we observed that the youngest showed a clear tendency to accept the new family conformation models with respect to the oldest ones.

When comparing by generations, Centennials showed a strong agreement for single women (63%), single men (52%), female couples (60%) and male couples (58%). However, Baby Boomers express agreement on single women (33%), single men (24%), female partners (24%), male partners (22%). So, our data reveals that the prejudices concerning the different family conformations models are less among the youngest.

We also observe a tendency towards believing that happiness is not related to parenthood by the younger (Centennials 75%, Millennials 67%, X Generation 64%, Baby Boomers 60%).

This is a representative sample of the Argentinean populations, based upon official National census. Thus, it accurately represents the local distribution concerning age, gender, socioeconomic level, and geographic location.
Limitations, reasons for caution: Our investigation is a descriptive and observational study
Wider implications of the findings: This is the first study about new family models in Latin America. The study sample represents the national population and reflects clearly social trends. Therefore, it allows predicting future scenarios for policy makers to plan effective education strategies and to consider the distribution of public health funds for fertility treatments.

Abstract text
"The ovarian endometriotic cyst"

Ovarian endometriomas affect 17 to 44% of women with endometriosis, and are often associated with pelvic pain and infertility.

Patients suffering from endometriosis frequently present an already reduced ovarian reserve, assessed by AMH dosage or by antral follicular count during TVS.

Pain and infertility are the main indications for endometrioma surgery which is a complex procedure as endometriosis leads to inflammation around the lesions, causing fibrosis.

Three main surgical procedures have been described: the ovarian cystectomy, the endometrioma ablation or the combined technique.

During the cystectomy, after ovarian mobilization and adhesions lifting, an incision of the cortex is realized to find a cleavage plane between the cyst wall and the ovarian cortex. Traction and countertraction movements are performed to carefuly dissociate the cyst from the ovarian cortex. It is crucial to handle the ovarian tissue as atraumatically as possible. With this technique, the cyst wall as well as the surrounding fibrosis are excised with the risk of oocytes removal responsible for decreased ovarian reserve.

The ablative surgery is defined by the fenestration and vaporization of the endometrioma cyst. The ablation is carried out using a laser or plasma energy

or electrocoagulation. Once the endometrial cyst has been emptied of its contents, the entire internal surface of the endometrioma must be sprayed or evaporated using the different chosen techniques. Where feasible, the cyst may be turned inside out to facilitate further treatment.

The combined technique associates partial cystectomy (80-90%) and ablation of the 10-20% remaining endometrioma. This method is especially useful while operating large endometriomas. It prevents excessive bleeding or damage to the ovarian tissue.

In cases of large ovarian endometrioma, the three-step approach has been proposed, consisting on an opening and drainage of the cyst followed by a 3 months' administration of Gn-RH agonists in order to reduce its diameter and vascularization. A second surgical procedure is then scheduled to ablate the remaining cyst wall.

In conclusion, it is crucial to keep in mind that endometriosis and especially the presence of endometrioma reduce fertility whereas in the majority of cases, the ovarian reserve is already diminished in relation to the patient's age. Ovarian preservation must be one of our priorities in young patients of childbearing age and it is therefore really important to carry out surgeries that are as atraumatic as possible.

[7]Ferring Pharmaceuticals, Reproductive Medicine & Maternal Health, Copenhagen, Denmark

Study question: Does addition of choriogonadotropin beta (CG beta) to follitropin delta increase the number of good-quality blastocysts following ovarian stimulation in a long GnRH agonist protocol?

Summary answer: At the doses investigated, the addition of CG beta reduced the number of intermediate follicles and decreased the number of oocytes and blastocysts.

What is known already: CG beta is a new recombinant hCG (rhCG) molecule expressed by a human cell line (PER.C6[a]) with a different glycosylation profile compared to urinary hCG or rhCG derived from a Chinese Hamster Ovary (CHO) cell-line. In the first-in-human trial, the CG beta pharmacokinetics were similar between men and women. In women, the area under the curve (AUC) and the peak serum concentration (C_{max}) increased dose proportionally following single and multiple daily doses. In men, a single dose of CG beta provided higher exposure with a longer half-life and proportionately higher testosterone production than rhCG derived from a CHO cell line.

Study design, size, duration: Placebo-controlled, double-blind, randomised trial (RAINBOW) to explore the efficacy and safety of CG beta as add-on treatment to follitropin delta in women undergoing COS in a long GnRH agonist protocol. The primary endpoint was the number of good-quality blastocysts (grade 3 BB or higher, Gardner and Schoolcraft, 1999). Subjects were randomised to receive either placebo or 1, 2, 4, 8, or 12 µg CG beta added to the daily individualised follitropin delta dose during COS.

Participants/materials, setting, methods: In total 619 women (30-42 years) with AMH levels between 5 and 35 pmol/L were randomized in equal proportions to the six treatment groups. All subjects were treated with an individualised dose of follitropin delta determined based on AMH (Elecsys AMH Plus Immunoassay) and body weight. Triggering was performed when 3 follicles were ≥17 mm but no more than 25 follicles ≥12 mm were reached

Main results and the role of chance: The incidence of cycle cancellation (range 0%-2.9%), total follitropin delta dose (mean 112 µg) and duration of stimulation (mean 10 days) were similar across the groups. A reduced number of intermediate follicles (12 to 17 mm) and fewer oocytes (mean range 9.7 to 11.2) were observed for all doses of CG beta compared to the follitropin delta only group (mean 12.5). The mean number of goodquality blastocysts was 3.3 in the follitropin delta group and ranged between 2.1 and 3.0 across the CG beta groups. The incidence of transfer cancellation was higher in the 4, 8 and 12 µg group, mostly as no blastocyst was available for transfer. In the group receiving only follitropin delta, the ongoing pregnancy rate (10-11 weeks after transfer) was high i.e. 43% per started cycle vs 28-39% in CG beta groups and 49% per transfer vs 38-50% in the CG beta groups. In line with the number of collected oocytes, the OHSS incidence was overall lower following follitropin delta with CG beta than following follitropin delta only treatment. Regardless of the dose, CG beta was safe and well-tolerated with low risk of immunogenicity.

Limitations, reasons for caution: The effect of the unique glycosylation of CG beta and the associated potency implications in women were not known prior to this trial. Further studies will be needed to evaluate potentially lower doses of CG beta for this and/or different indications.

Wider implications of the findings: The high ongoing pregnancy rate in the follitropin delta group supports the use of individualised follitropin delta dosing in a long GnRH agonist protocol. The differential potency of CG beta may have impaired the growth of intermediate follicles with the investigated doses without affecting the ongoing pregnancy rates per transfer.

Study question: To evaluate the efficacy and safety of individualised dosing with follitropin delta versus conventional dosing with follitropin alfa in an Asian population undergoing ovarian stimulation.

Summary answer: Individualised dosing with follitropin delta results in significantly higher live birth rate and fewer early OHSS and/or preventive interventions compared to conventional follitropin alfa dosing.

What is known already: Previous randomised controlled trials conducted in Europe, North- and South America mainly including Caucasian IVF/ICSI patients as well as in Japan have demonstrated that ovarian stimulation with the individualised follitropin delta dosing regimen based on serum AMH level and body weight modulated the ovarian response and reduced the risk of OHSS without compromising pregnancy and live birth rates.

Study design, size, duration: Randomised, controlled, assessor-blind trial conducted in 1,009 Asian patients from mainland China, South Korea, Vietnam and Taiwan, undergoing their first IVF/ICSI cycle. Randomisation was stratified by age (<35, 35-37, 38-40 years). The primary endpoint was ongoing pregnancy assessed 10-11 weeks after transfer (non-inferiority limit -10.0%; analysis adjusted for age strata). Patients <35 years underwent single embryo transfer if a good-quality embryo was available, otherwise double embryo transfer. Patients ≥35 years underwent double embryo transfer.

Participants/materials, setting, methods: Follitropin delta (Rekovelle, Ferring Pharmaceuticals) daily treatment consisted of a fixed dose individualised according to each patient's initial AMH level (<15 pmol/L: 12 µg; ≥15 pmol/L: 0.19 to 0.10 µg/kg; min-max 6-12 µg) and body weight. Follitropin alfa (Gonal-f, Merck Serono) dose was 150 IU/day for the first five days with subsequent potential dose adjustments according to individual response. A GnRH antagonist protocol was applied. OHSS was classified based on Golan's system.

Main results and the role of chance: The ongoing pregnancy rate was 31.3% with follitropin delta and 25.7% with follitropin alfa (adjusted difference 5.4% [95% CI: -0.2%; 11.0%]). The live birth rate was significantly higher at 31.3% with follitropin delta compared to 24.7% with follitropin alfa (adjusted difference 6.4% [95% CI: 0.9%; 11.9%]; p<0.05). Live birth rates per age stratum were as follows for follitropin delta and follitropin alfa; <35 years: 31.0% versus 25.0%, 3537 years: 35.3% versus 26.7%, 38-40 years: 20.0% versus 14.3%. Early OHSS risk, evaluated as the incidence of early OHSS and/or preventive interventions, was significantly (p<0.01) reduced from 9.6% with follitropin alfa to 5.0% with follitropin delta. The number of oocytes was 10.0±6.1 with follitropin delta and 12.4±7.3 with follitropin alfa. Individualised follitropin delta dosing compared to conventional follitropin alfa dosing resulted in 2 more oocytes (9.6±5.3 versus 7.6±3.5) in potential low responders (AMH <15 pmol/L) and 3 fewer oocytes (10.1±6.3 versus 13.8±7.5) in potential high responders (AMH ≥15 pmol/L). Among patients with AMH ≥15 pmol/L, excessive response occurred less frequently with individualised than conventional dosing (≥15 oocytes: 20.2% versus 39.1%; ≥20 oocytes: 6.7% versus 18.5%). Total gonadotropin dose was reduced from 109.9±32.9 µg with follitropin alfa to 77.5±24.4 µg with follitropin delta.

Limitations, reasons for caution: The trial only covered the clinical outcome of one treatment cycle with fresh cleavage-stage embryo transfers.

Wider implications of the findings: The present trial implies that in addition to reducing the early OHSS risk, individualised dosing has the potential to improve the take-home baby rate in fresh cycles across all ages and with a lower gonadotropin consumption. The benefits in outcomes appear to be explained by the modulation of ovarian response.

Trial registration number: NCT03296527

O-111 The DuoStim strategy shortens the time to obtain an euploid embryo in poor prognosis patients: a non-inferiority, randomized controlled trial

M. Cerrillo Martínez[1], G. N Cecchino[2], M. Cruz[3], M. Toribio[4], M.J. García Rubio[5], J.A. García Velasco[6]

[1]IVIRMA Madrid, Reproductive Medicine, Madrid, Spain ;
[2]Department of Reproductive Medicine- Mater Prime São Paulo- Brazil, Reproductive Medicine, São paulo, Brazil ;
[3]IVIRMA Madrid, Equipo IVI, Madrid, Spain ;
[4]IVIRMA Madrid, Nurse and investigation department, madrid, Spain ;
[5]IVRIMA Madrid, Reproductive medicine, Madrid, Spain ;
[6]IVIRMA Madrid- URJC, Director, Madrid, Spain

Study question: Is there any difference in the time to obtain euploid embryos from poor prognosis patients who performed two conventional cycles versus double stimulation (DuoStim) in the same cycle?

Summary answer: DuoStim showed similar ovarian response and *in vitro* fertilization (IVF) laboratory outcomes while shortening the time to obtain an euploid embryo in poor prognosis patients.

What is known already: Several waves of cyclic development of antral follicles within the same menstrual cycle have been demonstrated. Likewise, it has been shown that oocytes obtained from luteal phase ovarian stimulation (OS) have similar competence than those obtained in the follicular phase OS. Often, some patients require sequential OS in order to obtain more oocytes and increase their chances to reach embryo transfer. Thus, the DuoStim strategy could be an attractive alternative to reduce the time-to-pregnancy. However, prospective data and randomized trials that validate this strategy are lacking.

Study design, size, duration: We conducted a prospective, randomized controlled trial at our institution from[MCM1] [JAGV2] January 2017 to December 2020. A total of 80 poor prognosis patients aged over 38 years undergoing PGT-A were enrolled in two groups: 39 patients did two OS in consecutive cycles (control) whereas 41 women underwent two OS in the same menstrual cycle (DuoStim).

Participants/materials, setting, methods: Poor prognosis was defined as suboptimal responders. The primary outcome was the time needed to obtain an euploid embryo. The secondary outcomes were duration of stimulation, dose of gonadotropins, oocyte maturity rate, fertilization and blastocyst formation rates. Variables were expressed as mean ± standard deviation. Statistical analyses was performed by ANOVA and Chi-square tests, as appropriate. Differences were considered significant when *p-value* < 0.05.

Main results and the role of chance: The patients' baseline characteristics were similar between groups. We did not find any difference in the mean days of stimulation between the control and the DuoStim group (21.3 ± 1.6 *vs.* 23 ± 1.4, *p=0.105*), nor in the amount of gonadotropin required (4005 ± 450 *vs.* 4245 ± 430, *p=0.43*), number of MII oocyte (8.7 ± 1.8 *vs.* 6.8 ± 1.7, *p=0.159*), blastocyst rate (51.4% *vs.* 34.8%, *p=0.113*) and the number of euploid embryos (0.8 ± 0.4 *vs.* 0.6 ± 0.4, *p=0.45*). However, there was a significant difference in the average number of days until reaching an euploid blastocyst, favoring the DuoStim group (44.1 ± 2 *vs.* 23.3 ± 2.8, *p<0.001*). Comparing the follicular versus the luteal phase within the DuoStim group, the only difference detected concerns to the mean days of stimulation (10.3 ± 0.8 *vs.* 12.7 ± 0.9, *p<0.001*). We also observed a trend towards a higher fertilization (38.1% *vs.* 61.8%, *p=0.02*) and blastulation rate (23% *vs.* 53%, *p=0.03*) in the luteal phase of the DuoStim cycle.

Limitations, reasons for caution: The major limitation is related to the limited sample size, as it limits our power analysis (70%). On the other hand, it is one of the first randomized prospective pilot trial that compared the efficiency of performing two consecutive ovarian stimulation in different menstrual cycles with the DuoStim strategy.

Wider implications of the findings: This study clearly showed that the DuoStim protocol is not inferior to the conventional stimulation in terms of ovarian response and laboratory outcomes. Moreover, the DuoStim reduces the time to obtain an euploid embryo in poor prognosis patients, which is of great clinical utility.

Trial registration number: NCT03291821

O-112 Outcomes of random-start ovarian stimulation protocols as a possible evidence of the theory of antral follicles continuous recruitment

Y. Martirosyan[1], T. Nazarenko[1], A. Birukova[1], I. Dmitrieva[1]

[1]National Medical Research Center for Obstetrics- Gynecology and Perinatology named after V.I. Kulakov- Ministry of Health of Russia, Research and educational center for assisted reproductive technologies named after F. Paulsen-senior, Moscow, Russia C

Study question: We tried to validate the possibility and efficiency of ovarian stimulation (OS) started on any day of the menstrual cycle, based on a theory of continuous recruitment of antral follicles.

Summary answer: Formation of a pool of follicles with higher sensitivity to gonadotropic stimulation occurs several times during the menstrual cycle (MC).

What is known already: According to classical concepts and fundamental positions formulated in the middle of the last century, follicular recruitment occurs only once during the menstrual cycle - in the early follicular phase. Nowadays there is increasing evidence to suggest that there are multiple (two or three) antral follicular waves of recruitment during the MC. Also some researchers state that the process of follicle recruitment is continuous.

Study design, size, duration: This prospective clinical study was conducted at the V.I. Kulakov NMRC for OG&Pof Russia. The study included female cancer patients seeking retrieval and cryopreservation of oocytes and/or embryos before cancer treatment. 240 patients were selected for the study. The patients were divided into 5 groups depending on the cycle day on the moment when ovarian stimulation was initiated. All patients signed an informed consent form approved by the Ethics Committee.

Participants/materials, setting, methods: The 1st group consisted of patients who started standart OS from 1 to 5 days of the cycle (n=65); the 2nd - from 6 to 10 (n=36), the 3rd - from 11 to 15 (n=45), the 4th - from 16 to 22 (n=44), the 5th - from 23 to 28 (n=50). In the late follicular and luteal phase we performed OS without a pituitary modulator. The comparative analysis included features of oo-, embryogenesis and steroidogenesis.
Main results and the role of chance: The mean age, BMI and AMH were not different among groups. There were no LH rise or OHSS signs noticed in any groups, despite that OS in late follicular and luteal phase of the MC was performed with no GnRH antagonist addition.There was no statistically significant difference in the duration of stimulation, starting doses, total dose of FSH and HMG. The largest number of oocyte cumulus complexes was obtained in the 5th group (11 (9–21) vs 7 (3,5–15,5) in the 1st group, p=0,030). The greatest number of mature oocytes was obtained in the 4th and 1st groups. In the 2nd group the largest number of immature oocytes was obtained (37 (9.1%)). A smaller number of mature oocytes (165 (61.8%) vs 492 (72.9%) and 314 (77.5%), p = 0.001) was obtained in group 2 (compared with the 1st and the 4th groups), when stimulation was started in the presence of a dominant follicle . These periods coincided with higher estradiol and lower FSH serum levels. Based on our data the optimal moment for effective OS initiation starts with the decrease in serum estradiol which is approximately 48 hours before the menstrual bleeding.
Limitations, reasons for caution: The presented results could be applied mainly to young patients with high and normal ovarian reserve, who were in the main study group. In patients with low ovarian reserve, short menstrual cycle and early ovulation an issue of favorable time points for the initiation of OS should be resolved individually.
Wider implications of the findings: The data collected during our research could possibly contribute to future personification of OS protocols. Tailoring the ovarian stimulation protocols to the needs of the patients could decrease time needed for completing the protocol without affecting oocyte yield or their maturity.
Trial registration number: none

Study question: How effective is Assisted Reproduction Technology (ART) in terms of cumulative live birth rate (CLBR) in France, depending on the gonadotropin used?
Summary answer: Among 214,539 stimulations, originator follitropin-alfa was associated with significantly higher CLBR when compared to Highly Purified-Human Menopausal Gonadotropin (HP-HMG) and biosimilars.
What is known already: Deciding which type of gonadotropin to prescribe for a woman undergoing controlled ovarian stimulation (COS) remains difficult. The effectiveness of different gonadotropins is one factor to consider. However, studies comparing r-hFSH-alfa, its biosimilars and HP-HMG are scarce and are mostly based on a single ART treatment cycle and fresh embryo transfers. Some clinical trials have shown similar pregnancy, pregnancy loss, and live birth rates after fresh embryo transfer (ET) between HP-HMG and r-hFSH. However, because more oocytes are retrieved with r-hFSH when compared to HP-HMG, it is logical to hypothesize that the CLBR is higher with r-hFSH.
Study design, size, duration: A non-interventional study based on the French National Health System (SNDS) database was designed to assess the CLBR and treatment costs from the national payer perspective of four gonadotropin groups (originator follitropin-alfa (r-hFSH-alfa), its biosimilars, HP-HMG and r-hFSH-beta) used for COS cycles leading to oocyte pick-up (OPU) between 01/01/2013 and 31/12/2017 with a follow-up period up to 31/12/2018. The study compared CLBR, with originator r-hFSH-alfa as the reference.
Participants/materials, setting, methods: Women with COS cycles resulting in OPU with one of the specified gonadotropins were included. Data were extracted from billing and reimbursement records of outpatient healthcare consumption and national hospital discharge databases using a unique, anonymized patient number. CLBR was estimated using an Andersen–Gill model, adjusted for clinical baseline, stimulation and ET variables. Costs were reported as secondary outcomes.
Main results and the role of chance: 135,752 women (mean age 34.1), underwent 214,539 stimulations leading to OPU and contributed one (61.5%), two (24.8%), three (9.4%) or four (3.2%) COS cycles. COS cycles were stimulated with either Originator r-hFSH-alfa (46%), HP-HMG (29%), r-hFSH-beta (21%) or r-hFSH-alfa biosimilars (4%). Over the study period, CLBR reached 20.5%; 21.9% with originator r-hFSH-alfa, 17.9% with HP-HMG, 21.3% with r-hFSH-beta and 18.4% with r-hFSH-alfa biosimilars. After adjusting for age, pre-treatment, GnRH analog, ovulation triggering, luteal phase support, previous COS, fresh or frozen ET and type of center, as possible cofounding variables, the adjusted hazard ratio (HR) for CLBR (delivery [originator r-hFSH-alfa as reference]) was 0.88 (95% CI 0.86 to 0.95, p<0.0001) with HP-HMG; 0.98 (95% CI 0.95 to 1.00, p=0.1020) with r-hFSH-beta, and 0.84 (95% CI 0.79 to 0.90, p<0.0001) with r-hFSH-alfa biosimilars. Although the mean acquisition cost of r-hFSH-alfa during the study was 33% higher than HP-HMG and 20% higher than r-hFSH-alfa biosimilars, the global ART management costs were only 4% higher than HP-HMG, 3% higher than r-hFSH-beta, and similar to r-hFSH-alfa biosimilars.
Limitations, reasons for caution: Patients were included only from oocyte pick-up, due to missing data in the SNDS database, meaning that it was not possible to estimate the proportion of cancelled cycles. Furthermore, as r-hFSH-alfa biosimilars were only available since 2015, results for biosimilars should be interpreted with caution.
Wider implications of the findings: This population-wide French study confirms other Real-World and meta-analysis evidence that CLBR is higher with originator r-hFSH-alfa than with HP-HMG or r-hFSH-alfa biosimilars, respectively, and are relevant for healthcare professionals to support gonadotropin treatment decision making. To further support this, the cost analysis should be completed by a cost-effectiveness analysis.
Trial registration number: Not applicable

O-114 Improved safety and efficiency of individualised versus conventional gonadotropin dosing for ovarian stimulation in IVF/ICSI: an individual patient meta-analysis (IPD-MA)

F. Janse[1], M. Eijkemans[2], B. Fauser[3]

[1]Nij Barrahus fertility clinic, reproductive medicine, Amstelveen, The Netherlands ;
[2]University Medical Center Utrecht, Julius Center- Biostatistics, Utrecht, The Netherlands ;
[3]University Medical Center Utrecht, Department of Obstetrics and Gynaecology, Utrecht, The Netherlands

Study question: Does an individualised, weight- and AMH-based dosing approach with follitropin delta improve live birth rate, safety, and efficiency, compared to conventional dosing in IVF/ICSI?
Summary answer: Individualised ovarian stimulation performs similarly for live birth rate (increased in normal-high AMH), and reduces the incidence of OHSS and total FSH dosage.
What is known already: Previous studies investigated the effect of individualized gonadotropin dosing in IVF/ICSI using ovarian reserve tests such as anti-Müllerian hormone (AMH) and antral follicle count (AFC). A Cochrane Review concluded that individualised dosing in IVF is associated with a reduction of ovarian hyperstimulation syndrome (OHSS), but no effect on live birth rate. It is hypothesized that an individualised dosing approach is predominantly beneficial in the patients who are potentially normal or high responders. This study addresses the performance of a new human recombinant FSH (follitropin delta) with individualised dosing based on AMH and body weight.

Study design, size, duration: This is an individual participant data meta-analysis (IPD-MA) of three follitropin delta phase 3 trials, executed in Europe and North- and South America, South-East Asia, and Japan. All trials were randomized, controlled, assessor-blinded, multicenter studies in which individualised follitropin delta vs. conventional follitropin alpha or beta were compared. Women were followed from inclusion, at start of their first fresh IVF/ICSI cycle, until 4 weeks after live birth.
Participants/materials, setting, methods: Women aged 20-40 yrs, undergoing their first IVF/ICSI cycle, were randomly assigned to follitropin delta (AMH < 15 pmol/L: 12 µg/day; AMH ≥ 15 pmol/L: 0.10-0.19 µg/kg/day: maximum 12 µg/day) or conventional follitropin alpha or beta (150 IU/day for 5 days, possible subsequent dose adjustments). The IPD-MA was performed using logistic regression analysis. Planned subgroup analyses were performed for expected normal/ high responders (serum AMH ≥15 pmol/L), and expected low responders (serum AMH <15 pmol/L).
Main results and the role of chance: Nearly 2,700 women were randomised and exposed: n = 1,348 for conventional dosing regimen with follitropin alpha or beta, and n = 1,334 for individualised dosing with follitropin delta. Live birth rate was similar for both groups (29.5% in follitropin delta vs. 26.9% in follitropin alpha/beta; OR 1.14 (0.96-1.35)). However, in expected normal to high responders live birth rate was significantly increased for those receiving individualised follitropin delta (31.4% vs. 25.9%; OR 1.31 (1.06 - 1.62)). Mean number of transferred embryos/blastocysts was comparable (0.95 vs. 0.94, respectively; mean difference 0.0076; NS), and did not differ when subgroup analyses were performed for normal/high AMH and low AMH. The occurrence of early OHSS was significantly reduced in individualised follitropin delta (4.0% vs. 6.4%; OR 0.62 (95% CI 0.43-0.88)), in subgroup analyses a similar reduction was identified. Total dosage of FSH was significantly lower in individualized follitropin delta (84.5 vs. 112.1 µg; mean difference -27.5 µg (95% CI -30.0 - -25.1)), with a more pronounced effect in normal to high AMH (mean difference -36.5 µg (95% CI -39.2 - -33.7)). Gestational age and birth weight were similar. The IPD-MA identified similar findings among women from the three studies with their different ethnic backgrounds.
Limitations, reasons for caution: For individualised dosing with follitropin delta, it was observed that the number of cryopreserved embryos was significantly lower (2.4 vs. 3.0, mean difference -0.67 ($p < 0.05$)), and it remains unclear whether this affects cumulative live birth rate.
Wider implications of the findings: Individualised dosing with gonadotropin delta is similarly successful in terms of live birth (increased for normal-high AMH women), reduces safety risks, and is more effective with regard to gonadotropin dosage, compared with conventional dosing in IVF/ICSI. Treatment costs are reduced by prescription of lower gonadotropin doses and OHSS reduction.
Trial registration number: NCT01956110, NCT03228680, NCT03296527

Study question: Do whole-exome sequencing (WES) data from infertile women provide valuable information for the discovery of genes/pathways involved in extreme IVF phenotypes, i.e. oocyte/embryo developmental arrest?
Summary answer: The development of a specific bioinformatic WES pipeline revealed known and new candidate genes/pathways for isolated oocyte/embryo developmental failure,providing the foundation to scale up research.
What is known already: The use of *IVF* has made it possible to identify extreme and isolated infertility phenotypes such as recurrent low oocytes maturity (LMR), recurrent low fertilization rate (LFR), or preimplantation developmental arrest (PDA) that would remain concealed in natural conception attempts. Recent applications of WES in families with such extreme adverse IVF phenotypes have led to the discovery of new genes and pathways affecting unique functions of gametes and exclusive mechanisms necessary for early embryo development. Here, we apply a tailored bioinformatic approach to WES from women displaying extreme IVF phenotypes to discover new causative genes/pathways involved in unexplained infertility.
Study design, size, duration: Twenty-two infertile consanguineous women(December 2018-September 2020) suffering from long-term unexplained infertility. Eight cases were classified as PDA (<20% normally developed embryos in >2 IVF cycles), 8 as LMR (<20% mature oocytes in >2 IVF cycles), 4 as LFR (<20% of normally fertilized oocytes in >2 IVF cycles). Two women with recurrent IVF failure (>10 IVF cycles) were also included. A control set of 1660 WES from oocyte donors was used to control for false-positive discoveries.
Participants/materials, setting, methods: WES at 30X was performed on enrolled women's gDNA using Illumina short-reads technology. Following annotation, variants were filtered to prioritize putative detrimental variants in genes relevant for oocyte/embryonic development using a previously developed and validated pipeline that minimizes false-positive discoveries. Runs of homozygosity (ROH) within each sample were identified using Refined IBD software. Individual-level single-cell RNAseq (scRNAseq) dataset from 18 human oocytes was used to verify the expression of the identified target genes.
Main results and the role of chance: The variant prioritization pipeline employed identified 1,160 unique variants in 1,017 genes (average per sample 59.9 sd 8.5). 453 variants were private to this study compared to the 1000 Genomes and gnomAD databases, 3% affecting splicing and/or the gene product length. Significant 5-fold enrichment of 41 genes involved in DNA-damage and repair pathways commonly associated with ovarian function/oocyte quality was observed ($p<0.001$). TP53/AKT pathway also showed significant 5-fold enrichment for 45 genes ($p<0.001$). This finding is consistent with the known relationship between infertility and cell-cycle/cancer genes. Overall, 66.4% (675/1,017; 95%CI:63.4-69.3) of the targeted genes were expressed in MII human oocytes. Two women (9%) were homozygous carriers of missense pathogenic variants in known candidate genes previously associated to oocyte/embryo developmental arrest (TRIP13, chr5_901344_C/T, CADD percentile 0.999; PADI6, chr1_17394384_C/G, CADD percentile 0.999). Remarkably, four additional women were carriers of high-impact variants in JAKMIP1, a member of a recently characterized family of proteins involved in various cellular processes, including cytoskeleton rearrangement, cell polarization, and intracellular transport. High-impact JAKMP1 variants were never observed in the oocyte donor control dataset. JAKMIP1 mRNA was detected in each individual biological replicate of scRNAseq analysis of MII oocytes with a mean of 6 transcripts per million.
Limitations, reasons for caution: Functional analysis is ongoing to validate the newly identified genes, data need to be verified in different ethnicities. Nevertheless, this study demonstrates the establishment of a specific and scalable analytical framework that can be employed for the identification of genetic causes in unexplained infertility cases characterized by defective developmental patterns.
Wider implications of the findings: Scaling up this investigative approach would provide an effective strategy for discovering new genes/pathways in what is considered idiopathic infertility, further defining precision reproductive medicine interventions. Importantly, this study revealed lesions in genetic patterns involved in chronic diseases providing a molecular footprint of the well-established link between infertility and comorbidities.

O-116 Genetic association analyses identify links between pelvic prolapse (PP) and connective tissue biology, cardiovascular and reproductive health.

N. Pujol Gualdo[1], K. Läll[1], M. Lepamets[1], R. Arffman[2], T. Piltonen[2], R. Mägi[1], T. Laisk[1]

[1]Estonian Genome Centre- Institute of Genomics- University of Tartu, Bioinformatics group, Tartu, Estonia ;
[2]University of Oulu, PEDEGO Research Unit- Department of Obstetrics and Gynecology, Oulu, Finland

Study question: Can genome-wide association analysis unravel the biological underpinnings of PP and facilitate personalized risk assessment via genetic risk scores construction?
Summary answer: We unravel novel links with urogenital development and vascular health in PP and present polygenic risk score as a tool to stratify PP risk.
What is known already: Prolapse is characterized by a descent of the pelvic organs into the vaginal cavity. PP affects around 40% of women after menopause and is the main indication for major gynecological surgery, having an important health, social and economic burden. Although the etiology and biological mechanisms underlying PP remain poorly understood, prior studies suggest genetic factors might play a role. Recently, a genome-wide association study (GWAS) identified seven genome-wide significant loci, located in or near genes involved in connective tissue metabolism and estrogen exposure in the etiology of PP.
Study design, size, duration: We conducted a three-stage case-control genome-wide association study. Firstly, in the discovery phase, we meta-analyzed Icelandic, UK Biobank and the FinnGen R3 datasets, comprising a total of 20118 cases and 427426 controls of European ancestry. For replication we used an independent dataset from Estonian Biobank (7968 cases and 118895 controls). Finally, we conducted a joint meta-analysis, containing 28086 cases and 546321 controls, which is the largest GWAS of PP to date.
Participants/materials, setting, methods: We performed functional annotation on genetic variants unraveled by GWAS and integrated these with expression quantitative trait loci and chromatin interaction data. In addition, we looked at enrichment of association signal on gene-set, tissue and cell type level and analyzed associations with other phenotypes both on genetic and phenotypic level. Colocalisation analyses were conducted to help pinpoint causal genes. We further constructed polygenic risk scores to explore options for personalized risk assessment and prevention.
Main results and the role of chance: In the discovery phase, we identified 18 genetic loci and 20 genetic variants significantly associated with POP ($p<5\times10-8$) and 75% of the variants show nominal significance association ($p<0.05$) in the replication. Notably, the joint meta-analyses detected 20 genetic loci significantly associated with POP, from which 13 loci were novel. Novel genetic variants are located in or near genes involved in gestational duration and preterm birth (rs2687728 p=2.19x10-9, *EEFSEC*), cardiovascular health and pregnancy success (rs1247943 p=5.83x10-18, *KLF13*), endometriosis (rs12325192 p=3.72x10-18, *CRISPLD2*), urogenital tract development (rs7126322, p=4.35x10-15, *WT1* and rs42400, p=4.8x10-10, *ADAMTS16*) and regulation of the oxytocin receptor (rs2267372, p=4.49x10-13, *MAFF*). Further analyses demonstrated that POP GWAS signals colocalise with several eQTLS (including *EEFSEC, MAFF, KLF13*, etc.), providing further evidence for mapping associated genes. Tissue and cell enrichment analyses underlined the role of the urogenital system, muscle cells, myocytes and adipocytes ($p< 0.00001$, FDR<0.05). Furthermore, genetic correlation analyses supported a shared genetic background with gastrointestinal disorders, joint and musculoskeletal disorders and cardiovascular disease. Polygenic risk scores analyses included a total of 125551 people in the target dataset, with 5379 prevalent patients and 2517 incident patients. Analyzing the best GRS as a quintile showed association with incident disease (Harrell c-statistic= 0.603, SD=0.006).
Limitations, reasons for caution: This GWAS meta-analyses focused on European ancestry populations, which challenges the generalizability of GWAS findings to non-European populations. Moreover, this study included women with PP from population-based biobanks identified using the ICD-10 code N81, which limits analyses considering different disease stages and severity.
Wider implications of the findings: Our study provides genetic evidence to improve the current understanding of PP pathogenesis and serves as basis for further functional studies. Moreover, we provide a genetic tool for personalized risk stratification, which could help prevent PP development and improve the quality of a vast quantity of women.
Trial registration number: not applicable

O-117 Prevalence of Fragile X Mental Retardation 1 premutation (FMR1) in young infertile women with diminished ovarian reserve. Implications in clinical practice.

A. Borras Capo[1], I. Agustí[1], S. Peralta[1], Y. Barral[1], A. Goday[1], M. Guimerà[2], L. Rodriguez- Revenga[3], D. Manau[4], F. Carmona[5]

Study question: Are young infertile patients with diminished ovarian reserve (DOR) elegible to perform the FMR1 premutation study?
Summary answer: Study of the *FMR1* premutation should be considered in infertile young patients with DOR in order to give them an adequate genetic counselling.
What is known already: *FMR1* gene may have some reproductive implications. Most notable is that FMR1 premutation expansions are associated with premature ovarian insufficiency (POI), diagnosed by amenorrhea or oligomenorrhea and FSH hormonal levels >25U/L before 40 years old. Presence of FMR1 premutation implies a risk of develop POI up to 24% and having an offspring with fragile X syndrome.

The frequency of *FMR1* premutation in general population is estimated in 0.3-0.7%. The role of *FMR1* premutation expansions in diminished ovarian reserve (DOR) patients is not clearly established and could be considered as a previous step to POI that may be related to sterility.
Study design, size, duration: Retrospective review of the *FMR1* gene study requested in patients of an Assisted Reproduction Unit of a tertiary Hospital in Barcelone from January-2016 to December-2019. A total of 307 cases were evaluated to determine the number of CGG repeat and AGG interruptions to assess the *FMR1* gene status.
Participants/materials, setting, methods: A total of 307 samples were assessed. Clinical and reproductive data were collected.

The *FMR1* status was requested on patients who present: a) POI (n=60); b) Family history of the FMR1 mutation (n=11); c) Infertile normo-ovulatory and young (≤35 years old) women with DOR defined as antral follicle count (AFC) < 7 and antimüllerian hormone <0.8ng/ml (n=71); d) Miscellaneous (n=29)

FMR1 was studied in 136 oocyte donors (screened by protocol), this was considered control group.
Main results and the role of chance: Mean age (±SD) of infertile DOR group was 32.7 +/- 2.1 years old (range 26-35) and showed altered ovarian reserve markers: AMH 0.43 ng/ml (SD ± 0.28) and AFC 4.27 (SD ± 2.1) follicles. In this group, 4 *FMR1* premutation cases were found.

Mean age (±SD) in control group was 26.28 +/- 5.2 years old and presented normal AMH and AFC values. One *FRM1* premutation carrier was detected among 136 patients, prevalence comparable to the non-sterile population.

The prevalence of FRM1 premutation was significantly higher in the DOR infertile group 5,6% vs 0,73% in the donors' group (p=0.02). Significant differences were observed also in terms of age and ovarian reserve markers between both groups.

Very few cases of POI patients or family history of Fragile X Syndrome have been evaluated, due to the fact we are not a reference of these kind of patients.

Among patients with a family history, 1 case from 11 (9.1%) was detected. In the POI group, three cases of premutation out of 60 (5%) were found.
Limitations, reasons for caution: This is a retrospective study with limited determinations of FMR1 studies. Donor screening and young infertile patients with significant low ovarian reserve are the main indications to request FMR1 status gene, so may lead to a selection bias.
Wider implications of the findings: These results should be confirmed prospectively in a higher population of infertile young patients with DOR, in order to identify the profile of infertile patient with diminished ovarian reserve who are elegible to perfom FMR1 gene premutation to give them an adequate clinical and genetic counselling.
Trial registration number: not apllicable

O-118 New insight into the genetic contribution of common variants to the development of extreme phenotypes of unexplained male infertility: a multicenter genome-wide association study

Study question: What is the contribution of the common genetic variation to the development of unexplained male infertility due to severe spermatogenic failure (SPGF)?
Summary answer: Genetic polymorphisms of key immune and spermatogenesis loci are involved in the etiology of the most severe SPGF cases, defined by Sertoli cell-only (SCO) phenotype.
What is known already: Male infertility is a rising worldwide concern that affects millions of couples. Non-obstructive azoospermia (NOA) and severe oligospermia (SO) are two extreme manifestations characterized by SPGF. A genetic cause can be established in only around 20% of affected men, with the remaining cases being classified as otherwise unexplained. To date, the genome-wide association study (GWAS) strategy, although already successfully applied in several other complex traits and diseases, was less fruitful in studies that attempted to decipher the genetic component of unexplained SPGF, mainly due to both a lack of well-powered samples in different ancestries and limitations in study design.
Study design, size, duration: We designed a GWAS for unexplained male infertility due to SPGF including a total of 1,274 affected cases and 1,951 fertile controls from the Iberian Peninsula (Spain and Portugal) and Germany. Different biostatistics and bioinformatics approaches were used to evaluate the possible effect of single-nucleotide polymorphisms (SNPs) across the whole genome in the susceptibility to specific subtypes of unexplained SPGF.
Participants/materials, setting, methods: The case cohort comprised 502 SO and 772 NOA patients, who were subdivided according to histological phenotypes (SCO, maturation arrest, and hypospermatogenesis) and the outcome of testicular sperm extraction techniques (TESE) from testis biopsies. Genotyping was performed with the GSA platform (Illumina). After quality-control and genotype imputation, 6,539,982 SNPs remained for the analysis, which was performed by logistic regression models. The datasets went through a meta-analysis by the inverse variance weighted method under fixed effects.
Main results and the role of chance: Genetic associations with SCO at the genome-wide-level of significance were identified in the major histocompatibility (MHC) class II region (rs1136759, OR=1.80, P=1.32E-08) and in a regulatory region of chromosome 14 nearby the vaccinia-related kinase 1 (*VRK1*) gene (rs115054029, OR=3.14, P=4.37-08). VRK1 is a relevant proliferative factor for spermatogenesis that causes progressive loss of spermatogonia when disrupted in mouse models. The role of the MHC system in SCO susceptibility was comprehensively evaluated through a validated imputation method that infers classical MHC alleles and polymorphic amino acid positions. A serine at position 13 of the HLA-DRβ1 protein (defined by the risk allele of the lead variant rs1136759) explained most of the SCO association signals within the MHC class II region. This residue is located in the binding pocket of the HLA-DR molecule and interacts directly with the presented antigen. Interestingly, position 13 of HLA-DRβ1 is the most relevant risk amino acid position for a wide spectrum of immune-mediated disorders. The HLA-DRB1*13 haplotype (which includes the serine at position 13 and represents the strongest NOA-associated marker in Asians to date) was the strongest signal amongst the classical MHC alleles in our study cohort (OR=1.93, P=9.90E-07).
Limitations, reasons for caution: Although the statistical power for the overall analysis was appropriate, the subphenotype analyses performed had considerably lower counts, which may influence the identification of genetic variants conferring low to moderate risk effects. Independent studies in larger SCO study cohorts should be performed to confirm our findings.
Wider implications of the findings: The molecular mechanisms underlying unexplained SPGF are largely unknown. Our data suggest a relevant role of common genetic variation in the development of SCO, the most extreme histological phenotype of NOA. SCO is characterized by the loss of germ cells and, therefore, implies a considerably higher probability of unsuccessful TESE.
Trial registration number: N/A

O-119 Evaluating the reproductive potential of azoospermic men by germline mutation profiling

S. Cheung[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can whole exome sequencing (WES) of spermatozoa from azoospermic men identify mutations related to the etiology of their infertility and ability to support a pregnancy?
Summary answer: Key de novo germline mutations that affect sperm production and/or embryo developmental competence may explain reproductive failure in azoospermic men, regardless of the etiology.
What is known already: Azoospermia accounts for approximately 15% of male factor infertility cases. Although it can be caused by pre-testicular factors, the most recognized forms are testicular and post-testicular. While post-testicular azoospermia is mainly due to a mechanical obstruction, testicular azoospermia, the most severe form, is characterized by scattered functional germinal epithelia that strive to support the meiotic process during gamete development. To shed light on the etiology of this condition, genetic studies have been performed, albeit exclusively on peripheral blood. We chose to perform a genomic assessment of spermatozoa to preferentially detect germline mutations that may be passed to the progeny.
Study design, size, duration: In a 2-year period, we recruited infertile men undergoing epididymal aspiration for acquired obstructive azoospermia (OA; n=19) or testicular retrieval for nonobstructive azoospermia (NOA; n=10). Four additional men were included as fertile controls. Following WES, copy number variants (CNVs) and gene mutation profiles were compared between

the OA and NOA patients, and within those two categories, in relation to whether they generated a clinical pregnancy (fertile) or not (infertile).

Participants/materials, setting, methods: Spermatozoal DNA was extracted and amplified from the surgically retrieved specimens of consenting men (DNA concentration, 762±492 ng/ul; quality, 1.7±0.1 nm). CNVs, gene mutations, duplications, and deletions were detected using the CLC Genomic Server 9.0. Genes were considered duplicated or deleted when the read depth was >1.5 or <0.5 times the median read depth in the control. Common mutations in the OA and NOA cohorts were assessed according to the couples' clinical outcome.

Main results and the role of chance: Of 29 couples (maternal age, 41.9±7yrs; paternal age, 42.5±7yrs), 19 OA men underwent epididymal sperm retrieval (1.1±4x10^6/ml concentration, 9±12% motility) while 10 NOA men underwent testicular biopsy (0.03±0.2x10^6/ml concentration, 0.5±1% motility). WES did not reveal a significant difference in sperm aneuploidy between the two etiologies (OA, 1.8%; NOA, 1.9%).

In OA patients, only 3 genes were deleted, mainly housekeeping-related, while in the NOA cohort, 5 genes were deleted, involved in RNA transcription (POLR2L) and apoptosis (AP5M1), in addition to spermiogenic functions (AP1S2, AP1G2, APOE).

OA patients and their partners (maternal age, 36.8±4yrs) underwent 19 ICSI cycles that resulted in a pregnancy and delivery rate of 47.4% (9/19). Those able to reproduce (n=9) shared a mutation in ZNF749, a gene affecting only sperm production. The infertile individuals (n=10) all had a deletion on PRB1, controlling essential DNA replication.

NOA men and their partners (maternal age, 38.2±2yrs) underwent 10 ICSI cycles, yielding a clinical pregnancy rate of 70% (7/10). The fertile men (n=7) had a concurrent gene deletion involved in stem cell lineage differentiation (MPIG6B). Their infertile counterparts (n=3) had deleted genes involved in spermato/spermio-genesis (n=6) and, most importantly, in early embryonic development (MBD5, CCAR1, PMEPA1, POLK, REC9, REPIN1, MAPRE3, and ARL4C).

Limitations, reasons for caution: This is a novel study with limited observations. The presence of housekeeping-related mutations in fertile OA men as well as the DNA replication mutation in infertile OA patients, considering the acquired condition, remains puzzling. Although maternal age was controlled for, confounding factors related to the female partner cannot be excluded.

Wider implications of the findings: Screening men for germline mutations provides valuable information on their ability to reproduce, regardless of the etiology of azoospermia. Genome profiling was able to identify reasons for failed reproductive performance in azoospermic men, particularly those individuals with secretory azoospermia (NOA). Genomic profiling may identify gametes with retained embryo developmental competence.

Trial registration number: n/a

O-120 Unravelling reproductive failure by scrutinizing the male germline code

P. Chung[1], S. Cheung[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York- N.Y., U.S.A.

Study question: Can whole exome sequencing (WES) of spermatozoal DNA provide insight into understanding the different steps that lead to inability of a couple to reproduce?

Summary answer: The identification of germline mutations can clarify different aspects of reproductive failure in couples with unexplained infertility.

What is known already: The limitation of a routine semen analysis in evaluating sperm characteristics, even according to the most stringent criteria, lies in its inability to provide substantial information on spermatozoa performance in ART. As a result, ancillary tests are being used to further assess the male gamete's reproductive potential. More recently, WES of the male genome, carried out on somatic cells, has become a powerful technique that can potentially shed light on the genetic causes of infertility. Here, we aim to preferentially detect germline mutations by sequencing spermatozoal DNA to pinpoint genes related to different underlying etiologies for reproductive failure.

Study design, size, duration: In a 5-year period, 25 couples subdivided according to their ICSI outcomes were included in this study. Sperm aneuploidy assessment by fluorescent in situ hybridization (FISH) and copy number variant (CNV) analysis by WES were carried out on ejaculated specimens from consenting male partners. Following CNV analysis, gene mutation profiles were compared between the fertile (n=10) and infertile cohorts (n=15), as well as in relation to the reasons for reproductive failure.

Participants/materials, setting, methods: FISH was performed on at least 1,000 sperm cells with a threshold of >1.6%. DNA was extracted and amplified from at least 500 spermatozoa (DNA concentration, 605±137 ng/ul; quality, 1.7±0.1 nm) for CNV analysis by WES. Mutations corresponding to the CNV were annotated and assessed using the CLC Genomic Server 9.0. Genes were considered duplicated or deleted when their read depth was >1.5 or <0.5 times the median read depth in the control.

Main results and the role of chance: Couples (n=25) (maternal age, 38.6±3yrs; paternal age, 39.7±5yrs) had normal somatic karyotypes with normal semen parameters (59.2±30x10^6/mL concentration, 44.8±18% motility) by WHO standards.

The fertile (n=10) cohort underwent 12 ICSI cycles, achieving an 82.6% (57/69) fertilization rate and 10/12 (83.3%) term pregnancies. The infertile cohort (n=15) underwent 21 ICSI cycles, achieving a 66% (62/84) fertilization rate and 5/17 (29.4%) clinical pregnancies, all resulting in pregnancy loss.

Sperm aneuploidy was consistently higher in the infertile (8.4%) versus fertile (4.0%) cohort (P<0.00001), as observed by FISH and DNA sequencing.

For both cohorts, WES detected deletions responsible for sperm–egg fusion (ADAM3A) and acrosomal development (SPACA, SPATA), explaining the necessity for ICSI in these couples.

The infertile cohort was characterized by 4 reasons for cycle failure: complete fertilization failure, poor embryo development, implantation failure, and pregnancy loss. Couples with complete fertilization failure (n=4) had deletions (PLCZ1, PIWIL1) indicating a sperm-related oocyte-activating deficiency. Those with poor embryo development (n=5) had mutations (HAUS1, KIF4A, XRN1) essential for centrosome integrity and spindle/microtubular stabilization. Couples who did not achieve pregnancy (n=7) had a mutation (IL9R) in common related to cytokine constituents in the implantation pathway. Those with pregnancy losses (n=5) had mutations (NLRP7, TP53) on post-implantation genes.

Limitations, reasons for caution: Several germline mutations, related to the different reasons for these couples' reproductive failure, were identified. Although intriguing, these findings are still new and need to be validated in a larger study population. In addition, while maternal age was controlled for, we cannot definitively exclude other confounding female factors.

Wider implications of the findings: Additional screening methods for infertile couples, particularly those with unexplained infertility, can be used to clarify elusive factors underlying their reproductive ability. A genetic screening of spermatozoal DNA may therefore be considered a potential tool in precision medicine for the treatment of subtle male factor infertility.

INVITED SESSION

SESSION 29: THE ENIGMA OF ECTOPIC PREGNANCY

29 June 2021 Stream 1 11:45 - 12:45

O-031 Importance of blood flow to human implantation

P. Pierzynski[1]

[1]Oviklinika Warszawa, Oviklinika Warszawa, Warszawa, Poland

Abstract text

The success of embryo implantation depends on a plethora of factors, with embryo quality and endometrial receptivity belonging to the most important ones. The receptive phenotype of endometrium develops in reaction to appropriate estrogen stimulation in the proliferative phase and embryo-synchronized maturation warranted by the action of progesterone. Uterine blood supply, myometrial contractions and the activity of local immune cells also belong to important factors affecting the outcome of both natural and assisted reproduction. Endometrial perfusion was shown to be an independent receptivity parameter, showing a

direct association with pregnancy outcomes. Historically, the use of Doppler parameters of uterine vessels was studied as a reflection of blood flow to the endometrium. Although some authors showed a correlation between blood flow in uterine arteries and success rates in IVF cycles, it might not reflect the actual endometrial flow as most of the blood volume goes through myometrium, not endometrium. Currently, using available ultrasound tools – 2D/3D Power Doppler with VOCAL (Virtual Organ Computer-Aided Analysis) software enables clinicians to evaluate parameters of endometrial perfusion in a matter of minutes. In this method, ultrasound system can calculate indices reflecting endometrial blood flow - vascularity index (VI), endometrial flow index (FI), and endometrial vascularity flow index (VFI) which are based on the total and relative amounts of Power Doppler signal (corresponding to the blood flow) within the volume of interest. Endometrial blood flow parameters can be altered in implantation limiting conditions such as endometriosis or chronic intrauterine inflammation. It was also shown to be influenced by implantation-related hormones such as oxytocin.

Oxytocin receptor antagonists were shown to decrease uterine contractions in non-pregnant uteri of women being prepared for embryo transfer procedure. This class of medications has been extensively studied as potential candidates for medications promoting embryo implantation in IVF-ET treatments. In several studies, it was shown that mixed oxytocin/vasopressin V1A receptor antagonist atosiban, which is currently registered in Europe for the tocolysis in preterm labour, had the potential of improving implantation rates. Interestingly, this effect was confirmed also in women without pronounced contractions. Additionally, it has been demonstrated that oxytocin antagonism enhances endometrial decidualization and influences other parameters necessary for the acquisition of the endometrial receptivity phenotype. Considering that atosiban and other oxytocin antagonists relax uterine blood vessels and increase endometrial blood flow, it was hypothesized that improvement in endometrial perfusion could be an additional mechanism for observed support of embryo implantation.

A similar finding was confirmed in our study on nolasiban – a non-peptide, orally active, oxytocin receptor-specific antagonist. In the 1st phase study on volunteers undergoing estrogen/progesterone endometrial preparation reflecting the synchronization for embryo transfer, it was confirmed that application of nolasiban decreased uterine contractions and improved FI and VFI parameters of endometrial perfusion. Such an effect lasted for more than 24 hours after dosing. The study results suggested that oxytocin antagonism could have an effect on endometrial perfusion, and its potential clinical significance requires further investigation. In a longer perspective, once confirmed it would mean that, apart from the possibility of observation of endometrial blood flow, we could have a tool for improving it, which would hopefully lead to improved outcomes of assisted reproduction treatments.

O-033 Where ethics hits the patients needs - Case germany

K. Kordic[1]

[1]*RODA - roditelji u Akciji Parents in Action NGO, Association/NGO Infertility // MAR section, ZAGREB, Croatia*

Abstract text

The German Embryo Protection Act was passed in 1990 and has never been changed since, other than minor changes in 2011 regarding PGD.

Germany is a country with 83 million inhabitants, where more than 6 million people of reproductive age are facing infertility or difficulties conceiving and delivering a healthy child. Germany also has the oldest and arguably most restrictive law regulating reproductive medicine, especially IVF. By passing a law with such an imposing title and starting the act with a list of prohibitions, 31 years ago German legislators made their intentions very clear: to protect the embryo rather than to help infertile people to become parents using assisted reproductive technology.

Since reproductive medicine has developed tremendously in the last 30 years and since the number of people in need of medical assistance to have a child is constantly growing,Germany now is not only far behind other European countries with its legislation but also seems to be against its patients and citizens in need of the assistance of modern medicine to have children.

How can we change an inappropriate and archaic law? How can we create a modern law which suits patients' needs without compromising ethics?

How can reproductive medicine in Germany come back on track again and serve the people by evidence based medicine in the first place?I

O-034 Infertility treatment law making in Europe: the clash of knowledge, ethics and business

A. Wilinska-Zelek[1]

[1]*Fertility Europe, Our Stork Association, Warszawa, Poland*

Abstract text

Infertility treatment law making in Europe: the clash of knowledge, ethics and business

Today, there is no common European set of rules for Assisted Reproduction Technology (ART). ART is now controlled by legislation in almost all European countries, substantial variations exist within the detail of that legislation.

Main legal differences between countries relate to: embryo selection, particularly by genetic screening, embryo freezing and embryo transfer, preimplantation genetic diagnosis (PGD), oocyte donation, anonymity of gamete donors, surrogacy, patient eligibility criteria (eg, sexual orientation, age), reimbursement and state funding.

The most complete survey ever of the ART legal and funding framework of 43 European countries was published in the ESHRE medical journal Human Reproduction Open: Calhaz-Jorge C, De Geyter C, Kupka MS, et al. Survey on ART and IUI: Legislation, regulation, funding and registries in European countries. Hum Reprod Open 2020; doi:10.1093/hropen/hoz044.

Unfortunately, changes of legislation are so dynamic that much of the information in this article is no longer up-to-date.

Lawyers observe that one of the most important rule of law "When the Law ceases to reflect the realities of Life, it is the Law that will Change" does not work in ART. In regard to this matter dominant rule is: "The Law will change only when it ceases to reflect the government's point of view and lobbyists' needs". Modern medical knowledge and the society's needs are often not the main concern during the law making discussion.

The speech discusses the issues related to infertility treatment law making in Europe with a focus of the problem that modern medical knowledge in this process is not taken into account at all. The author diagnoses numerous problem related to determining the border between medical knowledge, ethics and business in law making process.

The observed problems will be discussed on selected examples (from Poland, Greece and the United Kingdom) during presentation at the ESHRE on-line 37th Annual Meeting.

O-035 Searching for the perfect country - mapping out differences in fertility treatments and access to treatments across europe

K. Bye[1]

[1]*Ønskebarn, Norway, Bekkestua, Norway*

Abstract text

Fertility Europe has established a working group that is examining secondary data on legislation, regulation and funding of fertility treatment across Europe. The data has been mapped in order to easily visualize the "perfect country" in terms of fertility treatments[Vi1] . The map will be updated every two years in order to show progress towards more countries reaching the status of "perfect country". As the map provides a clear picture on the differences in access to treatments[Vi2] across Europe, it is expected to be a useful advocacy tool for

patient[Vi3] associations working to influence the current treatment situation in their country. This talk focuses on the work that has been done by the Fertility Europe working group to date, to create the map of the "perfect country", and the possibilities that such a map represents from a patient advocacy perspective.

O-037 The impact of COVID-19 on male fertility: what do we know?"

A. Pacey[1]

[1]*University of Sheffield, Oncology and Metabolism, Sheffield, United Kingdom*

Abstract text

Since the very early days of the COVID-19 pandemic, concern has been raised about the possibility of damage to the male reproductive system in those men who are infected with SARS-CoV-2. This was first raised by the early observation (January 2020) that the route of infection was via the Angiotensin Converting Enzyme 2 (ACE-2) receptor present on host cells. ACE-2 was first described in the year 2000 and subsequently shown in 2004 to be selectively expressed in the Leydig cells of the adult testis. This opens up the possibility that although COVID-19 is primarily a respiratory infection, it may also infect the male reproductive system. The authors of several review articles have proposed that male fertility may be theoretically impacted by SARS-CoV-2 in a number of ways. This includes alteration of: (i) testicular architecture; (ii) reproductive hormone profiles (LH/FSH); (iii) spermatogenesis as evidenced by changes to ejaculate quality; (iv) sperm function (e.g., DNA damage); (v) sexual/erectile function; or a combination of all five. Clearly each of these individually may impact on the chance of pregnancy or live birth either in natural or medically assisted reproduction. There is also the possibility that SARS-CoV-2 may be transmitted sexually if sufficient numbers of SARS-CoV-2 are found in semen. Reassuringly, of 14 studies published to date, there is little evidence to suggest that SARS-CoV-2 is present in semen and so the possibility of sexual transmission in patient or donor samples can probably be discounted. However, there is currently an incomplete picture of whether semen quality is affected by SARS-CoV-2 infection as studies are often limited by the fact that no pre-infection control samples are available for direct comparison or they are too short to identify any long-term effects. Nevertheless, the few case-controlled studies published which compare semen quality infected with non-infected (control) individuals suggest that there may be a statistically significant alteration in sperm concentration and motility, although it is not clear whether this is linked to infection by the SARS-CoV-2 virus or simply a consequence of febrile illness and fever (or medication given to combat the infection). There is currently a lack of long-term data on any impact of COVID-19 on male reproductive hormones (although much speculation about the role that testosterone might play in the severity of disease). There are also emerging reports of increased risk of erectile dysfunction in men following SARS-CoV-2. In terms of birth rates, it is simply too early to tell whether these have been affected by the pandemic, given the possibility of lockdown affecting sexual behaviour in fertile couples and IVF clinic closures in infertile couples. In conclusion, although the COVID-19 pandemic has infected over 130 million people worldwide we still know too little about the impact of SARS-CoV-2 on the male reproductive system. Given the incidence of long-COVID, and the asymptomatic nature of the infection for some, it is important to commission and conduct long-term studies which can monitor the reproductive outcomes of young men who have survived a SARS-CoV-2 infection.

O-039 Mitochondrial ATP generation in mammalian eggs and Ca2+ signalling

K. Swann[1]

[1]*Cardiff University, Dept. of Obstetrics and Gynaecology, Cardiff- Wales, United Kingdom*

Abstract text

In metaphase II arrested mammalian oocytes (eggs) and cleavage stage embryos the mitochondria are responsible for nearly all ATP production because glycolysis is inactivated. Luciferase assays show that ATP levels in eggs are strictly dependent upon pyruvate and fatty acid oxidation. The level of ATP in eggs appears to be maximal in conventional medium because the addition of extra mitochondrial substrates to eggs does not increase cytosolic ATP. The only clear elevation of ATP is seen at fertilization and is associated with sperm induced Ca2+ oscillations. Our recent findings suggest that the level of ATP modulates events at fertilization.

At fertilization, the egg is activated by sperm derived PLCzeta which triggers a series of Ca2+ oscillations, with each Ca2+ release event causes by inositol trisphosphate (InsP3). Previous studies have shown that mouse eggs are more sensitive to PLCzeta, and generate higher frequency Ca2+ oscillations, than human eggs. Mouse eggs also generate Ca2+ oscillations and activate in response to Sr2+ that directly stimulates InsP3 receptors. In contrast, human eggs that contain the same type of InsP3 receptors do not generate Ca2+ oscillations in response to Sr2+.

The difference in sensitivity of Ca2+ release between species can be explained by the fact that mouse eggs are about ten times more sensitive to InsP3 than human eggs. The reason for this difference appears to be due to ATP. The ATP level in unfertilized mouse eggs is about twice that in human eggs. Furthermore, the ability of mouse eggs to Sr2+ medium can be abolished by removing the mitochondrial substrate pyruvate, which reduces the ATP level. Adding back pyruvate to such eggs restores ATP levels promotes Sr2+ induced Ca2+ levels in mouse eggs. These data suggest that the level of ATP, possibly as ATP4-, modulates the sensitivity of the InsP3 receptor and the ability of eggs to generate Ca2+ oscillations. The level of cytosolic ATP may represent a significant 'egg factor' in determining the success of fertilization in humans. Enhancing mitochondrial ATP production could be useful in improving activation and embryo development after fertilization, or after artificial egg activation.

SESSION 33: SEMEN ANALYSIS 2021: FROM THE ANCIENT TO THE MODERN TIMES?

29 June 2021 Stream 2 14:00 - 15:00

O-040 The evolution of WHO Manual. Where are we now?

S. Esteves[1,2,3]

[1]*ANDROFERT, Andrology & Human Reproduction Clinic, Campinas, Brazil ;* [2]*Faculty of Health, Department of Clinical Medicine- Aarhus University, Aarhus, Denmark ;* [3]*Faculty of Medical Sciences- University of Campinas UNICAMP, Department of Surgery Division of Urology, Campinas, Brazil*

Abstract text

Male factor infertility is associated with impaired overall health, decreased life expectancy, lower quality of life and may affect reproductive outcomes even under assisted reproductive technology (ART) settings. Male factors, alone or combined with female factors, contribute to at least 50% of reported infertility cases. Despite this, the male partner is often overlooked in the evaluation and treatment of infertility. A routine semen analysis is frequently the only test carried out to assess a man's fertility potential.

The state-of-art on how the human semen should be assessed is provided by the World Health Organization (WHO), which periodically releases manuals that include specific protocols and reference standards. These manuals include detailed laboratory methods for semen examination, protocols for sperm preparation and cryopreservation, quality assurance and quality control, results' interpretation, and reference ranges. Unlike the previous four versions, the latest 2010 WHO reference values relied on clinical chemistry principles to generate 95% intervals for sperm volume, count, motility, vitality, and morphology from recent fathers. The fifth centile was deemed suitable for representing semen characteristics at lower limits. The reference values ultimately obtained were markedly lower than those previously reported, raising concerns about its clinical utility and generalizability. Criticisms included the limited geographical area of patients analyzed, the methods used for semen evaluation, and the potential impact of the new reference range on patient referral, diagnosis, and treatment guidance. An updated new WHO manual (6th edition) is about to be released with much expectation.

Although semen analysis remains one of the cornerstones of the infertility evaluation, a male infertility workup primarily based on routine semen analysis does not provide men with an optimal fertility pathway for many reasons. First, reference intervals do not reliably distinguish fertile from subfertile subjects. Second, an individual patient's results have limited prognostic value for both natural and assisted conception unless at extreme lower limits. Third, there is a wide variation in how laboratories perform a semen analysis. Lastly, routine semen analysis does not detect sperm DNA defects that might adversely impact embryo development, implantation, and offspring's health.

Guidelines issued by professional societies recommend that a full andrological assessment be performed in all men with couple infertility. Well-trained reproductive urologists or clinical andrologists should perform the male evaluation, including a detailed history, physical examination, semen analysis, endocrine assessment, and other tests as needed. Therefore, the importance of WHO manuals remains critical. However, the goals of a comprehensive male infertility workup go beyond the laboratory assessment of human semen. It comprises i. *Diagnosis*, i.e., detection of any underlying relevant medical or lifestyle conditions potentially impairing the (reproductive) health of the male or his offspring; ii. *Counselling*, particularly regarding the impact of infertility, genetic factors, age, and lifestyle on pregnancy prospects, reproductive and overall health, and offspring's well-being; and iii. *Management Guidance*, i.e., identifying optimal treatment options to improve the likelihood of achieving natural pregnancy or ART success. The prevention and management of male infertility are integral components of comprehensive sexual and reproductive health services needed to attain a sustainable development goal.

O-041 Functional sperm diagnostics: The evidence behind commercially available tests

J. Hotaling[1]

[1]*University of Utah School of Medicine, Urology, Salt Lake City, U.S.A.*

Abstract text

Despite the fact that the semen analysis has remained the cornerstone of the male infertility evaluation for decades, it has significant limitations. Among them are the inability to completely predict reproductive potential and the inability to analyze the fitness of individual sperm. There remains a real need for novel tests that can determine which interventions for male infertility are the most likely to result in a significant improvement in reproductive potential, to analyze the chance of success or failure with ART and to determine if there exists a sub population of sperm whose use could lead to optimal chances of success with fertility treatments. In this talk we will cover what the limitations of the current semen analysis are, what novel tests are available and delve into the impact of future technologies such as microfluidics, machine learning and others to optimize the diagnostic armamentarium of male fertility assessment. We will also focus on tools that could, potentially, non-invasively image sperm and report reproductive fitness while maintaining viability for ART.

Study question: What are the reported data on cycles in ART, IUI and fertility preservation interventions in 2018 as compared to previous years, as well as the main trends over the years?

Summary answer: AUTHOR: The 22th ESHRE report on ART and IUI shows a progressive increase in reported treatment cycle numbers in Europe, a small decrease in the number of transfers (IVF + ICSI) with more than one embryo with a trend to decreasing multiple delivery rates, higher pregnancy and delivery rates after FER compared to fresh IVF and ICSI cycles, and outcomes for IUI cycles similar to previous years.

What is known already: Since 1997, ART aggregated data generated by national registries, clinics or professional societies have been collected, analysed by the European IVF-monitoring Consortium (EIM) and reported in 21 manuscripts published in Human Reproduction and Human Reproduction Open.

Study design, size, duration: Yearly collection of European medically assisted reproduction (MAR) data by EIM for ESHRE. The data on treatments performed between January 1 and December 31 2018 in 34 European countries were provided by either National Registries or registries based on personal initiatives of medical associations and scientific organisations.

Participants/materials, setting, methods: In all, 1004 clinics offering ART services in 34 countries reported a total of 827 545 treatment cycles, involving 132 332 with IVF, 342 589 with ICSI, 260 013 with frozen embryo replacement (FER), 44 854 with preimplantation genetic testing (PGT), 42 869 with egg donation (ED), 406 with IVM of oocytes and 4482 cycles with frozen oocyte replacement (FOR). European data on IUI using husband/partner's semen (IUI-H) and donor semen (IUI-D) were reported from 783 institutions offering IUI

in 24 and 20 countries, respectively. A total of 132 624 treatments with IUI-H and 43 140 treatments with IUI-D were included. A total of 12 609 fertility preservation (FP) interventions from 13 countries including oocyte, ovarian tissue, semen and testicular tissue banking in pre-and postpubertal patients were reported.
Main results and the role of chance: In total, 1004 IVF clinics participated (93.4% of registered clinics in the participating countries). Next to these also 783 IUI units reported their data. In the 34 reporting countries, after IVF the clinical pregnancy rates (PR) per aspiration and per transfer in 2018 were similar to those observed in 2017 (28.7% and 41.6% versus 29.4% and 39.0%, respectively). After ICSI the corresponding rates were also similar to those achieved in 2017 (26.3% en 40.9% versus 27.3% and 40.2%). After FER with own embryos the PR per thawing is still on the rise, from 30.2% in 2017 to 33.0% in 2018. After ED the PR per fresh embryo transfer was 49.8% (49.2% in 2017) and per FOR 39.6% (43.3% in 2017). In IVF and ICSI together, the trend towards the transfer of fewer embryos continues with the transfer of 1, 2, 3 and ≥4 embryos in 51.1%, 45.4%, 3.4% and 0.1% of all treatments, respectively (corresponding to 46.0%, 49.2%, 4.5% and 0.3% in 2017). This resulted in a proportion of singleton, twin and triplet DRs of 86.9%, 12.8% and 0.3%, respectively (compared to 85.5%, 14.2% and 0.3%, respectively in 2017). Treatments with FER in 2017 resulted in twin and triplet DR of 9.3% and 0.1%, respectively (versus 11.2% and 0.2% in 2017). After IUI, the DRs remained similar at 9.1% after IUI-H (8.9% in 2017) and at 12.3% after IUI-D (12.4% in 2017). Twin and triplet DRs after IUI-H were 8.4% and 0.3%, respectively (in 2017: 8.1% and 0.3%) and 6.7% and 0.2% after IUI-D (in 2017: 6.9% and 0.2%). The majority of FP interventions included the cryopreservation of ejaculated sperm (n=8 257 from 13 countries) and of oocytes (n=3230 from 13 countries).
Limitations, reasons for caution: As the methods of data collection and levels of completeness of reported data vary among European countries, the results should be interpreted with caution. For this abstract a number of countries was not able to provide adequate data about the number of centers and initiated cycles and deliveries.
Wider implications of the findings: The 22nd ESHRE report on ART and IUI shows a continuous increase of reported treatment numbers and MAR-derived livebirths in Europe. Being already the largest data collection on MAR in Europe, continuous efforts to stimulate data collection and reporting strive for future quality control and completeness of the data and offer higher transparency and vigilance in the field of reproductive medicine.

Abstract text
Objective: To analysis the Chinese ART data in 2018 to provide evidence for utilization of various ART.
Methods: The data of ART of 263 Reproductive Centers in the mainland of China in 2018 were collected by CSRM ART Data Reporting System. A cross-sectional survey of the use of ART technology was performed.
Results: In 2018, the CSRM data reporting system reported 105 610 AID/AIH cycles, 323 938 oocyte retrieval cycles, 147 129 fresh embryo transfer cycles, 254 012 frozen-thawed embryo transfer (FET) cycles, and 204 688 newborn . The patient's age was mainly concentrated in the group <35 years old, accounting for 63.75%. The pregnancy rate and live birth rate of retrieval cycles were 52.49% and 42.23% respectively. The pregnancy rate and live birth rate of FET cycles were 48.71% and 37.68% respectively. Among ART complications, the incidence of moderate to severe OHSS was 1.42%, 0.03% postoperative bleeding, 0.01% postoperative pelvic infection, and 0.04% the other complications. The incidence of birth defects of IVF was 0.87%.
Conclusions: This study uses "CSRM data reporting system" data to describe and analyze the current status of ART, basically consistent with the comparison in 2016 and 2017 that most cycles with good outcomes. However, no clear conclusions have been drawn on the changes of PGD/PGS cycle, all-freeze cycle and comprehensive analysis should be conducted by combining with laboratory data.

SESSION 35: MODELLING HUMAN REPRODUCTION: HOW FAR ARE WE?

29 June 2021 Stream 4 14:00 - 15:00

O-045 Synthetic human embryo-like structures: a new paradigm for human embryology

J. Fu[1]

[1]*University of Michigan- Ann Arbor, Mechanical Engineering- Biomedical Engineering- Cell and Developmental Biology, Ann Arbor, U.S.A.*

Abstract text
Early human development remains mysterious and very difficult to study. Recent advances in mammalian embryology, stem cell biology, organoid technology, and bioengineering have contributed to a significant interest in bottom-up, synthetic stem cell-derived models of human development (or embryoids). The controllability and reproducibility of human embryoids coupled with the ease of genetically modifying stem cell lines, the ability to manipulate culture conditions and the simplicity of live imaging make them robust and attractive systems to disentangle cellular behaviors and signaling interactions that drive human embryogenesis. In this talk, I will describe our effort in using human pluripotent stem cells (hPSCs) to develop tractable experimental models of the peri-implantation embryonic development and neurulation. The peri-implantation human embryoids developed by us recapitulate key early post-implantation developmental landmarks successively, including pro-amniotic cavity formation, amniotic ectoderm-epiblast patterning, primordial germ cell specification, and development of the primitive streak with controlled anteroposterior polarity. I will further discuss an hPSC-based neuroectoderm patterning model to recapitulate the formation of the neural plate and another patterned neural tube model with fully defined anterior-posterior and dorsal-ventral axes.

O-046 Implantation and beyond, the endometrial perspective

J. Aplin[1]

[1]*University of Manchester, Maternal and Fetal Health, Manchester, United Kingdom*

Abstract text
Early pregnancy failures are spread throughout the first few weeks, suggesting that impairment of normal biological processes can occur at sequential stages: epithelial attachment and breaching, early stromal and then decidual invasion, glandular and vascular invasion. Biopsy-based transcriptomics and proteomics have failed to demonstrate a reproducible or interpretable molecular signature for endometrial receptivity, but single cell RNAseq suggests a step change in the epithelial transcriptome in the mid secretory phase, consistent with the appearance of new cell phenotype(s). Previously unseen heterogeneity in both epithelial and stromal cell populations has become evident, but gene signatures have not yet achieved a level of resolution that allows insights clear enough to decode the biology of the receptive state. However, methodology for propagating and recombining endometrial cell populations into 3D engineered tissue models has advanced, so that new mechanistic questions can be asked. Initial acquisition of receptivity to implantation is followed by the development of a

supportive environment for embryos that possess the capacity to progress, with maternal cell populations (epithelial, stromal, immune and vascular) acting cooperatively within a remodelling extracellular matrix (ECM). A balance must be achieved in the ECM between breakdown, with opening of hydrated spaces to allow expansion of the embryonic sac while maintaining a substrate for stable physical attachment to allow invasion by extravillous trophoblast. The extent and nature of cellular trafficking to and from the uterus is important before and during early pregnancy. There is evidence that regulation of a resident senescent cell subpopulation by uterine NK cells occurs in concert with ECM remodelling to achieve a functionally supportive environment in the early first trimester. Access of bone marrow-derived cells to vessel walls is regulated by placental-endothelial signalling to initiate remodelling for the increased blood flow to the conceptus that is required in later pregnancy. Thus 'receptivity' and 'supportiveness' require normal cell proportions and functional phenotypes in multiple endometrial cell populations and their physical environment in order to allow a well-calibrated sequential developmental response in the conceptus.

29 June 2021 Stream 1 15:15 - 16:30

O-121 Exploring non-invasive methods to predict Ploidy Status: Combination of blastocyst morphology image analysis and proteomic profiles by using Artificial Neural Networks

A. Garg[1], L. Bari[1], M.A. Valera[1], E.I. Fernandez[2], J.C. Rocha[2], A. Quiñonero[3], F. Domínguez[3], M. Meseguer[4]

[1]IVIRMA, Research laboratory, Valencia, Spain ;
[2]Universidade Estadual Paulista UNESP, Faculdade de Ciências e Letras - Câmpus de Assis, São Paulo, Brazil ;
[3]IVIRMA Foundation, Innovation, Valencia, Spain ;
[4]IVIRMA, IVF laboratory, Valencia, Spain

Study question: Is the blastocyst morphology image analysis combined with the protein content of spent embryo culture medium a suitable way to predict embryo ploidy?
Summary answer: Morphological variables from blastocyst image analysis combined with IL-6 or MMP-1 concentration in spent culture medium showed more than 80% of accuracy for euploidy prediction.
What is known already: An artificial intelligence model based on the proteomic profile of euploid embryos and morphological data from blastocyst time-lapse images has been recently published (Bori et al., 2020). The most promising artificial neural network (ANN) algorithm considered 20 morphological variables extracted from image analysis and two proteins detected in embryo culture medium (MMP-1 and IL-6). The overall success rate on blind test data was 72.7% for live birth prediction. The main aim of the present study was to check if the same morphological variables combined with MMP-1 or IL-6 with a cost-effective technique could discriminate between euploid and aneuploid embryos.
Study design, size, duration: This prospective study included 120 embryos from the preimplantation genetic testing for aneuploidies (PGT-A) program. A single blastocyst image was obtained for each embryo and their spent culture medium was collected on the day 5/6 of embryo development (day of trophectoderm biopsy). Morphological variables were extracted for all the blastocyst. On the other hand, we quantified IL-6 levels of 67 embryos and MMP-1 levels of 53 embryos. Resulting parameters were used to predict PGT-A results.
Participants/materials, setting, methods: Blastocyst images were imported into Matlab software and segmented into regions of interest. We obtained 20 mathematical variables related to measurements of areas, number of pixels and texture analysis. Chromosome analysis was performed using next-generation sequence technology. In parallel, 20 µL of spent culture medium from each blastocyst was analyzed with ELISA kits (IL-6 or MMP-1). Protein concentrations and morphological variables were used as input data for an ANN associated with genetic algorithms.
Main results and the role of chance: The euploid rate for the set of embryos included in the IL-6 group was 51.4%. The ANN was trained with 49 embryos and blind tested with 18 embryos. Following results correspond to euploidy prediction on the blind test. The sensitivity, specificity, accuracy and area under the ROC curve (AUC) were: 0.56, 0.78, 0.67 and 0.72 considering only IL-6 values; 0.88, 0.78, 0.83 and 0.61 considering IL-6 values and blastocyst morphological data extracted from the image analysis. The euploid rate for the set of embryos included in the MMP-1 group was 51.9%. The ANN was trained with 39 embryos and blind tested with 14 embryos. Following results correspond to euploidy prediction on the blind test. The sensitivity, specificity, accuracy and AUC were: 0.71, 0.57, 0.64 and 0.67 considering only MMP-1 values; 0.86, 0.86, 0.86 and 0.61 considering MMP-1 values and morphological data extracted from the image analysis.
Limitations, reasons for caution: The detection limit in protein quantification is the main limitation of our study. The small number of embryos and the specific culture medium used should be considered for the model application.
Wider implications of the findings: Our preliminary results showed that blastocyst morphology and embryo secretomics could be useful for euploidy prediction by using artificial intelligence techniques. These findings may contribute to the emerging era of non-invasive preimplantation genetic testing (ni-PGT-A).
Trial registration number: not applicable

O-122 ICSI in a box: development of a successful automated sperm injection robot with external supervision and minimal manual intervention.

N. Costa-Borges[1], G. Giralt[2], E. Albó[2], A. Alvarez[3], J. Ramos[3], I. Hernandez[3], M. Luis[2], G. Calderón[1], S. Munne[2]

[1]Embryotools S.L., Research and Development, Barcelona, Spain ;
[2]Overture, Research and Development, Barcelona, Spain ;
[3]Overture, Research and Development, Madrid, Spain

Study question: Is it possible to automate the way sperm is injected in an oocyte and improve ICSI consistency between embryologists?
Summary answer: The developed ICSI robot demonstrated a high degree of consistency and operator skill independence, allowing human supervision and external control, but minimal manual intervention.
What is known already: ICSI is a clinical procedure that is currently performed worldwide in most IVF centers and its use will only increase with more utilization of egg freezing. Since its implementation, the technique has been conducted manually by highly skilled embryologists. However, success rates can vary significantly depending on the experience of the operator. We leverage our experience in robotics, AI algorithms and embryology to develop an automated ICSI robot that requires minimal manual intervention with the aim to standardize the consistency of the procedure and, ultimately, improve overall results maintaining embryologist oversight.
Study design, size, duration: The ICSI robot was developed to have supervised automated control on critical steps of the injection procedure, including injection pipette advancement, zona pellucida and oolemma penetration with piezo-pulses, and pipette removal after injection. Manual intervention is required only for immobilization and capture of spermatozoa with a joystick gamepad and to release the sperm in the ooplasm, without the need for micromanipulation skills. In parallel, piezo-ICSI was performed in a conventional micromanipulation station as a control.
Participants/materials, setting, methods: Hamster and mouse oocytes were collected from superovulated females. For testing the efficiency of the automated system, hamster oocytes were injected with human donor sperm, as historically used in manual ICSI training programs, and survival rates evaluated after overnight culture. Mouse oocytes were injected with mouse sperm heads and subsequently cultured *in vitro* for five days. Blastocysts obtained were vitrified and embryo transfers are ongoing to evaluate term developmental rates.
Main results and the role of chance: The technical components of the ICSI robot were engineered to integrate AI algorithms, optics, cell microinjectors and mechatronics. AI algorithms were developed to identify the morphological structures of MII oocytes, including the zona pellucida, perivitelline space and polar body, both in the hamster and mouse models. The system detects and analyzes both the pipette and the oocyte and chooses the best area and plane for injection, allowing automated control of the subsequent injection steps. Using the hamster oocyte-human sperm model, a survival rate of 91% (n=110) was

achieved with the robot, which was statistically similar (p=0.335) to the results obtained in the controls injected manually (96%, n=28). The average time spent in each injection cycle, which includes scanning of the oocyte and injection pipette, and injection of the sperm into the oocyte, was approximately two minutes per ICSI operation. This time was comparable to the time required by highly experienced operators with manual piezo-injection. In the mouse, 91% (n=53) of the oocytes injected survived the procedure, of which, 92% developed to two-cells and 87% to the blastocyst stage. No statistical differences were found when compared these efficiencies with manual controls (n=40, 98%, 97% and 92%, respectively).

Limitations, reasons for caution: The developed ICSI robot has shown highly consistent results, independently of operator skills, both in hamster and mouse oocytes. However, additional validations should be performed to enlarge the sample size of injected oocytes and to evaluate the efficiency of the system in other oocyte species, including translational studies to humans.

Wider implications of the findings: The combination of multidisciplinary teams allows the development of automated processes that can reduce variability in certain IVF procedures, while supervised and assisted by experienced embryologists. It is expected that other laboratory procedures can be automated in the field of assisted reproductive treatments in a near future.

Trial registration number: N/A

O-123 Calibration of artificial intelligence (AI) models is necessary to reflect actual implantation probabilities with image-based embryo selection

M.F. Kragh[1], J.T. Lassen[2], J. Rimestad[2], J. Berntsen[2]

[1]Vitrolife A/S & Aarhus University, Product Development, Viby J, Denmark ; [2]Vitrolife A/S, Product Development, Viby J, Denmark

Study question: Do AI models for embryo selection provide actual implantation probabilities that generalise across clinics and patient demographics?

Summary answer: AI models need to be calibrated on representative data before providing reasonable agreements between predicted scores and actual implantation probabilities.

What is known already: AI models have been shown to perform well at discriminating embryos according to implantation likelihood, measured by area under curve (AUC). However, discrimination performance does not relate to how models perform with regards to predicting actual implantation likelihood, especially across clinics and patient demographics. In general, prediction models must be calibrated on representative data to provide meaningful probabilities. Calibration can be evaluated and summarised by "expected calibration error" (ECE) on score deciles and tested for significant lack of calibration using Hosmer-Lemeshow goodness-of-fit. ECE describes the average deviation between predicted probabilities and observed implantation rates and is 0 for perfect calibration.

Study design, size, duration: Time-lapse embryo videos from 18 clinics were used to develop AI models for prediction of fetal heartbeat (FHB). Model generalisation was evaluated on clinic hold-out models for the three largest clinics. Calibration curves were used to evaluate the agreement between AI-predicted scores and observed FHB outcome and summarised by ECE. Models were evaluated 1) without calibration, 2) calibration (Platt scaling) on other clinics' data, and 3) calibration on the clinic's own data (30%/70% for calibration/evaluation).

Participants/materials, setting, methods: A previously described AI algorithm, iDAScore, based on 115,842 time-lapse sequences of embryos, including 14,644 transferred embryos with known implantation data (KID), was used as foundation for training hold-out AI models for the three largest clinics (n=2,829;2,673;1,327 KID embryos), such that their data were not included during model training. ECEs across the three clinics (mean±SD) were compared for models with/without calibration using KID embryos only, both overall and within subgroups of patient age (<36,36-40,>40 years).

Main results and the role of chance: The AUC across the three clinics was 0.675±0.041 (mean±SD) and unaffected by calibration. Without calibration, overall ECE was 0.223±0.057, indicating weak agreements between scores and actual implantation rates. With calibration on other clinics' data, overall ECE was 0.040±0.013, indicating considerable improvements with moderate clinical variation.

As implantation probabilities are both affected by clinical practice and patient demographics, subgroup analysis was conducted on patient age (<36,36-40,>40 years). With calibration on other clinics' data, age-group ECEs were (0.129±0.055 vs. 0.078±0.033 vs. 0.072±0.015). These calibration errors were thus larger than the overall average ECE of 0.040, indicating poor generalisation across age. Including age as input to the calibration, age-group ECEs were (0.088±0.042 vs. 0.075±0.046 vs. 0.051±0.025), indicating improved agreements between scores and implantation rates across both clinics and age groups. With calibration including age on the clinic's own data, however, the best calibrations were obtained with ECEs (0.060±0.017 vs. 0.040±0.010 vs. 0.039±0.009). The results indicate that both clinical practice and patient demographics influence calibration and thus ideally should be adjusted for.

Testing lack of calibration using Hosmer-Lemeshow goodness-of-fit, only one age-group from one clinic appeared miscalibrated (P=0.02), whereas all other age-groups from the three clinics were appropriately calibrated (P>0.10).

Limitations, reasons for caution: In this study, AI model calibration was conducted based on clinic and age. Other patient metadata such as BMI and patient diagnosis may be relevant to calibrate as well. However, for both calibration and evaluation on the clinic's own data, a substantiate amount of data for each subgroup is needed.

Wider implications of the findings: With calibrated scores, AI models can predict actual implantation likelihood for each embryo. Probability estimates are a strong tool for patient communication and clinical decisions such as deciding when to discard/freeze embryos. Model calibration may thus be the next step in improving clinical outcome and shortening time to live birth.

Trial registration number: This work is partly funded by the Innovation Fund Denmark (IFD) under File No. 7039-00068B and partly funded by Vitrolife A/S

O-124 Contact-free oocyte denudation in a chip-scale ultrasonic microfluidic device

A. Mokhtare[1], P. Xie[2], B. Davaji[3], A. Abbaspourrad[1], Z. Rosenwaks[2], G. Palermo[2]

[1]Cornell University, Department of Food Science and Technology, Ithaca, U.S.A. ; [2]Weill Cornell Medicine, Reproductive Medicine-, New York, U.S.A. ; [3]Cornell University, Department of Electrical and Computer Engineering, Ithaca, U.S.A.

Study question: To design and test an automated microfluidic device to revolutionize the cumulus-oocyte-complex (COC) denudation procedure for intracytoplasmic sperm injection (ICSI) using murine oocytes.

Summary answer: Oocyte exposure to temperature variation, mechanical stress, and prolonged chemical treatment during denudation was mitigated using our microfluidic device based on surface acoustic waves (SAWs).

What is known already: COC denudation is a prerequisite for many ART procedures such as ICSI. However, this procedure is based on manual pipetting (MP), which lacks standardization and requires experienced embryologists to perform. Inadequate MP may damage oocytes through prolonged enzymatic treatment or high fluidic stresses and may jeopardize gamete competence. The use of microfluidic devices based on porous membranes or microchannels has been adopted by many laboratories for sperm selection. Of these, microchannel devices may also be adapted for denudation with minimal mechanical stress in a controlled microenvironment. However, oocyte manipulation and extraction have proven difficult to achieve.

Study design, size, duration: We developed a novel ultrasonic microfluidic device based on a microwell design manufactured with Polydimethylsiloxane (PDMS). The SAWs were generated by 4 interdigitated transducers (IDTs) arranged in an orthogonally symmetric pattern. A non-toxic dosage of ultrasonic waves, similar to those used in gynecology and obstetrics, was applied. COCs were denuded by induced acoustic streaming and acoustic radiation force. Denudation rate, embryo development, and pregnancy outcomes were assessed and compared to control oocytes denuded by MP.

Participants/materials, setting, methods: For each run, up to 10 individual COCs from super-ovulated B6D2F1 mice were loaded into the microwell alongside diluted hyaluronidase (20 IU/ml) and denuded by 80 or 200 MHz SAWs. Denuded oocytes were fertilized by piezo-actuated ICSI using spermatozoa from the same strain. Pre-implantation embryo development was assessed in a time-lapse incubator for up to 96 h. High-quality blastocysts were transferred to 2.5-dpc pseudo-pregnant CD-1 surrogates. Pregnancy and offspring health were observed.

Main results and the role of chance: Using alternating frequency sweep in a pulse-repetition mode, we swirled the fluid inside the microwell consistently and tumbled COCs inside the microwell to expose them to acoustic steaming-induced drag forces and acoustic radiation force. Using a high-speed camera and particle-tracking technique, we observed that the drag force generated by the SAWs fulfilled the denudation mechanism. Additionally, due to the small attenuation coefficient in water, thermal absorption heating remains minuscule, preventing any thermal-induced damage.

Our device significantly reduced the time and labor of the denudation process. It also yielded proper denudation quality without oocyte loss. To ensure that SAWs do not damage oocytes, 40 oocytes denuded by 80 MHz SAWs, 25 oocytes denuded by 200 MHz SAWs, and 30 oocytes denuded by MP were inseminated by piezo-actuated ICSI. The 80-MHz, 200-MHz, and MP groups yielded comparable post-ICSI survival (82.5% vs. 84.0% vs. 83.3%, respectively), fertilization (80.0% vs. 80.0% vs. 83.3%,respectively), and blastulation rates (72.5% vs. 82.0% vs. 66.7%, respectively). Embryo morphokinetics were also not impacted. After transferring all blastocysts into recipient mice, 8 live births were achieved from the 80-MHz group, while 5 were achieved from the 200-MHz group.

Limitations, reasons for caution: Although PDMS is a popular material due to its high optical transparency and biocompatibility, adverse effects due to gas permeability and small-molecule adsorption cannot be excluded. Large-scale mouse embryo assays should be performed to assess the teratogenicity of PDMS. Operation parameters must be optimized for human COCs in clinical application.

Wider implications of the findings: Adopting widely used ultrasound techniques with emerging SAW technology is a major step toward advancing and standardizing oocyte denudation—a laborious yet delicate procedure. We predict it will be further integrated with AI and miniaturized robotics, modules specialized in gamete assessment, ICSI, and embryo evaluation in the near future.

Trial registration number: 'not applicable'

O-125 Development of an artificial intelligence embryo witnessing system to accurately track and identify patient specific embryos in a human IVF laboratory.

C. Bormann[1], M. Kanakasabapathy[2], P. Thirumalaraju[2], I. Dimitriadis[1], I. Souter[1], K. Hammer[1], H. Shafiee[2]

[1]Harvard Medical School, Obstetrics and Gynecology, Boston, U.S.A. ;
[2]Harvard Medical School, Division of Engineering in Medicine- Department of Medicine, Boston, U.S.A.

Study question: Can convolutional neural networks (CNN) be used as a witnessing system to accurately track and identify patient specific embryos at the cleavage stage of development?

Summary answer: We developed the first artificial intelligence driven witnessing system to accurately track cleavage and blastocyst stage embryos in a human ART laboratory.

What is known already: There are reports of human errors in embryo tracking that have led to the births of children with different genetic makeup than their birth parents. Clinical practices rely on manual identification, barcodes or radio-frequency identification technology to track embryos. These systems are designed to track culture dishes but are unable to monitor developing embryos within the dish to help ensure an error-free patient match. Previously, we developed an AI witnessing system to track blastocysts with 100% accuracy. The goal of this study was to determine whether an AI witnessing system could be developed that accurately tracks cleavage stage embryos.

Study design, size, duration: A pre-developed deep neural network technology was first trained and tested on 4944 embryos images. The algorithm processed embryo images for each patient and produced a unique key that was associated with the patient ID at 60 hpi, which formed our library. When the algorithm evaluated embryos at 64 hpi it generated another key that was matched with the patient's unique key available in the library.

Participants/materials, setting, methods: A total of 3068 embryos from 412 patients were examined by the CNN at both 60 hpi and 64 hpi. These timepoints were chosen as they reflect the time our laboratory evaluates Day 3 embryos (60 hpi) and the time we move them to another dish and prepare them for transfer (64 hpi). The patient cohorts ranged from 3-12 embryos per patient.

Main results and the role of chance: The accuracy of the CNN in correctly matching the patient identification with the patient embryo cohort was 100% (CI: 99.1% to 100.0%, n = 412).

Limitations, reasons for caution: Limitations of this study include that all embryos were imaged under identical conditions and within the same EmbryoScope. Additionally, this study only examined fresh Day 3 embryos cultured over a span of 4 hours. Future studies should include images of fresh and frozen/thawed embryos captured using different imaging systems.

Wider implications of the findings: This study describes the first artificial intelligence-based approach for cleavage stage embryo tracking and patient specimen identification in the IVF laboratory. This technology offers a robust witnessing step based on unique morphological features that are specific to each individual embryo.

Trial registration number: This work was partially supported by the Brigham Precision Medicine Developmental Award (Brigham Precision Medicine Program, Brigham and Women's Hospital), Partners Innovation Discovery Grant (Partners Healthcare), and R01AI118502, and R01AI138800.

SESSION 37: THE ENDOMETRIUM IN IMPLANTATION EARLY PREGNANCY

29 June 2021 Stream 2 15:15 - 16:30

O-126 Endometrial microbiota composition is associated with reproductive outcome in infertile patients

I. Moreno[1], I. Garcia-Grau[2], D. Perez-Villaroya[3], M. Gonzalez-Monfort[4], D. Bau[3], C. Gomez[5], D. Valbuena[6], F. Vilella[4], C. Simon[2]

[1]Igenomix Foundation, Research, Valencia, Spain ;
[2]University of Valencia, Pediatrics- Obstetrics and Gynecology, Valencia, Spain ;
[3]Igenomix R&D, Bioinformatics, Valencia, Spain ;
[4]Igenomix Foundation-INCLIVA, Research, Valencia, Spain ;
[5]Igenomix R&D, Clinical studies, Valencia, Spain ;
[6]Igenomix R&D, Medical department, Valencia, Spain

Study question: Is there an association between the composition of the endometrial microbiota and the reproductive outcomes in infertile patients undergoing in vitro fertilization (IVF)?

Summary answer: The composition of the endometrial microbiota (EM) prior to embryo transfer is associated with the different reproductive outcomes: live birth, no pregnancy or clinical miscarriage.

What is known already: The investigation of bacterial communities in the female reproductive tract using molecular methods has revealed the existence of a continuum microbiota that extends from the vagina to the upper genital tract. Previous evidence suggests the existence of an association between the vaginal and endometrial microbiome composition with reproductive and obstetrical outcomes. Specifically, the presence of specific pathogens together with low abundance of Lactobacilli has been associated with poor IVF outcomes.

Study design, size, duration: Multicentre prospective observational clinical study analysing the EM of infertile patients undergoing IVF (with maternal age ≤40) or ovum donation (≤50 years). A total of 452 infertile patients undergoing IVF/ovum donation were assessed for eligibility in 13 reproductive clinics in Europe, America, and Asia. The duration of the study was 30 months and the recruitment period extended between August 2017 and February 2019 (ct.gov 03330444).

Participants/materials, setting, methods: Endometrial fluid and endometrial biopsy were collected during a hormonal replacement therapy cycle after 5 days of progesterone (P) administration prior to a frozen embryo transfer cycle. Endometrial microbiota (EM) composition was analyzed using 16S rRNA gene sequencing using compositional data to transform scale-invariant values in both sample types. The EM in fluid and biopsy was associated with live birth, biochemical pregnancy, clinical miscarriage, or no pregnancy.

Main results and the role of chance: Of the 452 patients assessed, 44 did not meet the selection criteria and were excluded for the study and 66 patients

were lost to follow-up. Of the 342 remaining patients, 198 (57.9%) became pregnant [141 (41.2%) had a live birth, 27 (7.9%) had a biochemical pregnancy, 2 (0.6%) had an ectopic pregnancy, and 28 (8.2%) a clinical miscarriage], while 144 (42.1%) did not become pregnant. The baseline characteristics, clinical and embryological variables were homogeneous and no bias toward the clinical outcome categories was observed.

Our association study showed that the composition of the EM was associated with the reproductive outcome in both endometrial fluid and biopsy. A dysbiotic endometrial microbiota profile composed of *Atopobium*, *Bifidobacterium*, *Chryseobacterium*, *Gardnerella, Haemophilus, Klebsiella, Neisseria, Staphylococcus* and *Streptococcus* was significantly associated with unsuccessful outcomes, especially no pregnancy and clinical miscarriage. In contrast, *Lactobacillus* was consistently enriched in patients with live birth outcomes. The EM in endometrial fluid did not fully reflect that in endometrial biopsy, although their association with clinical outcome was consistent.

Limitations, reasons for caution: The main limitation was the small number of biochemical pregnancy and clinical miscarriage analysed. During transcervical collection of endometrial samples caution was taken to avoid contamination with the cervix although cervical contamination cannot be fully discarded.

Wider implications of the findings: Our data indicate that EM dysbiosis is associated with poor clinical outcome in ART. Thus, the EM composition before embryo transfer could be a useful biomarker to consider offering an opportunity to further improve diagnosis and treatment strategies.

Trial registration number: Clinical trials.gov 03330444

O-127 The endometrial tissue microbiota of women who did or did not achieve a live birth within 12 months after a first failed IVF/ICSI cycle

B. Bui[1], N. Van Hoogenhuijze[1], M. Viveen[2], S. Mackens[3], J. Van de Wijgert[4], F. Broekmans[1], F. Paganelli[2], G. Steba[1]

[1]University Medical Centre Utrecht, Department of Reproductive Medicine, Utrecht, The Netherlands ;
[2]University Medical Centre Utrecht, Department of Medical Microbiology, Utrecht, The Netherlands ;
[3]Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium ;
[4]Utrecht University, Julius Center for Health Sciences and Primary Care, Utrecht, The Netherlands

Study question: After one failed IVF/ICSI cycle, does the endometrial microbiota composition differ between women who will or will not reach a live birth within 12 months?

Summary answer: The endometrial microbiota composition did not significantly differ in women with one failed IVF/ICSI cycle with or without live birth, but statistical power was low.

What is known already: Evidence for the presence of an indigenous endometrial microbiome is mounting, and its composition may be associated with implantation success. However, a 'core' endometrial microbiome has not yet been defined, and its role in embryo implantation is still poorly understood. Further investigation of this topic may allow improvement and personalisation of clinical care for infertile couples. Endometrial microbiome analysis in infertile women has not yet been performed using transcervically obtained endometrial tissue. Using endometrial tissue instead of swabs or fluid may increase the bacterial DNA yield and therefore the precision of microbiome analyses.

Study design, size, duration: Endometrial tissue was obtained from a cohort of 141 infertile women undergoing endometrial scratching within a randomised controlled trial (RCT) (SCRaTCH trial, NL5193/NTR5342). Briefly, women aged 18-44 years with failed implantation after one full IVF/ICSI cycle and planning a subsequent IVF/ICSI cycle, were eligible. Participants were followed-up until 12 months after randomisation, with the primary outcome being live birth, defined as the delivery of at least one live foetus after 24 weeks of gestation.

Participants/materials, setting, methods: Endometrial tissue was obtained with an endometrial biopsy catheter in the midluteal phase of a natural cycle preceding subsequent IVF/ICSI, snap-frozen and stored at -80°C until use. Total DNA was isolated from these biopsies, followed by 16S rRNA sequencing (V3-V4 region) to determine the endometrial microbiota composition. Positive (mock communities) and negative controls (DNA extraction and PCRs) were included. QIIME2 and DADA2 were used for the data analysis, followed by statistical analysis in R studio.

Main results and the role of chance: During the 12-month follow-up, 61/141 women (43.3%) reached a live birth. While endometrial microbiota profiles of all 141 women were analysed, only samples with ≥100 reads were included in the analysis, resulting in a total of 46 samples (32.6%) that were included in the analysis, which consisted of samples from 25 women who did not have and 21 women who did have a live birth within 12 months. The median number of reads per sample was not significantly different between the two groups (respectively 2,317 (IQR 651-19,031) and 1,335 (IQR 296-3,180), p=0.29 by Mann-Whitney test). The endometrial microbiota detected, were bacterial genera frequently reported within the vaginal microbiota (e.g. *Lactobacillus*, *Atopobium* and *Gardnerella*). A clear dominance of *Lactobacillus* (relative abundance 55-100%, n=22) or an unclassified bacterium genus (relative abundance 52-76%, n=18) was observed in the majority of the samples; however, this dominance was not associated with the outcome of live birth. In addition, the samples dominated by Lactobacillus genera were mostly dominated by one species of *Lactobacillus* each (*L. crispatus*, *L. iners*, *L. gasseri* or *L. jensenii*).

Limitations, reasons for caution: The low biomass and the low ratio of bacterial versus human DNA in endometrial tissue were limiting factors in endometrial microbiota analysis. Furthermore, tissue was obtained transcervically, and contamination with vaginal/cervical microbiota could therefore have occurred. In the SCRaTCH trial no vaginal swabs were taken to serve as internal controls.

Wider implications of the findings: Future endometrial microbiota studies should consider the use of samples with a lower proportion of human DNA to maximize bacterial DNA yield. Furthermore, for endometrial microbiota research, sampling devices avoiding cervicovaginal contamination are desirable and may be developed in the future.

Trial registration number: SCRaTCH trial, NL5193/NTR5342

O-128 Intra-cycle alterations of the uterine microbiota in patients with recurrent miscarriage or recurrent implantation failure and healthy controls

K. Vomstein[1], S. Reider[2], B. Boettcher[1], K. Feil[1], A. Moschen[3], B. Toth[1]

[1]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria ;
[2]Medical University Innsbruck, Department of Internal Medicine I-Gastroenterology- Hepatology- Endocrinology & Metabolism, Innsbruck, Austria ;
[3]Kepler University Hospital, Department of Internal Medicine- Gastroenterology-Hepatology, Linz, Austria

Study question: Uterine microbiota: are there differences within three major time points of the menstrual cycle in healthy controls, recurrent miscarriage (RM) and recurrent implantation failure (RIF) patients?

Summary answer: Compared to controls, RM and RIF patients showed an altered uterine microbiota throughout the menstrual cycle, with a lower dominance of lactobacilli.

What is known already: In contrast to the former notion of a sterile womb, bacterial colonization in the uterus and the placenta has been demonstrated. Studies showed that Lactobacillus-dominated endometrial microbiota correlate with reproductive success. Moreover, the presence of non-Lactobacillus-dominated microbiota, especially with detection of Gardnerella and Streptococcus in the endometrial fluid, seems to be associated with lower implantation-, ongoing pregnancy- and live birth-rates. However, intra-cycle variations in healthy women as well as possible alterations in patients with RM or RIF remain unknown.

Study design, size, duration: In total, n=20 RM patients (≥ 3 consecutive miscarriages), n=20 RIF patients (≥3 fresh or frozen embryo transfers with negative serum hCG, good quality embryos) and n=10 healthy controls (no pregnancy) were included in this study. All patients had a 28 day menstrual cycle. During follicular, ovulatory and luteal-phase, after a thorough cleaning of the cervix, a flexible catheter was introduced into the uterine cavity and a uterine flushing with 1ml of NaCl was performed.

Participants/materials, setting, methods: Bacterial DNA was extracted using a QIAamp DNA kit (Qiagen) in combination with a PrecellysR24 homogenizer (Peqlab, Erlangen, Germany) according to the manufacturer's instructions. The V3-V4 region of the bacterial 16S rRNA gene was amplified. Samples were

pooled in equimolar ratios and progressed to pyrosequencing using an Illumina MiSeq se-quencer with MiSeq Kit V2 (250 bp paired-end). Analysis of 16S rRNA data, including alpha- and beta-diversity, were calculated using the phyloseq package in R.

Main results and the role of chance: For the Shannon index (species richness and evenness) a significant decrease during the ovulation period was shown in the control group, indicating a more uniform microbiota ($p < 0.05$). This loss of diversity was not shown in RIF and RM patients. Overall, we could observe a higher similarity in taxonomic distribution in RM compared to the RIF patients. Longitudinal dynamics included increases in Firmicutes (CTRL and RM only) and a concomitant loss of Proteobacteria. Notably, significant amounts of bacteroides were only detected in the RIF patients. Actinobacteria were more frequent in both, RM and RIF as compared to controls.

Limitations, reasons for caution: To minimize the impact of a potential contamination, we performed pre-experiments with paired samples both from the vaginal fornix and the endometrial cavum and could show a significant difference in overall microbiome configuration. However, the route of sample can still be prone to contamination.

Wider implications of the findings: For the first time, we were able to show cycle-dependent alterations in the endometrial microbiome. These findings underline the role of an altered endometrial microbiome as a cause for RM and RIF and can contribute to the future establishment of therapeutic strategies in cases of a dysbalanced microbiome.

Trial registration number: Drks00020803

O-129 Lactobacillus deplete vaginal microbial composition is associated with chromosomally normal miscarriage and local inflammation.

K. Grewal[1], Y. Lee[1], A. Smith[2], J. Brosens[3], M. Al-Memar[1], T. Bourne[4], S. Kundu[1], D. MacInytre[4], P. Bennett[4]

[1]Imperial College London, Metabolism- Digestion and Reproduction, London, United Kingdom ;
[2]University West of England, Faculty of Health and Applied Sciences, Bristol, United Kingdom ;
[3]University of Warwick, Division of Biomedical Sciences, Warwick, United Kingdom ;
[4]Imperial College London, Metabolism- Digestation and Reproduction, London, United Kingdom

Study question: To investigate the vaginal microbial composition and the local immune response in chromosomally normal and abnormal miscarriages and compare this to uncomplicated pregnancies delivering at term.

Summary answer: We show that euploid miscarriage is associated with a significantly higher prevalence of *Lactobacillus* spp. deplete vaginal microbial communities compared to aneuploid miscarriage.

What is known already: Emerging evidence supports the role of the vaginal microbiota in adverse pregnancy outcome, but the underlying mechanisms are poorly understood. A dominance of *Lactobacillus* spp. in pregnancy provides protection against pathogenic bacteria by producing lactic acid and antimicrobial compounds. A depletion in Lactobacillus spp. is often linked to adverse pregnancy outcomes.Current work also implicates the reproductive tract microbiota as a key modulator of local inflammatory and immune pathways. We have previously shown that miscarriage is associated with vaginal dysbiosis but without knowledge of the cytogenetic status of those miscarriages or the local immune profile.

Study design, size, duration: This study was a prospective observational cohort study based at Queen Charlotte's & Chelsea Hospital, Early Pregnancy Unit, London between March 2014-February 2019. Vaginal swabs were collected from the posterior vaginal fornix of 167 patients.

Participants/materials, setting, methods: We used 16S rRNA gene based metataxonomics to interrogate the vaginal microbiota in a cohort of 167 women, 93 miscarriage patients (54 euploid and 39 aneuploid using molecular cytogenetics) and 74 women who delivered at term and correlate this with the aneuploidy status of the miscarriages. We also measured the concentrations of IL-2, IL-4, IL-6, IL-8, TNF-α, IFN-γ, IL-1β, IL-18 and IL-10 in cervical vaginal fluid using Human Magnetic Luminex Screening Assay (8-plex).

Main results and the role of chance: We show that euploid miscarriage is associated with a significantly higher prevalence of *Lactobacillus* spp. deplete vaginal microbial communities compared to aneuploid miscarriage (P=0.008). In women having *Lactobacillus* spp. deplete vaginal microbial communities, euploid miscarriage associates with higher concentrations of pro-inflammatory cytokines IL-1β, IL-8, IL-6 (P<0.001, P=0.01 and P<0.001 respectively) and lower concentrations of anti-inflammatory cytokines IL10 (P<0.001) when compared to viable term pregnancy. We identified *Prevotella bivia* and *Streptococcus* as particularly common in euploid miscarriage and as drivers of pro-inflammatory cytokines (IL-1β, IL-6 and TNF-α). Co-occurrence network analyses revealed low levels of co-occurrence between *Lactobacillus crispatus* and other organisms and strong co-occurrence between Streptococcal species. Our data show a combination of both an adverse vaginal microbiota and a cytokine response to it influences early pregnancy outcome. Although this may be a reflection of intrinsic maternal immune response, it appears that the cytokine response is largely driven by the bacterial taxa present in the vagina, which presents an opportunity for specific, directed intervention. The negative co-occurrence between *L.crispatus* and all other organisms suggests a possible therapeutic role for probiotics containing this organism. The influence of Streptococci also suggests a potential benefit of targeted antibiotics with probiotics for some patients.

Limitations, reasons for caution: There were no longitudinal samples in this cohort and our results are based on the assumption that the vaginal microbial composition is stable throughout the first trimester.Future longitudinal studies with larger sample sizes are needed to corroborate these findings and provide insights to the mechanisms that trigger the inflammatory response.

Wider implications of the findings: These findings support the hypothesis that the vaginal microbiota plays an important aetiological role in euploid miscarriage and may represent a target to modify the risk of pregnancy loss.

Trial registration number: n/a

O-130 The influence of vaginal microbiota on frozen blastocyst implantation after transfer: a prospective study through next-generation 16S rRNA sequencing

H. Asakura[1], Y. Nakahara[1], Y. Nagai[2], Y. Sakuraba[2]

[1]Ohgimachi Ladeis' Clinic, Reproductive Medicine, Osaka, Japan ;
[2]Varinos- Inc., DNA Laboratory, Tokyo, Japan

Study question: A prospective study to investigate the relationship between the composition of vaginal microbiota through next-generation sequencing and the efficacy of single frozen blastocyst transfer in the same cycle.

Summary answer: Dominant presence of lactobacillus and other lactate producing microbes in the upper vagina was highly correlated with implantation of transferred blastocyst in this pilot study.

What is known already: Next-generation sequencing of 16S rRNA detected microbes in the uterine cavity and recent studies indicated that dominant presence of *Lactobacillus* correlated highly with successful implantation of the transferred embryos. Aberrant vaginal microbiota has been known to cause poor obstetrical outcomes, however little is known for its effect on embryo implantation in assisted reproduction.

Study design, size, duration: A prospective study with 25 female subjects transferring a frozen blastocyst using autologous oocyte, over 14 months period in 2019-2020.

Participants/materials, setting, methods: 25 female patients without tubal and uterine pathology and no history of multiple miscarriages and implantation failures were recruited with consent at a private ART clinic. Transdermal estrogen was used to prepare endometrium. Upper vaginal fluid was obtained in follicular phase of the the same cycle and analyzed through next-generation sequencing, but the result was reported after pregnancy confirmation. Single frozen blastocyst transfer and standard luteal phase support were performed. Institutional IRB approved the protocol.

Main results and the role of chance: The mean age was 36.2 y.o.(range 29-41 y.o.), and 14 gestational sacs (implantation rate 56%), and 3 miscarriage (21.4%) were observed. Next-generation sequencing for 16S rRNA revealed average 69.2% presence of *Lactobacillus* (0-100%) and average 78.0% (0.2-100%) lactate producing microbes (LPM: *Lactobacillus, Bifidobacterium, Streptococcus,* and *Enterococcus*) in the vaginal fluid. Using 90% as cut-off, implantation rates were 11/15 (73.3%) and 3/10 (30%) with *Lactobacillus* dominant and non-dominant, 12/16 (75%) and 2/9 (22.2%) with LPM dominant and non-dominant microbiota, respectively. The difference in each group were not statistically significant. The relative risks for pregnancy were 2.63 (95%CI 1.03-6.67, P=0.04)

for *Lactobacillus* and 3.11 (95%CI 1.24-7.79, *P*=0.02) for LPM. As for ROC analysis for embryo implantation and dominant microbes, AUC and associated criterion were 0.62 and 90.7% (sensitivity 78.6%, specificity 72.7%) for *Lactobacillus,* 0.69 and 96.6% (sensitivity 85.7%, specificity 72.7%) for LPM, respectively. The difference of AUC was not significant (*P*=0.24).

Limitations, reasons for caution: Despite prospective nature of the study, small sample size limited the analytical power of the study. Aneuploidy screening was not performed to remove confounding factor.

Wider implications of the findings: Our pilot study revealed possible relationship between vaginal microbiota and embryo implantation. Dominance of *Lactobacillus* or other lactate producing microbes may be advantageous for successful ART. Sampling vaginal fluid for microbe analysis is less invasive than endometrial sampling and can obtain more abundant RNA with possible higher accuracy of analysis.

Trial registration number: not applicable

[6]University of Michigan, Department of Obstetrics and Gynecology, Ann Arbor, U.S.A.

Study question: To assess the efficacy of Relugolix-CT vs placebo in women who were surgically diagnosed with endometriosis <5 and >= 5 years ago.

Summary answer: Treatment outcomes did not differ for dysmenorrhea and daily functioning between subgroups of patients with <5 years or ≥5 years since surgical diagnosis.

What is known already: Time since clinical manifestation and diagnosis of endometriosis may influence the treatment success of patients with endometriosis-associated pain. SPIRIT 1 and 2 were randomized, double-blind, placebo-controlled Phase 3 studies of Relugolix-CT (relugolix 40 mg, estradiol 1 mg, norethindrone acetate 0.5 mg) in premenopausal women (age 18–50 years) with surgically diagnosed endometriosis and a history of moderate-to-severe dysmenorrhea and non-menstrual pelvic pain (NMPP). These studies previously demonstrated that Relugolix-CT significantly reduced dysmenorrhea and NMPP, and improved daily functioning measured by the Endometriosis Health Profile-30 (EHP-30) pain domain score vs placebo over 24 weeks.

Study design, size, duration: Premenopausal women with surgically diagnosed endometriosis and moderate-to-severe dysmenorrhea and NMPP at baseline were randomized 1:1:1 to 24 weeks of treatment with once daily oral Relugolix-CT, delayed Relugolix-CT (relugolix 40 mg monotherapy for 12 weeks followed by Relugolix-CT for 12 weeks), or placebo. The proportion of dysmenorrhea and NMPP responders at Week 24/End-of-Treatment (EoT), based on daily Numerical Rating Scale (NRS), and analgesic use status were co-primary endpoints.

Participants/materials, setting, methods: Pooled SPIRIT 1 and 2 data of patients who received 24 weeks of treatment with once daily Relugolix-CT (N=418) or placebo (N=416) are presented. Outcomes for the delayed Relugolix-CT group were only for the safety assessment and therefore not reported here. Analyses of NRS scores for dysmenorrhea, NMPP, and EHP-30 pain domain score were carried out in the subgroups of patients with time since diagnosis of <5 years (N=579) and ≥5 years (N=255).

Main results and the role of chance: Baseline demographics and clinical characteristics were comparable between the time since diagnosis subgroups except for a numerically higher mean age in the ≥5-years subgroup. Mean time since diagnosis (standard deviation) was 2.1 (1.5) years with both Relugolix-CT and placebo for <5-years subgroup, and 8.0 (2.8) and 7.8 (2.3) years, respectively, for ≥5-years subgroup.

In Relugolix-CT-treated patients, mean NRS score for dysmenorrhea decreased from 7.5 (severe) to 1.8 (mild) in the <5-years subgroup and from 6.9 (moderate) to 1.8 (mild) in the ≥5-years subgroup with a significant difference to placebo (p<0.0001, both subgroups), and demonstrating 74.8% and 72.7% reduction in pain from baseline to Week 24/EoT, respectively. Mean NRS score for NMPP decreased from 6.0 (moderate) to 3.0 (mild) with a significant difference compared with placebo (p<0.0001), equating to 48.8% pain reduction in the <5-years subgroup, and from 5.6 (moderate) to 2.7 (mild) equating to 51.5% pain reduction (p=0.089) in the ≥5-years subgroup. Improvement of daily functioning as measured by EHP-30 pain domain score was significantly greater with Relugolix-CT vs placebo in both subgroups, with decrease in EHP-30 pain score from 59.1 to 24.0 in the <5-years subgroup, and from 57.4 to 21.1 in the ≥5-years subgroup (p<0.0001, both subgroups).

Limitations, reasons for caution: A lower number of patients were included into the subgroup with ≥5-years since surgically diagnosed endometriosis. Five-year dichotomy was close to the mean time since surgical diagnosis in the studies and to certain extent is arbitrary. Furthermore, time since surgical diagnosis is not the same as time since symptom onset.

Wider implications of the findings: In women with endometriosis-associated pain, Relugolix-CT vs placebo significantly reduced dysmenorrhea and improved daily functioning in both groups: with surgical diagnosis of <5 years or ≥5 years. Substantial decrease in NMPP was also observed and was significantly different to placebo in the <5-years subgroup.

Trial registration number: NCT03204318 and NCT03204331

O-132 Sustained efficacy and safety of relugolix combination therapy in women with endometriosis-associated pain: SPIRIT 52-week data

S. As-Sanie[1], L. Giudice[2], M.S. Abrao[3], K. Wilk[4], C. Mehedintu[5], C. Becker[6], J.C. Arjona Ferreira[7], R.B. Wagman[7], F. Wang[7], Q.A. Warsi[7], J. Neil[8]

[6]John Radcliffe Hospital, Nuffield Department of Women's and Reproductive Health, Headington Oxford, United Kingdom ;
[7]Myovant Sciences- Inc., Clinical Development, Brisbane- California, U.S.A. ;
[8]Robinson Research Institute- Auckland Gynaecology Group and Repromed Auckland, Gynaecology, Auckland, New Zealand

Study question: To assess the long-term (52-week) efficacy and safety of relugolix combination therapy (Relugolix-CT) in the treatment of endometriosis-associated pain.

Summary answer: Relugolix-CT demonstrated a sustained improvement of endometriosis-associated pain and maintenance of bone mineral density (BMD) over the extension treatment period. It was well tolerated.

What is known already: Endometriosis is a chronic condition characterized by symptoms of menstrual and non-menstrual pain, and dyspareunia, which have a substantial impact on women's lives. SPIRIT 1 and 2 were Phase 3, randomized, double-blind, placebo-controlled studies of once-daily Relugolix-CT (relugolix 40 mg, estradiol 1 mg, norethindrone acetate 0.5 mg) in premenopausal women (age 18–50 years) with surgically diagnosed endometriosis and moderate-to-severe dysmenorrhea and non-menstrual pelvic pain (NMPP) at baseline. These trials demonstrated a significant improvement of dysmenorrhea, NMPP and dyspareunia in women treated with Relugolix-CT, with a minimal decline in BMD vs placebo over 24 weeks.

Study design, size, duration: Women who completed the 24-week pivotal studies (SPIRIT 1 and 2 trials) were eligible to enroll in an open-label, single-arm, long-term safety and efficacy extension study for an additional 80 weeks. All women received once-daily oral Relugolix-CT. Analyses were done based on original randomization in pivotal studies: Relugolix-CT, delayed Relugolix-CT (relugolix 40 mg alone for 12 weeks, then Relugolix-CT for 12 weeks), or placebo. Here, 52-week efficacy and safety outcomes are presented.
Participants/materials, setting, methods: The primary endpoints were the proportion of dysmenorrhea and NMPP responders at Week 52, based on daily Numerical Rating Scale (NRS) scores (0=no pain, 10=worst pain imaginable). A responder was a woman who achieved a predefined, clinically meaningful reduction from baseline in NRS score with no increase in analgesic use. Secondary efficacy endpoints included change in Endometriosis Health Profile-30 (EHP-30) pain domain scores, and analgesic/opioid use. Safety endpoints included adverse events (AEs) and BMD evaluation.
Main results and the role of chance: Of 1261 randomized patients, 1044 completed the primary studies; 802 enrolled in the long-term extension and 681 completed 52 weeks of treatment. Baseline demographics and clinical characteristics of the extension population were consistent with those of the original randomized population.

Sustained improvement of endometriosis-associated pain was demonstrated with Relugolix-CT through 52 weeks, the proportion of responders for dysmenorrhea was 84.8% and 73.3% for NMPP.

NRS least squares (LS) mean scores for dysmenorrhea and NMPP decreased from 7.4 (severe) and 6.0 (moderate) at SPIRIT study baseline to 1.3 (mild) and 2.2 (mild) at Week 52, equating to 82.8% and 62.9% reduction in dysmenorrhea and NMPP, respectively. Mean NRS for dyspareunia decreased from 5.9 (moderate) to 2.4 (mild), demonstrating 60.1% reduction with Relugolix-CT.

Daily functioning measured by the EHP-30 pain domain score was improved (–38.1 point) and the majority of women (85.6%) were opioid-free at Week 52. There was no disproportionate increase in the incidence of AEs in the Relugolix-CT group with no new safety signals identified through the 52 weeks. BMD was preserved over the extension period with overall LS mean change from baseline to Week 52 of –0.83% (95% CI: –1.34, –0.32) for lumbar spine in the Relugolix-CT group.
Limitations, reasons for caution: The study was conducted as an open-label study without a control group over the 28 weeks of the extension period.
Wider implications of the findings: Relugolix-CT demonstrated a sustained improvement of dysmenorrhea, NMPP, and dyspareunia, and reduced pain-related functional limitations and the need for opioids over 52 weeks in women with moderate-to-severe endometriosis-associated pain. Relugolix-CT was generally well tolerated and associated with minimal BMD loss after treatment initiation followed by BMD maintenance over 52 weeks.
Trial registration number: NCT03654274

O-133 Effect of non-surgical treatments on the size of endometrioma: A systematic review and Meta-Analysis

S. Mekki[1], M. Hamdan[2], S.Z. Omar[3], R.H. Shunmugam2[4]

[1]Dr.Sulaiman Al Habib hospital, obs&gyne, Alkhober, Saudi Arabia ;
[2-]Faculty of Medicine- University of Malaya- Malaysia, 1Department of Obstetrics & Gynaecology, - Kuala Lumpur, Malaysia ;
[3]Faculty of Medicine- University of Malaya- Kuala Lumpur- Malaysia, 1Department of Obstetrics & Gynaecology-, Kuala Lumpur, Malaysia ;
[4]University of Malaya- Kuala Lumpur- Malaysia, University of Malaya Library, Kuala Lumpur, Malaysia

Study question: This review aims to determine the effectiveness of medical preparations in the management of endometrioma size
Summary answer: Medical treatment from different groups significantly reduces the endometrioma size, and relives painful symptoms
What is known already: Endometrioma is usually found in more severe stage of endometriosis and likely to be treated surgically. However, surgery of an endometrioma always destroys ovarian tissue and eventually reduces the ovarian reserve.
Study design, size, duration: Systematic review and analysis.The studies included 810 women in the intervention groups and 442 in the control groups
Participants/materials, setting, methods: 810 women included in the intervention groups . 442 in the control . All were women with endometrioma; 30-60% had pelvic pain. age was 33.4 years (range 27-39.8).

Four electronic databases search PubMed, Embase, CINAHL Google Scholar from each database inception date until 10 .9. 2019 using the specific search term. randomized and nonrandomized were included. trials comparing different medications for endometiotic cyst medical treatment, without language restriction and in consultation with a search methodologist
Main results and the role of chance: We found 3121studies from the initial search and out of which 3102 were excluded due to they did not fulfil the selection criteria, We included 14 studies for the systematic review leaving 4/14 for the meta-analysis. 14 final studies included for the systematic review out of which 6/14 were uncontrolled. The majority of the studies were prospective (10/14), and four were RCTs. 2/4 (n=395). controlled studies patient treated with a low-dose (OCP) or NET and dienogest +EE compared with patients treated with placebo, the endometrioma size significantly reduced (odds ratio[OR]1.32;95%CI [0.61,2.84],2studies, 255women, I= 0%).2/4 studies included in meta-analysis patients treated with dienogest versus norethendrone or ethinyl estradiol [EE] plus dienogest (SMD - 6.73;95%CI[-16.53, 3.06],2studies,185 women, I= 83%)
Conclusions: Medical treatment from different groups significantly reduces the endometrioma size, and relives painful symptoms.
Limitations, reasons for caution: Despite the nature of the randomized includedstudies, the results of this study are still subjected to confounders relating to clinical and statistical heterogeneity. the studies reported the outcomes differently
Wider implications of the findings: medical treatment can be given the surgery can be avoided, therefore preserve the ovarian tissue. There is limited controlled study to examine the effectiveness of the treatment for endometrioma.

O-134 Cochrane review on the effect of pentoxifylline for endometriosis

A. Grammatis[1], E.X. Georgiou[2], C.M. Becker[3]

[1]Centre of Reproductive Medicine, Barts Health NHS Trust, London, United Kingdom ;
[2]Complete Fertility Unit, University Hospital Southampton NHS Trust, Southampton, United Kingdom ;
[3]Endometriosis CaRe Centre Oxford, Nuffield Department of Women's & Reproductive Health, University of Oxford, United Kingdom

Study question: To assess the effect of pentoxifylline, a methyl-xanthine with anti-inflammatory effects, for the management of premenopausal women with endometriosis.
Summary answer: There is not enough evidence to support the use of pentoxifylline in the management of premenopausal women with endometriosis to improve fertility and pain outcomes.
What is known already: Endometriosis is a chronic, inflammatory condition that occurs mainly during the reproductive years. It is characterized by endometrium-like tissue developing outside the uterine cavity. This endometriotic tissue development is dependent on estrogen produced primarily by the ovaries and partially by the endometriotic tissue itself and, therefore, hormonal management is traditionally used. In light of the body of evidence suggesting an immunological component to the pathophysiology of endometriosis, the anti-inflammatory agent pentoxifylline has been proposed as an alternative therapeutic agent.
Study design, size, duration: A Cochrane systematic review and meta analysis was performed. Electronic searches of the Cochrane Gynaecology and Fertility Specialised Register of Controlled Searches, CENTRAL, MEDLINE, EMBASE, PsycINFO, CINAHL and AMED OVID were conducted to December 2020 to identify relevant randomised controlled trials (RCTs). In addition, electronic searches were conducted on the Epistemonikos database, Human Reproduction, Web of Knowedlge, OpenGrey, LILACS, Pubmed and Google.
Participants/materials, setting, methods: Participants: premenopausal women with endometriosis via laparoscopy/laparotomy. For extent of endometriosis, grades according to the AFS/rASRM scoring system were used.
Intervention: pentoxifylline treatment for any period of time
Comparisons: placebo, no treatment, medical treatment, surgical treatment.
Two independent authors screened studies and extracted data. Risk ratios were calculated for dichotomous data (Peto odds ratio for low event rates) and mean differences (MD) for continuous data, with 95% confidence intervals (CI).

Main results and the role of chance: Five RCTs were included, involving 415 participants.

Pentoxifylline vs placebo

No trials reported on live birth or reduction of pain. We are uncertain whether pentoxifylline affects the clinical pregnancy rate (Peto OR 1.53, 95% CI 0.89 to 2.63; 3 RCTs, n=285; $I^2 = 0\%$; very low-quality evidence), recurrence rate (Peto OR 0.83, 95% CI 0.26 to 2.60; 1 RCT, n=121; very low-quality evidence), or miscarriage rate (Peto OR 1.99, 95% CI 0.20 to 19.37; 2 RCTs, n=164; $I^2 = 0\%$; very low-quality evidence).

Pentoxifylline vs no treatment

We are uncertain whether pentoxifylline impacts on pain reduction when compared to no treatment at one month (MD -0.36, 95% CI -2.08 to 1.36; 1 RCT; n = 34; very low-quality evidence), two months (MD -1.25, 95% CI -2.67 to 0.17; 1 RCT; n = 34; very low-quality evidence) or three months (MD -1.60; 95% CI -3.32 to 0.12; n = 34; very low-quality evidence). No studies reported on live birth.

Pentoxifylline vs medical treatment

One study compared pentoxifylline with the combined contraceptive pill, but could not be included in the meta-analysis, as it was unclear if the data were presented as +/- standard deviation.

Pentoxifylline vs surgical treatment

No study reported on this comparison

Limitations, reasons for caution: Based on the GRADE criteria, the quality of evidence was classified as very low with issues arising due to risk of bias and imprecision. Four studies did not apply the intention-to-treat principle. None of the studies reported on live birth rate, one of the primary outcomes of the review.

Wider implications of the findings: Future research should prioritise live birth and overall pain as the primary outcome and include patients with all endometriosis severity types. All included studies compared pentoxifylline with placebo or no treatment after surgery, which highlights the need for more types of comparisons, such as to hormonal contraception.

Trial registration number: Not applicable

Study question: Are symptomatic improvements in women with UF observed after 24 weeks of linzagolix treatment with or without add-back therapy (ABT) maintained over 52 weeks?

Summary answer: Improvements in anemia, pain and quality of life previously reported at 24 weeks were maintained at 52 weeks.

What is known already: We previously reported that partial or full suppression of estradiol (E2) with once daily doses of either 100 or 200 mg linzagolix for 24 weeks, with or without ABT, were effective in reducing heavy menstrual bleeding associated with uterine fibroids, improving other symptoms such as pain and anemia and improving quality of life. Here we report the maintenance of effect on secondary endpoints after 52 weeks of treatment.

Study design, size, duration: Linzagolix is an investigational, oral GnRH antagonist being developed to treat HMB due to UF. PRIMROSE 1 (P1, USA, NCT03070899) and PRIMROSE 2 (P2, Europe and USA, NCT03070951) are randomized, double-blind, placebo-controlled Phase 3 trials, with essentially identical design, investigating the efficacy and safety of linzagolix with and without hormonal add-back therapy (ABT: 1 mg estradiol/0.5 mg norethindrone acetate) once daily for 52 weeks.

Participants/materials, setting, methods: Participants had HMB due to UF (>80mL menstrual blood loss (MBL)/cycle) and were equally randomized to: placebo, linzagolix 100mg, linzagolix 100mg+ABT, linzagolix 200mg, or linzagolix 200mg+ABT. After 24 weeks, subjects originally randomized to placebo or linzagolix 200mg were switched to linzagolix 200mg+ABT except in P1 where 50% placebo subjects continued placebo until 52 weeks. Secondary efficacy assessments included hemoglobin, pain (0–10 numeric rating scale) and health related quality of life (HRQL) on the UF-QoL questionnaire.

Main results and the role of chance: P1 trial subjects (n=526) had a mean age of 42 years, pain score of 6.6 and HRQL total score (0–100) of 36.4 and 63% were Black. P2 trial subjects (n=511) had a mean age of 43 years, pain score 4.8 and HRQL total score of 46.1 and 5% were Black. Mean baseline MBL was about 200 mL per cycle in both studies. In both trials, significant improvements compared to placebo observed at week 24 for secondary endpoints, including pain, anemia and QoL in all linzagolix treatment groups were maintained at 52 weeks.

Mean±SD hemoglobin levels in anemic patients (<12 g/dL) increased from baseline by 1.7±1.9, 1.9±1.7, 2.2±2.4, 2.7±1.9 in P1 and 1.2±1.9, 2.9±1.8, 2.4±2.1, 3.0±1.4 in P2 in the 100mg, 100mg+ABT, 200mg/200mg+ABT, 200mg+ABT groups, respectively, compared to 0.6±1.8 with placebo (P1).

Mean±SD change from baseline in pain scores were -3.3±3.1, -2.7±3.2, -2.6±3.0, -3.9±3.2 in P1 and -2.6±3.1, -2.6±2.8, -3.0±2.6, -2.8±3.0 in P2 in the 100mg, 100mg+ABT, 200mg/200mg+ABT, 200mg+ABT groups, respectively, compared to -0.4±2.5 with placebo (P1).

Mean±SD change in HRQL total scores were 25.0±26.2, 34.2±30.1, 29.7±29.2, 38.3±29.2 in P1 and 16.8±24.0, 29.6±23.2, 31.9±26.8, 30.7±26.0 in P2 in the 100mg, 100mg+ABT, 200mg/200mg+ABT, 200mg+ABT groups, respectively, compared to 14.6±23.9 with placebo (P1).

Limitations, reasons for caution: Here we report data in both trials up to 52 weeks of treatment. No statistical comparisons were done at 52 weeks (the primary analysis was done after 24 weeks treatment). Post-treatment follow-up will provide more information in symptom recurrence after stopping treatment.

Wider implications of the findings: All linzagolix treatments provided sustained benefit. Two regimens previously identified for potential long-term treatment, 200mg with ABT and 100mg without ABT, provided sustained improvements of anemia, pain and associated quality of life. These different treatment regimens could be important to address the diverse needs of women suffering from uterine fibroids.

Trial registration number: ClinicalTrials.gov: NCT03070899, NCT03070951

Study question: What is the effect of relugolix combination therapy (Relugolix-CT) on symptom burden and health-related quality-of-life (HR-QoL) in patients with uterine fibroids (UF) over 52 weeks?

Summary answer: Relugolix-CT demonstrated sustained, clinically meaningful improvement in patient-reported symptom severity and HR-QoL over 52 weeks in women with UF.

What is known already: In LIBERTY 1 and 2 randomized clinical trials, once-daily Relugolix-CT (40 mg relugolix, an oral gonadotropin-releasing hormone

receptor antagonist, estradiol 1 mg, norethindrone acetate 0.5 mg) significantly reduced menstrual blood loss (MBL) and UF-associated pain versus placebo in women with UF and heavy menstrual bleeding (HMB), and was well tolerated, with bone mineral density (BMD) preservation through 24 weeks. In the LIBERTY long-term extension study, a sustained reduction in MBL was observed along with no new safety signals and BMD maintenance through 52 weeks. Relugolix-CT was previously shown to significantly improve patient-reported symptom severity and HR-QoL through 24 weeks.

Study design, size, duration: In the LIBERTY 1 and 2 studies, 770 premenopausal women with ultrasound-documented clinically significant UF and alkaline-hematin documented HMB were randomized 1:1:1 to Relugolix-CT for 24 weeks, relugolix 40 mg for 12 weeks followed by Relugolix-CT for 12 weeks, or placebo for 24 weeks. Women who completed the pivotal studies were eligible to enroll in the 28-week extension study (N=477 enrolled). Patients included in the extension study received open-label once-daily Relugolix-CT.

Participants/materials, setting, methods: Changes from baseline to Weeks 24 and 52 in the Uterine Fibroid Symptom (UFS)-QoL symptom severity scale, Bleeding and Pelvic Discomfort scale (BPD; assessing distress due to HMB, passing blood clots, pelvic pressure/tightness); and HR-QoL (sub)scales were assessed. Higher symptom severity and BPD scores reflect higher severity and distress, respectively; higher HR-QoL scores indicate better outcomes. Least-squares mean changes were provided for the original pivotal-study randomized treatment groups Relugolix-CT and placebo.

Main results and the role of chance: A sustained improvement in symptom severity was observed for the Relugolix-CT group from baseline to Weeks 24 and 52, with LS mean changes of –36.9 and –37.3 points, respectively. In patients initially treated with placebo, small changes were observed at Week 24 (–10.8 points), whereas a greater reduction from baseline was demonstrated at Week 52 (–35.0 points) after transitioning to Relugolix-CT.

Considering the BPD, measuring distress from key UF symptoms, LS mean changes of –50.9 and –51.3 points were observed in the Relugolix-CT group from baseline to Week 24 and 52, respectively. In patients initially treated with placebo, small changes were observed at Week 24 (–15.9 points), whereas a greater reduction from baseline was demonstrated at Week 52 (–48.6 points) after transitioning to Relugolix-CT.

Treatment with Relugolix-CT also resulted in a sustained improvement in different aspects of HR-QoL. LS mean total HR-QoL score increased from baseline to Weeks 24 and 52 by 40.8 and 40.4 points, respectively. In patients initially treated with placebo, small changes were observed at Week 24 (11.4 points), whereas a greater increase from baseline was demonstrated at Week 52 (39.0 points) after transitioning to Relugolix-CT at Week 24.

Limitations, reasons for caution: The 28-week LIBERTY long-term extension study was non-comparative. Analyses were performed in a subset of patients who completed the LIBERTY pivotal studies and were eligible for the extension study. However, it is important to note that the demographic and baseline disease characteristics were similar between pivotal and long-term extension populations.

Wider implications of the findings: Relugolix-CT resulted in a sustained reduction in UF symptom burden, particularly in terms of distress from key UF symptoms, and a sustained improvement of HR-QoL over 52 weeks. Improvements observed after transitioning from placebo to Relugolix-CT at 24 weeks confirmed the positive effect of Relugolix-CT on UF-associated symptoms and HR-QoL.

Abstract text

ART is one of the fastest-growing fields in medicine. Besides the advancements in the hormonal stimulation and treatment regimes, the laboratory aspect of IVF showed emerged development in science and especially technology. The emphasis of future IVF treatments and laboratory procedures is on the non-invasive methods of embryo evaluation and selection. The application of Artificial Intelligence (AI) in daily life prompts us to evaluate this technology in this context. The AI is one of the main candidates to drive future IVF not only in the lab but also in all aspects of the IVF procedures. The benefit of AI technology involves "big data" analysis, objectivity, standardization, and precision. The most advancement of AI application is in the IVF lab where technology can be used as a tool to enhance our ability to select the "best" viable embryo objectively. As a new technology, it is important to evaluate it on the large scale. The AI technology will also enable us to standardize clinical parameters of patient reproductive potential and objectively predict each patient reproductive outcome per cycle. Ultimately, AI will help us to achieve the personalized and precision medicine needed in our field.

O-050 Virtual reality applications in ultrasound

Abstract text

Surgical simulation has been introduced in surgical training since 1920 following the example of airline and military industry. Recently, the Association of American Medical Colleges commented on the increased use of simulation in different medical specialties, recognizing its potential ability to improve patients safety and to enhance healthcare in general. Historically, graduating obstetrics and gynecology residents have been expected to learn following the adage 'see one, do one, teach one', which required a high volume experience. Nowadays, as the complexity of procedures increases and surgical volume decreases, in order to acquire surgical skills rapidly there is the need to integrate surgical and ultrasound virtual simulation into modern residency training alongside traditional teaching methods. In addition, recent changes in the field (e.g. work-hours restrictions, decreased bedside teaching) have high lightened these necessities.

Ultrasonography is a skill that requires a complex interplay of motor skills and visual-cognitive skill. The learning process include two steps: an initial global assessment followed by a focal search for pathology and key landmarks. Recently more attention has been paid to design increasingly sophisticated simulators for ultrasound in obstetrics and gynecology. These are broadly divided into to major categories: physical mannequins and virtual reality simulators. The physical mannequins practically consist in low cost silicon dummies that enable learners to discover basic anatomical and pathological findings using real ultrasound equipment. This type of simulators allows the trainees to learn haw to use the

equipment in order to obtain proper scans. However, the case complexity is limited due to the low fidelity of the physical mannequins. In addition there is no automated feedback and a supervisor is always needed during the practice.

The virtual reality simulators usually rely on haptic devices or physical mannequins that record probe movements during transabdominal or transvaginal scans and combined them with computer-animated/real ultrasound images. Instructions and automated feedback are provided during the practice. They often contains multiple cases allowing the trainees to be exposed to different clinical scenarios.

In the field of Reproductive Endocrinology and Infertility some ultrasound and surgical skills are required for independent practice including transvaginal oocyte pick-up, hysterosalpingocontrastsonography (HyCoSy) and embryo-transfer. Considering advantages and disadvantages of both apprenticeship models (traditional training and simulator-based training), a blended approach which combines simulator-based training with didactic and more traditional training on real patients could be introduced. So far the use of simulation-based training has shown promising results in terms of moderate effects on patient outcomes and large effects on trainee behavior in the clinical setting. It could be useful especially in the initial part of a structured training for novices, enabling them to acquire basic skills and to reach a predefined level of performance in a safe and controlled environment, before applying the procedure to real patients.

INVITED SESSION

SESSION 41: MODERN FORMATS OF NURSE-PATIENT COMMUNICATION

29 June 2021 Stream 3 17:00 - 18:00

O-051 Telenursing within fertility

V. Peddie[1]

[1]*University of Aberdeen, Institute of Applied Health Sciences School of Medicine- Medical Sciences- Nutrition, Aberdeen, United Kingdom*

Abstract text

Aberdeen Fertility Centre provides fertility investigation and treatment across the north east, highlands and islands (Orkney & Shetland) of Scotland, which includes rural and remote communities. Whilst the SARS-Cov-2 pandemic has accelerated the delivery of *Tele-fertility Nursing*, the National Health Service (NHS) in Grampian, Scotland launched both '*No Delays*' and '*Near Me*' platforms in 2019 to keep pace with the digital age and with the intention of improving the quality of patient care.

No Delays (series of video packages and virtual consultations) has revolutionised clinical pathways, providing individualised patient information from investigation to treatment, permitting email 'prescription' of digital postcards (personalised package of short videos introducing members of the team and explaining their role) that explain the fertility journey and management plan in detail, from investigation (ie., tubal evaluation), to treatment (ie., ovulation induction or IVF), and self-administration of medicines.

Thereafter, patients receive invitation to virtual '*Near Me*' consultation which can take place in the comfort of their own home whilst acknowledging flexibility in lifestyle (partner can remotely access consultation from workplace, including overseas).

Electronic patient records (EPR's) provide immediate access to complete, accurate and up to date clinical patient data, which, together with Electronic Consents compliment the tele-nursing experience through a complete library of consent forms, automatically allocated to patient and partner according to treatment type and personal circumstances: information being provided in video format to meet the requirements for informed consent. Forms are completed online, at home or in the 'virtual' clinic via computers, tablets or smartphones, with workflow automation tools allowing for digital signature/s. The complete digital package ensures patients have an early understanding of the process, therefore better prepared for face-to-face appointments and ensuring quality care delivered at point of contact.

The aims and objectives of '*Tele-fertility Nursing*' were to: (1) reinforce key information routinely provided at consultation which may not always be understood, (2) meet patient need and lifestyle, (3) increase patient choice, (4) save time and money by reducing unnecessary travel (often complicated by adverse weather conditions from rural communities), (5) avoid unnecessary time off work, and (6) reduce environmental impact of attended appointments (health miles and miles not travelled).

Whilst concern remains around the digital interface and nurse/patient relationship, preliminary evaluation of '*Near Me*' consultations and patient feedback - relative to electronic consent - suggests overall patient satisfaction; the above aims and objectives being met. However, full evaluation of the patient and fertility nurse experience of the 'digital fertility journey' is required.

[5]*Amsterdam Reproduction and Development Research institute- Amsterdam University Medical Centre, Department of Obstetrics and Gynecology, Amsterdam, New Zealand*

Study question: What is the comparative effectiveness between salpingectomy and neosalpingostomy in the treatment of bilateral severe hydrosalpinx?
Summary answer: In women with bilateral severe hydrosalpinx, salpingectomy combined with In Vitro Fertilization (IVF) treatment resulted in a higher cumulative live birth rate than neosalpingostomy.
What is known already: Hydrosalpinx accounts for 25% to 35% of female subfertility and has a negative effect on pregnancy rates in women who undergo IVF. So far salpingectomy before in vitro fertilization treatment has been suggested for the treatment of hydrosalpinx in order to improve the chance of a live birth. Previous studies have reported a pooled live birth rate of 25% through natural conception after neosalpingostomy and an ongoing pregnancy rate of 55.8% after salpingectomy with IVF. Direct comparison of the cumulative live birth rate after salpingectomy versus neosalpingostomy, both followed by IVF is lacking.
Study design, size, duration: We performed a single center, prospective comparative cohort study in the International Peace Maternity and Child Health Hospital affiliated to Shanghai Jiao Tong University School of Medicine, China. We studied women diagnosed with tubal subfertility with bilateral hydrosalpinx between January 2005 and December 2012. Based on a shared decision approach, they had bilateral salpingectomy or neosalpingostomy followed by IVF. They were annually followed up until July 2020 for the occurrence of live birth.
Participants/materials, setting, methods: Out of 113 women, 55 had bilateral salpingectomy and 58 had bilateral neosalpingostomy. Primary outcome

was cumulative live birth rate, defined as the cumulative birth rate of the first living neonate through either natural conception or in vitro fertilization. Both intention-to-treat (ITT) and per-protocol (PP) analysis were processed. Cox proportional hazards regression model with potential variables was performed to identify predictors of successful live birth.

Main results and the role of chance: Baseline characteristics were comparable between two groups. There were 42 live births in the salpingectomy and 36 in the neosalpingostomy group. When the result of IVF was incorporated (55/55 in salpingectomy group and 25/58 in neosalpingostomy group underwent IVF), salpingectomy resulted in a higher cumulative live birth rate (85.3% vs 76.0%; hazard ratio of the whole survival curve, 2.18; 95% CI, 1.37 - 3.45; P = 0.001), a lower risk of ectopic pregnancy (1.8% vs 20.7%; risk ratio, 0.07; 95% CI, 0.01 - 0.57; P = 0.013), and a shorter time to live birth (19 [14,27] versus 36 [17,76] months, P = 0.001).The number of live birth rates after natural conception was 0% (0/55) in the salpingectomy group and 28% (16/58) in neosalpingostomy group.The results of PP analyses were comparable with the ITT analyses apart from the biochemical pregnancy rate and the overall live birth rate, they were higher (the former: 76% (42/55) versus 58% (29/50), P = 0.045; the latter: 76% (42/55) versus 56% (28/50), P = 0.027) in salpingectomy group.

Limitations, reasons for caution: This is an observational study. The small sample size along with the data was obtained from a cohort study in a single center.

Wider implications of the findings: In women with confirmed bilateral severe hydrosalpinx, salpingectomy followed by IVF results in a higher cumulative live birth rate and decreases the risk of EP as compared to neosalpingostomy. However, neosalpingostomy is the only option to achieve a live birth by natural conception that should be discussed with patients preoperatively.

Trial registration number: not applicable

O-138 Reproductive performance of women with and without intrauterine adhesions following recurrent dilatation and curettage for miscarriage: long-term follow-up of a randomized controlled trial

A. Hooker[1], R.A. Leeuw[2], J. Twisk[3], H. Brolmann[2], J. Huirne[2]

[1]Zaans Medical Center ZMC, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands ;
[2]Amsterdam UMC- Location VU University Medical Center- Amsterdam- the Netherlands, Department of Obstetrics and Gynecology, Amsterdam, The Netherlands ;
[3]Amsterdam UMC- Location VU University Medical Center- Amsterdam- the Netherlands, Department of Epidemiology and Biostatistics-, Amsterdam, The Netherlands

Study question: Are the long-term reproductive outcomes following recurrent dilatation and curettage (D&C) for miscarriage in women with identified and treated intrauterine adhesions (IUAs) comparable to women without IUAs.

Summary answer: Reproductive outcomes in women with identified and treated IUAs following recurrent D&C for miscarriage are impaired compared to women without IUAs.

What is known already: The Prevention of Adhesions Post Abortion (PAPA) study showed that application of auto-crosslinked hyaluronic acid (ACP) gel, an absorbable barrier in women undergoing recurrent D&C for miscarriage resulted in a lower rate of IUAs, 13% versus 31% (relative risk 0.43, 95% CI 0.22 to 0.83), lower mean adhesion score and significant less moderate to severe IUAs. It is unclear what the impact is of IUAs on long-term reproductive performance.

Study design, size, duration: This was a follow-up of the PAPA study, a multicenter randomized controlled trial evaluating the application of ACP gel in women undergoing recurrent D&C for miscarriage. All included women received a diagnostic hysteroscopy 8–12 weeks after randomization to evaluate the uterine cavity and for adhesiolysis if IUAs were present. Here, we present the reproductive outcomes in women with identified and treated IUAs versus women without IUAs, 46 months after randomization.

Participants/materials, setting, methods: Between December 2011 and July 2015, 152 women with a first-trimester miscarriage with at least one previous D&C, were randomized for D&C alone or D&C with immediate intrauterine application of ACP gel. Participants were approached at least 30 months after randomization to evaluate reproductive performance, obstetric and neonatal outcomes and cycle characteristics. Main outcome was ongoing pregnancy. Outcomes of subsequent pregnancies, time to conception and time to live birth were also recorded.

Main results and the role of chance: In women pursuing a pregnancy, 14/24 (58%) ongoing pregnancies were recorded in women with identified and treated IUAs versus 80/89 (90%) ongoing pregnancies in women without IUAs odds ratio (OR) 0.18 (95% CI 0.06 to 0.50, P-value <0.001). Documented live birth was also lower in women with IUAs; 13/24 (54%) with versus 75/89 (84%) without IUAs, OR 0.22 (95% CI: 0.08 to-0.59, P-value 0.004). The median time to conception was 7 months in women with identified and treated IUAs versus 5 months in women without IUAs (hazard ratio (HR) 0.84 (95% CI 0.54 to 1.33)) and time to conception leading to a live birth 15 months versus 5.0 months (HR 0.54 (95% CI: 0.30 to 0.97)). In women with identified and treated IUAs, premature deliveries were recorded in 3/16 (19%) versus 4/88 (5%) in women without IUAs, P-value 0.01. Complications were recorded in respectively 12/16 (75%) versus 26/88 (30%), P-value 0.001. No differences were recorded in mean birth weight between the groups.

Limitations, reasons for caution: In the original PAPA study, randomization was applied for ACP gel application. Comparing women with and without IUAs is not in line with the randomization and therefore confounding of the results cannot be excluded. IUAs, if visible during routine hysteroscopy after randomization were removed as part of the study protocol.

Wider implications of the findings: As IUAs have an impact on reproductive performance, even after hysteroscopic adhesiolysis, primary prevention is essential. Expectative and medical management should therefore be considered as serious alternatives for D&C in women with a miscarriage. In case D&C is necessary, application of ACP gel should be considered.

Trial registration number: Netherlands Trial Register NTR 3120.

O-139 Complete removal of uterine septum tissue as a wedge, an alternative method for patients suffering from recurrent pregnancy loss or infertility, a retrospective cohort study

F. Razzaghi Kashani[1], R. Zargham[1], S. Amirajam[1], H. Jadda[2], S. Razi[1], A. Jadda[1]

[1]Avicenna Research Institute, Dept. of Ob/Gyn, Tehran, Iran ;
[2]Avicenna Research Institute, Dept. of Embryology, Tehran, Iran

Study question: Is hysteroscopic wedge septectomy (HWS) an effective and safe method for reducing the risk of miscarriage and improving the reproductive outcome in patients with recurrent pregnancy loss or infertility history?

Summary answer: HWS is a safe and effective method for RPL and infertility cases with statistically significant improvement in pregnancy chances and reproductive outcomes.

What is known already: With regard to the persisting uncertainty around the effectiveness of septum resection in recurrent miscarriage and infertility cases, there may be alternative methods to better address the pathophysiology of septum. There are different explanations for the poor reproductive performance with uterine septum: poor vascularisation of a highly fibrous implantation site, low sensitivity of endometrial receptors covering the septa, its "myoma-like" composition, and finally higher uterine vascular resistance. Complete removal of this abnormal tissue rather than just incising it may not only enhance challenging the pathogenesis but also expand the endometrial volume, an objective parameter by which to predict endometrial receptivity.

Study design, size, duration: In this retrospective cohort study, 214 consecutive patients, aged 33.3±4.8, diagnosed with a septate uterus based on ESHRE classification who had been under HWS between April 2017 and January 2020 due to recurrent miscarriage or at least one failed embryo transfer, met the enrollment criteria. With 11 to 36 months follow up, gathering of follow up data was managed between August till the end of Nov 2020, when the last new information was included.

Participants/materials, setting, methods: Patients with a history of RPL or at least one failed ET who were diagnosed as septate uterus by 2D, 3D, or hysteroscopy have been under HWS in a tertiary infertility and recurrent abortion treatment/educational setting. Those with BMI≥32, day 3 FSH≥13 mIU/mL, acquired or hereditary thrombophilia, thyroid disease, and myomatous uterus were excluded. HWS's goal was to remove the septum as a wedge, cutting with 7Fr scissors, in its entirety as much as possible.

Main results and the role of chance: 39 patients who experienced 1 to 8 failed ET and 175 with 2 to 10 miscarriages, were enrolled in the study. The

average septum size based on the depth of the removed wedge was 1.73±0.86 cm. There was an increase of 1.68±0.9 cm in uterine depth and 2.28±0.6 ml in uterine capacity measured by uterine sound and inflation of 8F Folley catheter balloon inside the cavity, respectively. The procedure took 35.75±8.7 minutes. Intraoperative, postoperative, or late complications during the next pregnancies were not reported. 7 patients (17.9%) in failed ET group, conceived spontaneously, before another embryo transfer attempt. Embryo transfer in the remaining 32 cases resulted in 25 (78.1%) clinical pregnancies. 2 miscarried (6.2%), 5(15.6%) are ongoing after 20 weeks of gestation and 25 (78.1%) have resulted in live births. Among 126 clinical pregnancies in RPL group, 16 patients (12.6%) experienced another miscarriage; 6%, 11.3%, and 25% in patients with a previous history of 2, 3, and 4 or more miscarriages, respectively. There was a significant drop in odds of post-procedure miscarriage from 22.7% to 6% (p:0.005) and from 27.8% to 11.3% (p:0.27) with 2 and 3 miscarriage history, respectively. This reduction was not significant with more than 3 losses.

Limitations, reasons for caution: We acknowledge the inherent limitations of this retrospective observational study, confining direct inferences. Our goal is to encourage future prospective studies to compare the effectiveness of different methods of hysteroscopy with or without involving the removal of septal tissue. An RCT comparing metroplasty vs expectant management seems infeasible, though.

Wider implications of the findings: Our findings suggest that timely removal of the uterine septal tissue with hysteroscopy will result in favorable reproductive outcomes in patients with RPL and/or infertility. Also, a history of a normal term pregnancy before subsequent successive losses does not rule out the uterine septum and calls for a thorough assessment.

O-140 Uterine septum: clinical implications on fertility and obstterics outcomes. A systematic review and meta-analysis

G. Spagnol[1], G. Bonaldo[1], M. Marchetti[1], A. Vitagliano[1], A.S. Laganà[2], M. Scioscia[3], A. Andrisani[1], G. Ambrosini[1], D. D'Antona[1], A. Riva[1], C. Saccardi[1], M. Noventa[1]

[1]University of Padua, Department of Woman and Child Health, Padua, Italy ; [2]University of Insubria, Department of Obstetrics and Gynecology- "Filippo Del Ponte" Hospital-, Varese, Italy ; [3]Unit of Gynecological Surgery, Mater Dei Hospital, Bari, Italy

Study question: How does the septate uterus and his metroplasty influence pregnancy rate (PR), live birth rate (LBR), spontaneous abortion rates (SA) and preterm labour rates (PL)?

Summary answer: Uterine septum is associated with a poor reproductive outcome. Metroplasty reduce the rate of SA but non-conclusive evidence can be extrapolated about PR and PL.

What is known already: Different studies evaluated the correlation between uterine septum and reproductive outcomes. On one hand, studies reported its association with poor obstetrics outcomes. On the other hand, recent studies raised doubts about the effectiveness of septum metroplasty to improve reproductive outcomes, although recent position papers continue to propose metroplasty in patients with a septate uterus and a history of infertility or miscarriages. Debate is still ongoing on reproductive outcomes of uterine septum on infertile patients and especially on patients with recurrent miscarriage, leading to an unanswered question whether or not these women should be treated.

Study design, size, duration: Systematic review and meta-analysis of published studies that evaluated the clinical impact of uterine septum and its metroplasty on reproductive and obstetrics outcomes. The meta-analysis included study with infertile patients or patients with a history of recurrent miscarriage. Searches were conducted using the following search terms: uterine septum, septate uterus, metroplasty, pregnancy rate, live birth rate, spontaneous miscarriage, infertility, preterm delivery. Primary outcomes were PR and LBR. Secondary outcomes were SA and PL.

Participants/materials, setting, methods: The meta-analysis was written following the PRISMA guidelines. Fifty-nine full-text articles were preselected based on title and abstract. Endpoints were evaluated in three subgroups: 1) infertile/recurrent miscarriage patients with septum versus no septum 2) infertile/recurrent miscarriage patients with treated versus untreated septum 3) infertile/recurrent miscarriage patients before-after septum removal. Odds-ratios (OR) with 95% confidence intervals (CI) were calculated for outcome measures. Random-effect meta-analysis was performed and a p-value less than 0.05 was considered statistically significant.

Main results and the role of chance: Data from 37 articles were extracted. In the first subgroup (10 studies), a lower PR and LBR were associated with septate uterus vs. controls, respectively (OR 0.39, 95% CI 0.26 to 0.58; p<0.000; low-heterogeneity and OR 0.21, 95% CI 0.12 to 0.39; p<0.0001; small-heterogeneity) and a higher proportion of SA and PL was associated with septate uterus vs. controls, respectively (OR 4.17, 95% CI 2.83 to 6.15; p<0.000; moderate-heterogeneity and OR 2.18, 95% CI 1.27 to 3.76; p=0.005; low-heterogeneity). In the second subgroup (8 studies), PR and PL were not different in removed vs. unremoved septum, respectively (OR 1.10, 95% CI 0.49 to 2.49; p=0.82; moderate heterogeneity and OR 0.44, 95% CI 0.18 to 1.08; p=0.08;low-heterogeneity) and a lower proportion of SA was associated with removed vs. unremoved septum (OR 0.40, 95% CI 0.17 to 0.95; p=0.001; substantial-heterogeneity). In the third subgroup (19 studies), the proportion of LBR was higher after the removal of septum (OR 49.58, 95% CI 29.93 to 82.13; p<0.0001; moderate-heterogeneity) and the proportion of SA and PL was lower after the removal of septum, respectively (OR 0.02, 95% CI 0.02 to 0.04; p<0.000; moderate-heterogeneity and OR 0.05, 95% CI 0.03 to 0.08; p=<0.000; low-heterogeneity).

Limitations, reasons for caution: The present meta-analysis is limited by the observational design of included studies because, in literature, there are no prospective randomized controlled trials (RCTs). In the second and third subgroup of analysis clinical heterogeneity within and between studies represents another limitation.

Wider implications of the findings: The results of this meta-analysis confirm the detrimental effect of uterine septum on PR, LBR, SA and PL. Its treatment seems to reduce the rate of SA. Metroplasty should still be considered as good clinical practice in patients with a history of infertility and recurrent abortion.

O-053 Early life factors that may influence adult male reproductive

R. Hart[1]

[1]*University of Western Australia & Fertility Specialists of WA, Division of Obstetrics and Gynaecology, Perth- Western Australia, Australia*

Abstract text

This presentation will provide a brief overview of testicular development and will describe a critical period of development at approximately 8-14 weeks of gestation, when the testicle may be vulnerable to external influences, potentially having a negative effect on subsequent development. The talk with then describe the testicular dysgenesis syndrome hypothesis, proposed by Niels Skakkebæk, and using the presenters work within the Western Australian (Raine) Cohort will go onto demonstrate how early life exposures may influence mature testicular function. Worryingly, the presentation will describe how adolescent features of early metabolic disturbance within the Raine Cohort are already having a determinantal effect on the reproductive function of these men in late adolescence, many years before the majority are seeking paternity.

O-055 Why we should be testing embryos for polygenic traits

J. Savulescu[1]

[1]*University of Oxford, Faculty of Philosophy, Oxford, United Kingdom*

Abstract text

The past few years have brought significant breakthroughs in understanding human genetics. This knowledge has been used to develop 'polygenic scores' (or 'polygenic risk scores') which provide probabilistic information about the development of polygenic conditions such as diabetes or schizophrenia. They are already being used in reproduction to select for embryos at lower risk of developing disease. The world's first baby, Aurea, has been born after being selected on the basis of a Genomic Health Index score provided by Genomic Prediction (https://www.youtube.com/watch?v=HE5ADe7BgdM&ab_channel=GenomicPrediction).

I argue for the use of this technology not only for the selection of embryos at lower risk of disease but for the selection of advantageous non-disease traits.

Currently, the use of polygenic scores for embryo selection is subject to existing regulations concerning embryo testing and selection. Existing regulatory approaches include 'disease-based' models which limit embryo selection to avoiding disease characteristics (employed in various formats in Australia, the UK, Italy, Switzerland and France, among others), and 'laissez-faire' or 'libertarian' models, under which embryo testing and selection remain unregulated (as in the USA). With Sarah Munday, I have introduced a novel 'Welfarist Model' which limits embryo selection according to the impact of the predicted trait on well-being. We compare the strengths and weaknesses of each model as a way of regulating polygenic scores. Polygenic scores create the potential for existing embryo selection technologies to be used to select for a wider range of predicted genetically influenced characteristics including continuous traits. Indeed, polygenic scores exist to predict future intelligence, and there have been suggestions that they will be used to make predictions within the normal range in the USA in embryo selection. We examine how these three models would apply to the prediction of non-disease traits such as intelligence. The genetics of intelligence remains controversial both scientifically and ethically. This paper does not attempt to resolve these issues. However, as with many biomedical advances, an effective regulatory regime must be in place as soon as the technology is available. If there is no regulation in place, then the market effectively decides ethical issues.

O-056 Evaluating the utility of screening human IVF embryos with polygenic risk scores for complex diseases

Study question: It is now feasible to screen human IVF embryos with "polygenic risk scores" for predicting complex disease risk. What is the expected risk reduction?

Summary answer: Under some conditions, prioritizing embryos based on polygenic risk scores can lead to substantial disease risk reductions. However, only excluding high-risk embryos is less effective.

What is known already: Recent genetic studies have identified numerous mutations associated with complex diseases, leading to the development of accurate polygenic risk scores (PRSs) for disease risk prediction. Given that genomes of human IVF embryos can now be sequenced with relative ease, it has become technically feasible to use PRSs for prioritization of embryos for transfer. Clearly, such use is associated with ethical and social concerns, from inequality to eugenics. Nevertheless, polygenic embryo screening is already offered to consumers, with little research so far on expected outcomes. Our previous evaluation of screening IVF embryos for polygenic traits showed little current utility.

Study design, size, duration: This is a theoretical/computational study based on statistical genetics theory and simulations.
Participants/materials, setting, methods: We used the liability threshold model to estimate the disease risk given the PRS. We considered screening for a single disease (with known prevalence and PRS accuracy), and assumed that n viable embryos are available. We calculated the risk of the child given these parameters and the prioritization strategy, either when parents are random or when their disease status is known. We also used simulations based on genomic data from a schizophrenia case-control study.
Main results and the role of chance: We modeled the disease risk of a hypothetical future child when the PRSs of embryos are used for prioritization, relative to random selection. When selecting an embryo at random among those who do not have an extremely high risk (typically, top 2% of the PRS distribution), the relative risk reduction (RRR) is limited, and is under 10% for currently realistic scenarios. In contrast, selecting the lowest risk embryo for implantation results in substantial RRRs of ~20-50% already with n=5 embryos and realistic disease parameters. For example, the RRR for schizophrenia is >40% with current PRSs, a result we validated with simulated genomes of parents and children based on genotypes from a schizophrenia study. When one of the parents is known to be affected, selecting the lowest risk embryo out of n=5 may restore the risk of the future child to nearly normal levels.
Limitations, reasons for caution: Our analytical modeling is based on several simplifying assumptions regarding the dependence of the risk on the PRS and the accuracy of the PRS. Further, the estimated risk reductions depend on the availability of n=5 embryos that could lead to a live birth.
Wider implications of the findings: Under some conditions, prioritizing embryos for transfer based on polygenic risk scores could lead to substantial disease risk reductions. However, predicted outcomes vary considerably with prioritization strategies and disease and PRS parameters. The emerging ethical and social concerns and the challenges in communicating these results need to be urgently discussed.

POSTER DISCUSSION

SESSION 45: MALE AND FEMALE FERTILITY PRESERVATION POSTER DISCUSSIONS

30 June 2021 Stream 3 08:30 - 09:30

P-437 The ovaries of transgender men indicate effects of high dose testosterone on the primordial and early growing follicle pool

E. Bailie[1], M. Maidarti[1], R. Hawthorn[2], S. Jack[3], N. Watson[4], E. Telfer[1], R. Anderson[1]

[1]University of Edinburgh, reproductive biology, Edinburgh, United Kingdom ; [2]Queen Elizabeth University Hospital, Gynaecology, Glasgow, United Kingdom ; [3]Royal Infirmary Edinburgh, Gynaecology, Edinburgh, United Kingdom ; [4]Spire Thames Valley Hospital, Gynaecology, London, United Kingdom

Study question: Does high-dose testosterone therapy affect the stage distribution, morphological health and DNA damage repair capacity of human ovarian follicles and their survival *in vitro*?
Summary answer: Testosterone exposure is associated with reduced follicle growth activation, reduced follicle health and increased DNA damage: these further deteriorate after six days of culture.
What is known already: Androgens have diverse actions within the ovary, however, there is a lack of information regarding the long-term effects of high-dose testosterone on ovarian function and reproductive potential. Cumulus-oocyte complexes recovered from transgender men have been successfully matured *in-vitro* but little is known regarding the impact of this gender affirming endocrine therapy on the primordial follicle pool.
Study design, size, duration: Whole ovaries were obtained from four transgender men aged 25-36 years with informed consent at oophorectomy. All patients had received 1000mg testosterone undecanoate intramuscularly at 12-16 week intervals for a minimum of 4 years pre-operatively. Cortical tissues were dissected into small pieces (≈1x1x0.5mm) and either immediately fixed for histological analysis or cultured for 6 days. Testosterone-treated ovaries were compared to cortical biopsies from age-matched healthy women obtained at caesarean section (n=4, age 26-36).
Participants/materials, setting, methods: Follicle number, classification of developmental stage and morphology were evaluated by histological analysis of ovarian cortical tissue from day 0 and 6 days post culture. Immunohistochemical analysis included γH2AX as a marker of DNA damage, and meiotic recombination 11 (MRE11), ataxia telangiectasia mutated (ATM) and Rad51 as DNA repair proteins. A total of 3802 follicles from testosterone exposed and 878 from control ovaries were analysed.
Main results and the role of chance: At day 0 (D0), transgender tissue had a higher proportion of non-growing follicles (92.7±1.7%) compared to control (85.4±6.2%, $p<0.05$) but a lower proportion of morphologically healthy follicles (non-growing 59%, primary 61%, secondary 36%; vs 83%, 75%, 80% in controls, all $p<0.005$). After 6 days in culture, the proportion of growing follicles increased (51.3% vs 46.5%) but follicle health further declined (all stages $p<0.005$).

DNA damage was assessed by expression of γH2AX. At D0, the proportion of oocytes showing DNA damage was significantly higher in transgender non-growing follicles (48.1±12.5%, vs 12.3±0.25%, $p<0.005$). After culture, γH2AX expression increased in both transgender ($p<0.005$) and controls ($p<0.005$) but remained higher in transgender oocytes (non-growing 72.2%, primary 71.7% vs 27.3%, 46.2%, all $p<0.05$).

At D0, there was no difference in expression of DNA repair enzymes ATM and RAD51 between transgender and control oocytes, and increased expression of MRE11 in control non-growing follicles ($p<0.05$). Post-culture, there was a significant increase in ATM expression in transgender non-growing oocytes compared to control (98.5% vs 77.8%, $p<0.05$) and a less marked decline in RAD51 expression($p<0.05$). The expression of MRE-11 in control non-growing oocytes dramatically declined (100% to 58.2%, $p<0.05$), unlike in transgender tissue where expression was comparable to D0.
Limitations, reasons for caution: A large number of follicles have been analysed, but only from a small number of ovaries. DNA damage at D0 and after 6 days of culture may not reflect DNA damage and repair capacity at later stages of follicle growth. The effect of duration of testosterone treatment was not investigated.
Wider implications of the findings: These data indicate that high circulating concentrations of testosterone have previously unrecognised effects on the primordial and small-growing follicles of the ovary. These results may have implications for transgender men receiving gender-affirming therapy prior to considering pregnancy or fertility preservation measures.
Trial registration number: n/a

P-444 Presence of pharmacological inhibitors of the PI3K/PTEN/Akt and mTOR signalling pathways during cryopreservation and organotypic cultures of murine ovaries limits early primordial follicle depletion

C. Terren[1], M. Nisolle[2], C. Munaut[1]

[1]University of Liège, Laboratory of Tumor and Development Biology GIGA-Cancer, Liège, Belgium ; [2]University of Liège, Department of Obstetrics and Gynecology Hôpital de la Citadelle, Liège, Belgium

Study question: Which signalling pathways are implicated in primordial follicle activation induced by cryopreservation and/or organotypic culture? Is it possible to limit this activation through pharmacological inhibitors?
Summary answer: Our findings provide support for the hypothesis that mTOR and PI3K inhibitors might represent an attractive tool to delay cryopreservation- and culture-induced primordial follicle activation.
What is known already: Cryopreservation of ovarian tissue containing immature primordial follicles followed by auto-transplantation (OTCTP) is the only option available to preserve the fertility of prepubertal patients or patients requiring urgent therapy for aggressive malignancies. However, a major obstacle in this process is follicular loss immediately after grafting, possibly due to slow neovascularization, apoptosis and/or massive follicular recruitment. *In vitro* and *in vivo* studies indicate that the PI3K/PTEN/Akt and mTOR signalling pathways are involved in follicle activation. The transplantation process seems to be the

major cause of primordial follicle activation after OTCTP but information about how cryopreservation itself impacts follicle activation is sparse.
Study design, size, duration: Whole murine ovaries (4-8-weeks old) were cryopreserved by slow freezing and exposed to LY294002 (a powerful PI3K inhibitor) or rapamycin (a specific mTOR inhibitor) during cryopreservation and/or organotypic *in vitro* culture for a 24 h or 2 days.
Participants/materials, setting, methods: Western Blot and immunofluorescence analyses were used to determine the activation of PI3K/PTEN/Akt and mTOR signalling pathways in murine ovaries cryopreserved and/or organotypically cultured with/without inhibitors.Follicles were quantified according to their maturation degree on H&E stained histological sections.
Main results and the role of chance: Ratio of phosphorylated Akt or rps6 to total proteins (p-Akt/Akt and p-rps6/rps6) was increased in slow-frozen murine ovaries compared to control fresh ovaries, indicating an activation of the PI3K/PTEN/Akt and mTOR signalling pathways. The use of pharmacological inhibitors of follicle signalling pathways (LY294002 (25µM) and rapamycin (1µM)) during the cryopreservation process decreased p-Akt/Akt and p-rps6/rps6 ratios. *In vitro* organotypic culture for 24 h increased only the activation of the PI3K/PTEN/Akt pathway, as shown by increased p-Akt/Akt ratio in fresh ovaries cultured for 24 h compared to fresh non-cultured ovaries. This activation can be counteracted by cryopreservation of murine ovaries with rapamycin followed by *in vitro* culture for 24 h in the presence of LY294002. Follicle density quantifications indicated that when cryopreserved ovaries were maintained in culture for 2 days, a decrease of primordial follicle density concomitant with an increase of secondary and more mature follicles were found in comparison to slow-frozen/thawed ovaries without culture. Supplementation of the culture medium with LY294002 and rapamycin for 24 h or 2 days preserved primordial follicle densities compared to ovaries cultured without inhibitors.
Limitations, reasons for caution: This study is an *in vitro* study using murine ovaries. To analyze the efficiency of LY294002 and rapamycin to limit cryopreservation and transplantation induced follicle recruitment, these inhibitors should be tested in an *in vivo* model. Furthermore, these findings will need to be confirmed with human samples.
Wider implications of the findings: We showed for the first-time that the sequential use of pharmacological inhibitors, rapamycin during the slow freezing process followed by organotypic culture supplemented with LY294002, is effective to limit early primordial follicle depletion.
Trial registration number: /

P-450 Effects of rheumatoid arthritis and methotrexate therapy on ovarian reserve in infertile women

G. Vlasova[1], S. Perminova[1]

[1]Russian Federation, Moscow, Moscow, Russia C.I.S.

Study question: Do patients with infertility and rheumatoid arthritis (RA) treated with methotrexate (MTX) have ovarian reserve alterations?
Summary answer: Women with infertility and RA treated with MTX were found to have statistically significant decrease of ovarian reserve.
What is known already: Rheumatoid arthritis (RA) is one of the most prominent inflammatory diseases affecting women of child-bearing age [Brouwer J. et al, 2014]. RA and its treatment may interfere with the female reproductive physiology. The vast majority of patients with RA are treated with methotrexate (MTX) which is a folate antagonist that inhibits DNA synthesis. MTX, which is the anchor drug in RA, targets actively proliferating cells including the oocytes and granulosa cells which may impair the ovarian reserve [Min Tun Kyaw et al, 2020].
Study design, size, duration: A prospective case-control study that enrolled 72 female patients with infertility was conducted in the 2-year time period of September 2018 to October 2020.
Participants/materials, setting, methods: The main group comprised 32 patients with infertility and RA;

the control group consisted of 40 women with infertility only. Patients with RA were stratified into subgroups based on whether or not they received MTX.

To investigate ovarian reserve measurement of serum anti-Müllerian hormone (AMH) was used. The level of AMH was evaluated concerning RA duration and activity, as well as the age at initiation of MTX therapy, dosage, and treatment duration.

Main results and the role of chance: The mean age of the study population was 36±3 years. The duration of RA was 4 [3;11] years. The low disease activity based on DAS28-ESR (disease activity score based on 28 joints using the erythrocyte sedimentation rate) prevailed(56.2%).

In the main group 19(59.4%) women received MTX therapy. The MTX dosage was 15 [15;20]mg /wk, the duration of MTX therapy by the day of inclusion in the study was 18.7[1;15]months.

The AMH level was significantly lower in the main group (2.1 n /ml vs 2.73ng /ml, p=0.043). The number of patients with decreased ovarian reserve (AMH level<1.0ng/ml) significantly prevailed in the group of patients with RA (25% vs 5%, p=0.015).

When assessing the AMH level in patients with RA who received MTX (n=19) and patients in the control group, there was a tendency towards a decrease in the indicator in the first subgroup, but no statistically difference was found (p=0.074).

Correlation analysis of the dependence of AMH level on the patient age showed the most significant decrease in AMH in the patients with RA receiving MTX compared to the patients with RA who did not, and compared to all patients with RA regardless of the therapy received (rs=-0.563)(p <0.05).
Limitations, reasons for caution: The lack of statistically significant data in certain cases may be due to the small sample size.
Wider implications of the findings: RA and MTX administration are associated with a significant decrease in AMH levels. The age of initiation of the therapy is negatively correlated with the AMH level. In this regard, patients with already compromised reproductive function who are planning to receive MTX should be advised to preserve the genetic material.
Trial registration number: 567890

P-461 Pre-selected for an award: A 16-year bicentric retrospective analysis of ovarian tissue cryopreservation (OTC) in paediatric patients: indications, results and outcome

M. Grellet-Grün[1], B. Delepine[1], P. Le Van Quyen[2], A. Durlach[3], C. Greze[4], L. Ladureau-Fritsch[4], I. Lichtblau[4], A.S. Canepa[1], F. Becmeur[5], A. Liné[6], C. Paillard[7], C. Pluchart[8], O. Pirello[9], M. Teletin[4]

[7]Hôpital de Hautepierre, Department of Pediatric Onco-Hematolology, Strasbourg, France ;
[8]Centre Hospitalier Universitaire de Reims, Department of Pediatric Onco-Hematolology, Reims, France ;
[9]Centre Médico-chirurgical Obstétrique, Department of Gynecology-Obstetric, Schiltigheim - Strasbourg, France

Study question: What is the outcome of ovarian tissue cryopreservation (OTC) in paediatric patients from the beginning of its setting in two different French centres?
Summary answer: In our cohort of 75 paediatric patients who underwent OTC, the mean age, malignancy rate and survival rate were 9.7 years, 70.7% and 77.3% respectively.
What is known already: Cancer treatments of last decades improve the survival rate of children and adolescents;

however chemo- and radiotherapy result in gonadal damage leading to acute ovarian failure and sterility. The preservation of fertility is now an integral part of care of children requiring gonadotoxic treatments.

Currently OTC represents the only possibility of preserving the potential fertility in prepubertal girls. OTC is an effective fertility preservation option which allows long-term storage of primordial follicles, subsequent transplantation restores endocrine function and fertility. The efficacy of these techniques is well-demonstrated within adult population but the data are poor for paediatric patients.

Study design, size, duration: This is a retrospective study of OTC practice of two French centres from January 2004 to May 2020.
Participants/materials, setting, methods: A total of 75 patients from paediatrics units underwent cryopreservation of ovarian tissue before gonadotoxic therapy for malignant or benign diseases. The ovarian cortex was cut into fragments and the number of follicles per square millimeter was evaluated histologically. The long-term follow-up includes survival rate, hormonal and fertility status.
Main results and the role of chance: The mean age at OTC of 75 patients was 9.7 years [0.2 – 20], 32% were postpubertal. 53 had malignant disease and 22 had non-malignant disease. The most frequent diagnoses in this cohort included acute leukemia, hemoglobinopathies and neuroblastoma. Indication for OTC was stem cell transplantation for 78.7% (n=59) girls.

A third of each ovary was collected for 62,7% (n=47) patients, a whole ovary for 33,3% (n=25) patients and a third of one ovary alone for 4,0% (n=3) patients. An average of 17 fragments [5-35] per patient was cryoconserved. A correlation was found between age and the number of fragments ($p < 0.001$). More fragments were obtained from partial bilateral harvesting than from whole ovary harvesting ($p<0.05$). Histological analysis of ovarian tissue showed a median of 6.0 primordial follicles/mm2 [0.0–106.5] and no malignant cells were identified. A negative correlation was found between age and follicular density ($p<0.001$).

Median post-harvest follow-up was 92 months [1–188]: 17 girls had died, 12 were still treated for their pathology and 46 were in complete remission. Of all patients, 29 have been subject to hormonal status evaluation and 26 were diagnosed with premature ovarian insufficiency ($p<0.001$). One patient had undergone thawed ovarian tissue transplantation.
Limitations, reasons for caution: This study is a retrospective analysis. The cohort was not compared with a control group who did not undergo OTC or with an adult population. Furthermore, many of these girls are still young and do not intend to use the transplantation of thawed ovarian tissue yet.
Wider implications of the findings: OTC should be proposed to all girls with high risk of developing premature ovarian insufficiency following gonadotoxic therapies in order to give them the possibility of fertility and endocrine restoration.
Trial registration number: Not applicable

O-141 Mapping of SARS-CoV-2-associated receptors and proteases mRNA in human endometrium during natural and stimulated cycles

D. Haouzi[1], F. Entezami[2], S. Brouillet[3], F. Barry[3], A. Gala[3], A. Ferrieres-Hoa[3], A. Tal[4], S. Hamamah[3]

[1]INSERM U1203, IRMB- Hôpital St-Eloi- CHRU Montpellier, MONTPELLIER, France ;
[2]American Hospital of Paris, ART department, Neuilly-Sur-Seine, France ;
[3]IRMB- Inserm U1203, Hôpital St-Eloi- CHRU Montpellier, Montpellier, France ;
[4]CHU and University of Montpellier, Department of Reproductive Medicine, Montpellier, France

Study question: Covid-19 pandemic has significantly affected the assisted reproductive technology (ART) practice. Understanding whether SARS-CoV-2 could infect endometrial tissues during ART is crucial for risk mitigation
Summary answer: Analyses of gene expression profiles of SARS-CoV-2 host entry candidates from microarray data suggest that endometrium should be considered as potential target for SARS-CoV-2 infection.
What is known already: Very few studies analyzed the gene expression profiles of SARS-CoV-2-associated receptors and proteases, mainly focusing on *ACE2* and *TMPRSS2* expression, resulting incomplete knowledge in different specimens from female genital tract. However, no studies have analyzed the potential impact of controlled ovarian stimulation (COS) protocols during ART procedure on the endometrial gene expression profiles of SARS-CoV-2-associated receptors and proteases
Study design, size, duration: To address this question, we retrospectively examined the gene expression profile of SARS-CoV-2-associated receptors and proteases in endometrial biopsies of a cohort of ART candidates using Affymetrix microarray data
Participants/materials, setting, methods: Human endometrial tissue under natural (n=62) and COS cycles (n=42) were analyzed. A focus was particularly made on the renin-angiotensin system relates genes with a prominent role in the virus infection, and gene expression levels of receptors and proteases closely related to SARS-CoV-2 infectionwas also studied.
Main results and the role of chance: Using our large cohort of endometrial samples, we reported a high prevalence of genes related to the ACE2 pathway, including *AGT*, *AGTR1*, *ANPEP*, *CTSA*, *ENPEP*, *LNPEP*, *MME*, *NLN*, *THOP1*, *BSG* and *CTSL* during both phases(early- and mid-secretory phase), and mainly during the mid-secretory phase for *ACE2*. The highest signal intensities were found for *CTSA*, *LNPEP*, *MME*, *NLN*, *BSG* and *CTSL*. The most representative of dual coexpression of SARS-CoV-2-associated receptor and protease in endometrium was *BSG-CSTL* and *BSG-CTSA*. It s also important to note high variation of SARS-CoV-2 receptors inter-patients under natural cycle.Globally, the impact of COS on endometrial gene expression profile of SARS-CoV-2-associated receptors and proteases of non Covid-19 patients is low, suggesting no additional potential risks of SARS-CoV-2 infection during stimulated ART procedure compared with natural cycles.
Limitations, reasons for caution: Analyses of Affymetrix microarray gene expression data were performed in non-COVID-19 patients. Whether the SARS-CoV-2 infection changes the endometrial gene expression profile of SARS-CoV-2-associated receptors and proteases is under investigation
Wider implications of the findings: Specimens from female genital tract may be considered as potential targets for SARS-CoV-2.
Trial registration number: not applicable

O-142 COVID19-free endometrium: Undetectable viral RNA in endometrial biopsies from positive symptomatic SARS-CoV-2 women

L. De Miguel-Gómez[1,2], M. Romeu[3,4], N. Pellicer[3,4], A. Faus[1], A. Pellicer[2,5], I. Cervelló[4]

[1]IVI Foundation, Research, Valencia, Spain ;

[3]Hospital Universitari i Politècnic La Fe, Women's Health Area- Human Reproduction Unit, Valencia, Spain ;
[4]Instituto de investigación sanitaria La Fe, Reproductive Medicine Research Group, Valencia, Spain ;
[5]IVIRMA Rome, Gynecology, Rome, Italy

Study question: Does SARS-CoV-2 infect the endometrial tissue in women with coronavirus disease 2019 (COVID-19)?
Summary answer: Symptomatic women with COVID-19 report no presence, in the short term, of viral RNA from SARS-CoV-2 in the endometrium.
What is known already: The recent emergence of COVID-19, caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), has not allowed yet to establish putative relations between this disorder and other existing pathologies. It is the case with fertility problems and the reproductive organs, including a possible endometrial disorder caused by the virus. Thus, an important step is to elucidate the viral presence in different human tissues to improve diagnostics, prevention and/or treatment. The hypothesis of the possible infection of the endometrial tissue comes from the described expression of ACE2 protein in the human endometrium, mainly in stromal cells during the secretory phase.
Study design, size, duration: 15 endometrial biopsies from symptomatic and hospitalized women with COVID-19 were collected. Endometrial samples were obtained from August to November 2020 at the Hospital Universitari i Politècnic La Fe (Valencia, Spain); the project received the approval of the hospital's medical ethics committee (registration number: 2020-268-1). The main objective was to study by real-time PCR (RT-PCR) the presence of viral RNA from SARS-CoV-2 as well as the expression of ACE2 receptor on the endometrial tissue.

Participants/materials, setting, methods: 15 women in the reproductive age (24-46 years) accepted to participate in the study and signed the informed consent. All these patients tested positive for SARS-CoV-2 by RT-PCR of nasopharyngeal swabs (1-17 days before the biopsy collection) and were hospitalized due to health complications (pneumonia) derived from COVID-19. Endometrial biopsies were taken by aspiration and preserved in RNA-later until -80°C cryopreservation in a biobank; RNA was extracted for RT-PCR for N1, N2, and ACE2 genes.

Main results and the role of chance: The 15 recruited patients represented the different phases of the menstrual cycle: proliferative (n=3) and secretory (n=10); 2 patients had amenorrhea. The viral RNA for SARS-CoV-2, measured by the detection of N1 and N2 gene targets (fragments of N gene, from the viral nucleocapsid) by RT-PCR methodology, was undetectable in all the endometrial biopsies analyzed (n=15). In all the cases the housekeeping gene RPP30 was used as positive control and to check RNA integrity. To correlate the presence or absence of SARS-CoV-2 with the organ-specific expression of ACE2 (angiotensin-converting enzyme 2), the main postulated entry receptor of SARS-CoV-2, the endometrial RNA was also analyzed by RT-PCR for the ACE2 receptor gene. This gene was only detectable in 10 of the 15 biopsies, and the levels ranged from 28.65 to 36.19 Ct values, revealing a very low expression of ACE2 in the tissue. Moreover, ACE2 results did not report any correlation with the phase of the menstrual cycle.

Limitations, reasons for caution: These results imply endometrium is safe from SARS-CoV-2 infection, at least in the short term. All the endometrial samples were taken at maximum of 17 days after a positive test by RT-PCR of nasopharyngeal swabs (to note that all were hospitalized during the early stages of the disease).

Wider implications of the findings: In conclusion, the SARS-CoV-2 RNA is not present in the human endometrial tissue of positive patients. This hypothesis was reinforced by the low ACE2 receptor levels. However, an in-depth genetic analysis comparing to a negative control group could elucidate a systemic affectation of the endometrium, despite the negative RT-PCR results.

Trial registration number: not applicable

O-143 Characterization of vaginal and endometrial microbiome in patients with chronic endometritis (CE).

P. LOZANO[1], A. Bernabeu[2], B. Lledó[1], R. Morales[1], F.I. Aranda[3], J. Llacer[2], R. Bernabeu[2]

[1]Instituto Bernabeu, Molecular Biology and Genetics, Alicante, Spain ;
[2]Instituto Bernabeu, Fertility and Gynecology, Alicante, Spain ;
[3]HGUA, Servicio Anatomía Patológica, Alicante, Spain

Study question: Could vaginal and endometrial microbiome by sequencing 16S rRNA be comparable to classic diagnostic methods or immunohistochemistry CD138 for diagnosis of chronic endometritis?

Summary answer: A characteristic endometrial and vaginal microbiome is present in patients with chronic endometritis. An abnormal vaginal microbiome correlates with the presence of chronic endometritis.

What is known already: Chronic endometritis is a disease characterized by persistent inflammation of the endometrial lining. Currently, histopathological evaluation by immunohistochemistry CD138 marker is most common diagnostic method for CE. Microbiome analysis based on subunit 16S rRNA sequencing is a fast tool that can enable the identification of pathogenic microorganisms associated with CE. The main bacteria at vaginal and endometrial level belong to genus *Lactobacillus*, producers of lactic acid that allows maintaining acidic pH of vagina and acts as barrier against pathogens. Investigations on the effect of an abnormal endometrial and vaginal microbiome could improve assisted reproductive technologies.

Study design, size, duration: This is a observational pilot study (60 patients and 120 samples). The study population consists of patients attending to our fertility clinic for frozen euploid embryo transfer (FET) from May 2017 to May 2019. Preimplantation Genetic Testing of aneuploidy (PGT-A) was performed at blastocyst stage using Veriseq (Illumina). The inclusion criteria to be meet by patients were: age between 18 and 50 years, own or donated oocytes and use of ICSI.

Participants/materials, setting, methods: Cohort study with sixty patients undergoing assisted reproductive treatment (TRA) with their own or donated gametes and PGT-A Vaginal and endometrial samples were taken in the cycle prior to embryo transfer. The vaginal and endometrial microbiome was analyzed by mass sequencing of the V3V4 region of 16S rRNA. Bioinformatics analysis was performed using QIIME2 and MicrobiomeAnalyst packages. Alpha, beta diversity and taxonomic characterization were compared with positive and negative CD138 groups for chronic endometritis (CE).

Main results and the role of chance: Different bacterial communities were detected when vaginal and endometrial samples were analyzed in patients with and without endometritis diagnosed with CD138 immunohistochemistry. In patients with endometritis, a higher alpha diversity index tendency was found in vaginal samples (p=0.15 for the Shannon index) and significant differences in endometrial samples (p=0.01 for the Shannon index). In the beta diversity analysis, no significant differences were observed between the groups established as per the diagnosis of endometritis. Vaginal and endometrial samples from women with endometritis showed a microbiome pattern not dominated by *Lactobacillus* spp. Relative abundance analysis identified the genera *Ralstonia* and *Gardnerella* in endometrial sample, and the genera *Streptoccoccus* and *Ureaplasma* in vaginal sample of patients diagnosed with CD138 for endometritis. Comparing endometrial and vaginal samples CD138 positive diagnosed for endometritis, alpha diversity (p=0.06 for the Shannon index and p=0.08 for the Simpson index) and beta diversity (p<0.001) showed significant differences. Relative abundance identified the genera *Lactobacillus* (p=3.76E-4), *Ralstonia* (p=8.19E-4), *Delftia* (p=0.004) and *Anaerobacillus* (p=0.004) in these sample groups.

Limitations, reasons for caution: The main limitation of this study is the small sample size. Larger studies including a higher number of samples are needed to confirm the different microbiome pattern observed at the vaginal and endometrial levels in correlation with chronic endometritis. The microbiome pattern has not been analyzed after treatment of CE.

Wider implications of the findings: Our findings suggest the existence of a characteristic vaginal and endometrial microbiota in patients with chronic endometritis. Different genera and species were identified in patients with and without endometritis depending on whether the sample was endometrial or vaginal. An abnormal vaginal microbiome appears to be strongly correlated with chronic endometritis.

Trial registration number: Not Applicable

O-144 Endometrial production of 17β-estradiol in relation to pregnancy outcome in women undergoing IVF/ICSI

L.B.P.M. Stevens Brentjens[1], B. Delvoux[1], J.E. Den Hartog[1], F. Morgan[2], M.B. Baker[2], L. Moroni[2], N.E. Van Hoogenhuijze[3], H.L. Torrance[3], F.J.M. Broekmans[3], SCRaTCH-2 Study Group(4), R.J.T. Van Golde[1], A. Romano[1]

[1]Maastricht University Medical Center+ and Maastricht University- GROW School for Oncology and Developmental Biology, Department of Obstetrics and Gynaecology, Maastricht, The Netherlands ;
[2]MERLN Institute, Department of Complex Tissue Regeneration, Maastricht, The Netherlands ;
[3]Universitair Medisch Centrum Utrecht, Divisie Vrouw en Baby- Gynaecologie & Voortplantingsgeneeskunde, Utrecht, The Netherlands ;
[4]Amsterdam Medisch Centrum, F. Mol, Jeroen Bosch Ziekenhuis

Study question: Does the endometrial synthesis and inactivation of 17β-estradiol differ between receptive and non-receptive endometrium in women undergoing IVF/ICSI?

Summary answer: The synthesis and inactivation of 17β-estradiol is similar in the endometrium of women who did and did not achieve a clinical pregnancy through IVF/ICSI.

What is known already: Implantation failure of high-quality embryos is a main concern in IVF/ICSI treatment. Blood sex-steroid concentrations do not reflect their corresponding concentrations in endometrial tissue. This is in line with the concept that blood steroids (and precursors) are locally converted to bioactive metabolites and vice versa, by expressing steroid-metabolising enzymes, such as 17β-hydroxy steroid dehydrogenase (17β-HSD). Studies indicate that alterations in intracrinology might modulate endometrial receptivity. We hypothesize that the local 17β-HSD activity during the window of implantation (WOI) differs between pregnant and non-pregnant IVF/ICSI patients.

Study design, size, duration: Case-control study of 40 patients that were recruited in the SCRaTCH study (NL5193/NTR5342), a randomised trial exploring whether 'endometrial scratching' in patients with a previous IVF/ICSI cycle

failure affects pregnancy outcome in a subsequent IVF/ICSI cycle. For the present investigation, 20 endometrial biopsies from women who achieved clinical pregnancy after fresh embryo transfer (ET) were compared with 20 endometrial biopsies of women that did not conceive after fresh ET.

Participants/materials, setting, methods: Endometrial biopsies and serum were obtained at LH+5-8 days (urinary test) in a natural cycle, prior to the fresh ET cycle. Cases (negative pregnancy test, n=20) and controls (clinically pregnant, n=20) were matched for primary vs. secondary infertility, embryo quality and age. Reduction of estrone to 17β-estradiol (synthesizing 17β-HSDs) and oxidation of 17β-estradiol to estrone (inactivating 17β-HSDs) were determined by high-performance liquid chromatography (HPLC). Results were compared with the Wilcoxon-Mann-Whitney Rank Sum Test.

Main results and the role of chance: Activity of 17β-HSDs responsible for the reduction of estrone to 17β-estradiol (mainly 17β-HSD type 1) was detected in all samples and ranged from 55 to 1864 pmol 17β-estradiol formed/mg protein/24 h. The values obtained from pregnant women (median: 1054) were not significantly different to those obtained from non-pregnant women (median: 997), p=0.97. The activity of enzymes responsible for the oxidation of 17β-estradiol (mainly 17β-HSD type 2) into the less active estrone ranged from 32 to 1731 estrone formed/mg protein/24 h. The values obtained from pregnant women (median: 737) were not significantly different to those obtained from non-pregnant women (median: 624), p=0.90. The ratio of 17β-HSD type 1:17β-HSD type 2 had a median of 1.63 in the pregnant woman compared to 1.95 in the group of non-pregnant woman (p=0.57).

Limitations, reasons for caution: The study is pilot in nature and study population is small. Primary and secondary infertility patients were analysed together. A chance phenomenon could have occurred as included women were included after their first IVF/ICSI cycle, hence not every included study person met the criteria for repeated implantation failure (RIF).

Wider implications of the findings: 17β-estradiol metabolism takes place during the WOI, controlling the final 17β-estradiol level. Although the present investigation did not show differences between pregnant and non-pregnant women, it remains important to explore if estrogen balance deviations, e.g. in other cycle phases plays a role in clinical conditions such as primary infertility/RIF.

Trial registration number: NL5193/NTR5342

O-145 Green Tea catechins EGCG and pro-drug of EGCG (Pro-EGCG) inhibit endometriosis through targeting molecules regulating macrophages and B cells

S.W. Hung[1], M. Gaetani[2], Z.Y.R. Tan[1], R.Z. Zhang[1], R.A. Zubarev[2], C.C. Wang[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics & Gynaecology, Hong Kong, Hong Kong ;
[2]Karolinska Institutet, Department of Medical Biochemistry and Biophysics, Stockholm, Sweden

Study question: What are the therapeutic targets and mechanisms of green tea EGCG and Pro-EGCG in treating endometriosis?

Summary answer: EGCG and Pro-EGCG have unique molecular targets to regulate interactions of B cells, macrophages and endometriotic cells and limit the growth and development of endometriosis.

What is known already: Current treatments of endometriosis are mainly hormonal suppression and surgical ablation or removal. Our previous studies showed EGCG significantly inhibits development of experimental endometriosis in mice. Pro-EGCG is more effective than EGCG in term of anti-endometriosis, anti-angiogenesis and anti-oxidation (Wang, et. al., 2013; Xu, et al., 2011). Dysfunctional immunological activities of macrophages and B cells were found in women with endometriosis. The molecular targets, underlying mechanism and differential therapeutic efficacy of EGCG and Pro-EGCG, as well as their anti-inflammatory activities are still not known.

Study design, size, duration: Multiplexed Proteome Integral Stability Alteration (PISA) assay (Gaetani et al.,2019), followed by MS/MS was applied to identify the molecular targets of EGCG and Pro-EGCG in endometriotic cells. Pharmacological studies of EGCG and Pro-EGCG on endometriotic cell line and endometriosis models in mice were performed to characterise their anti-endometriosis and anti-inflammatory effects. Gene silencing and over-expression experiments were conducted to confirm the immunoregulatory mechanisms.

Participants/materials, setting, methods: Endometriotic (Hs832(C)T) cell lines in culture and lysate were treated for chemical proteomics analysis. SiRNA and overexpression vectors were transfected to the cells *in vitro* and lesions *in vivo*. Hs832(C).T, monocytic cells (THP-1) and control B cell (Raji null) lines were used for co-culture assays to study the interaction between endometriotic and immune cells *in vitro*. Endometriosis mice model was established for immunostaining and microarray analysis of lesions to characterise the molecular pathways *in vivo*.

Main results and the role of chance: MTDH and PXK were the strongest and most differential targets of EGCG and Pro-EGCG in both cells lysate and cell culture of Hs832(C).T, respectively. Gene silencing and overexpression of the protein targets *in vitro* and *in vivo* significantly altered expressions of downstream proteins, including BLK and EGF after PXK, and MYC and AKT after MTDH, as well as endometriosis-related genes such as VEGFC and MMP9. Co-culture assays of Hs832(C).T with Raji null or THP-1 induced macrophages showed that expressions of PXK, MTDH, downstream targets, and immune-related genes were significantly increased after incubation of recombinant proteins, but were significantly decreased after EGCG and Pro-EGCG treatment. M1 and M2 macrophages, as well as B cells were significantly reduced after the treatments *in vitro* and *in vivo*. Double immunofluorescent staining of lesions showed that CD68, CD163 or CD20 co-expressed with MTDH, PXK and downstream targets, and numbers of the co-expressed cells were significantly reduced after treatments *in vivo*. Microarray experiment further identified the upstream and downstream genes of MTDH or PXK contributing to the growth and development of endometriosis.

Limitations, reasons for caution: Results of this pharmacological and mechanistic study require clinical samples to validate the anti-endometriosis effects of EGCG and Pro-EGCG. Effects of other potential pharmaceuticals targeting the macrophages and B cells on endometriosis are needed.

Wider implications of the findings: The findings provide pharmacological and mechanistic data for future development of EGCG and Pro-EGCG as new treatment for endometriosis. This study shows that macrophage and B cell could be potential therapeutic targets for treatment of endometriosis, which opens up new horizon for the novel immunotherapy for endometriosis.

Trial registration number: NA

O-146 Assessment of focal and diffuse adenomyosis lesions before and after pregnancy on magnetic resonance imaging : a cohort of 139 patients.

L. Legay[1], L. Marcellin[1], P. Santulli[1], A.E. Millischer[2], C. Bordonne[3], L. Maitrot Mantelet[1], C. Maignien[1], M. Bourdon[1], B. Borghese[1], F. Goffinet[1], C. Chapron[1]

[1]Hôpital Port Royal, gynecology, PARIS, France ;
[2]Centre imagerie femme enfant - IMPC Bachaumont, radiology, Paris, France ;
[3]Hôpital Hôtel Dieu, radiology, Paris, France

Study question: How to assess the different adenomyosis phenotype before and after pregnancy on magnetic resonance imaging according to stringent validated criteria ?

Summary answer: Diffuse adenomyosis increases significantly after pregnancy while the rate of focal adenomyosis and the mean volume of focal adenomyosis lesions decrease significantly after pregnancy.

What is known already: Adenomyosis and endometriosis are benign hormone-dependent disorders associated with pelvic pain, dysmenorrhea and/or infertility. The natural course of adenomyosis and endometriosis is still unclear, particularly during pregnancy. Pregnancy is considered to have a positive impact on endometriosis. Several studies regarding the impact of adenomyosis on pregnancy are available. Adenomyosis can cause fertility disorders, miscarriage, preterm birth. However, available data evaluating the effect of pregnancy on adenomyosis are lacking.

Study design, size, duration: Between January 1st 2010 and September 30th 2020, 139 patients were followed in our referral care center (Gynecology department of Port-Royal Hospital, Paris) for symptomatic adenomyosis and or endometriosis. For each of them, a magnetic resonance imaging were performed before and after pregnancy. The data based on magnetic resonance imaging, pre- and post-pregnancy, were analyzed in a single retrospective study.

Participants/materials, setting, methods: Patients had to be over 18 years old, to be pregnant and to be followed for symptomatic adenomyosis

or endometriosis without any previous surgery. Each pelvic magnetic resonance imaging were performed by a single experienced radiologist. The protocol was identical on a 1.5 T magnetic resonance imaging machine based on validated criteria. The rate of diffuse and focal adenomyosis, the volume of focal adenomyosis lesions and the thickness of maximal junctional zone were reported.

Main results and the role of chance: The mean age of patients was 34.6 ± 3.4 years old, 83 (59.7%) of patients underwent assisted reproductive technology to be pregnant. The mean time interval between the MRI and the delivery was 55.2 months and the mean time interval between the delivery and the MRI was 32.2 months. Before pregnancy, there was 96 (69.1%) patients with adenomyosis, all phenotype combined versus 111 (79.9%) after pregnancy (p=0.04) on magnetic resonance imaging. The rate of diffuse adenomyosis increased significantly on magnetic resonance imaging after pregnancy compared to before pregnancy (n=22 (15.8%) vs n=41 (29.5%), p =0.01). The thickness of junctional zone maximal was significantly higher after pregnancy (8.0 mm ± 5.1 vs 12.0 mm ± 4.8, p<0.01). The rate of focal adenomyosis (n=55 (39.6) vs n=34 (24.5), p=0.01) as well as the volume of focal adenomyosis lesions (6.7 mm^3 ± 2.5 vs 6.4 mm^3 ± 2.3, p<0.01) decreased significantly after pregnancy on magnetic resonance imaging.

Limitations, reasons for caution: This single-center study was conducted in a referral center whom patients presented more severe forms of adenomyosis, which could have affected the external validity of this study. The mean time interval between delivery and MRI was 32.2 month which implies a short follow up period to observe long term outcomes.

Wider implications of the findings: The hypothesis that a specific hormonal environment during pregnancy may imply a positively impact of the evolution of focal adenomyosis is raised by this study. The evolution of focal adenomyosis after pregnancy is similar to the evolution of endometriosis lesions volume that support shared etiopathogenic mechanisms between the two entities.

Study question: What is the entire metabolomic profile of human semen and does the metabolic composition differ between men with good-quality and low-quality semen?

Summary answer: Human semen contains ~700 different metabolites, and the metabolomic signature differs between normozoospermic men and men with altered seminal parameters.

What is known already: Semen contains a wide diversity of metabolites as has been identified in single and targeted metabolite studies. The full composition of metabolites in human semen, however, is not known. The knowledge of the complete metabolic signature in semen and whether there are differences between metabolic composition and seminal quality could enhance our knowledge of possible factors involved in reduced sperm quality and male infertility.

Study design, size, duration: Case-control study, where a total of 100 men (age= 29.73±8.9 years) from March 2019 to March 2020 participated. The study was approved by the Ethics Committee of Investigación Biomédica de Andalucia.

Participants/materials, setting, methods: Semen samples from 69 normozoospermic and 31 oligozoospermic men were collected at the University Hospital and sperm biobank (Ceifer Biobank - NextClinics). The complete metabolome from unprocessed seminal samples was analysed by Ultrahigh Performance Liquid Chromatography-Tandem Mass Spectroscopy (UPLC-MS/MS). Raw data were extracted, peak-identified and quality control processed using Metabolon's hardware and software (metabolon.com). Multiple regression models controlling for age and sample collection centres were applied using R software.

Main results and the role of chance: In total, 695 different metabolites were detected in the seminal samples, where docosahexaenoate (DHA; 22:6n3, PubChem ID 445580), choline phosphate (1014), dihomo-linolenate (20:3n3 or n6, 5280581), docosapentaenoate (n6 DPA; 22:5n6, 6441454), adenosine 3',5'-cyclic monophosphate (cAMP, 6076) and N-acetylalliin (122164824) metabolites were the most prevalent. The seminal metabolomic profiles differed significantly between men with normal and low sperm parameters. The most abundant metabolites in normozoospermic men belonged to Lipid Super-Pathway, while Nucleotide Super-Pathway was predominant in semen samples with low quality (p<0.05). More specifically, the leading Sub-Pathway in normozoospermic men was Long Chain Polyunsaturated Fatty Acid (n3 and n6), whereas Purine and Pyrimidine Metabolism Sub-Pathway prevailed in low-quality semen samples, where DHA and cAMP dominated in men with normal and low seminal quality parameters, respectively (p<0.05 in all comparisons).

Limitations, reasons for caution: This is the first study presenting the entire metabolome signature of unprocessed human semen, and these preliminary results need to be confirmed in a bigger sample size.

Wider implications of the findings: Semen analyses applied in clinics do not evaluate the functional status of sperm, leaving the infertility causes due to male factor frequently unknown. Our study results could help to understand the molecular background of reduced seminal quality and male infertility and lead to identification of molecular biomarkers of functional sperm.

Trial registration number: not applicable

O-148 Sperm Aminopeptidase N as a predictive biomarker of blastocyst development and embryo viability.

N. Subiran[1,2,3], I. Urizar-Arenaza[1,2], I. Muñoa-Hoyos[1,2], J. Irazusta[1], Z. Larreategui[4], N. Garrido[5], M. Gianzo[1]

[1]University of Basque Country, Physiology, Bilbao, Spain ;
[2]Biocruces-Bizkaia Health Research Institute, Innovation in Assisted Reproduction, Barakaldo, Spain ;
[3]MEPRO Medical Reproductive Solutions, Research and Development Department, San Sebastian, Spain ;
[4]IVI Bilbao, In Vitro Fertilization Laboratory, Leioa, Spain ;
[5]IVI Foundation. IVI Valencia, Laboratory of Andrology, Valencia, Spain

Study question: To evaluate human sperm APN as a prognostic factor for determining high-quality embryos.

Summary answer: The human sperm APN has the potential to become new molecular prognostic biomarker for having high-quality and viable embryos.

What is known already: Prognosis and diagnosis of male fertility is one of the major concerns in reproductive medicine. Approximately 30%-40% of men with otherwise normal fertility parameters are still unable to achieve pregnancy. The predictive clinical value of a semen analysis to identify fertile or infertile males is limited; therefore, new sperm diagnostic or prognostic methodologies are urgently required. Sperm Aminopeptidase N (APN) may be a relevant molecular marker due to its high concentration in sperm cells and its role in sperm physiology, such as motility, acrosome reaction, and embryo development.

Study design, size, duration: A prospective study that involves a total of 81 couples and 611 embryos who underwent oocyte-donation cycles at the Clínica IVI Bilbao (Spain) between September 2014 and July 2015.

Participants/materials, setting, methods: This study was set in an assisted reproduction unit and in an academic research laboratory. All semen samples were examined and classified following WHO guidelines. Spermatozoa were isolated from semen on discontinuous colloidal silica gradient (45%-90%) technique. Embryo quality and development were determined according to the Spanish Association of Reproduction Biology Studies (ASEBIR) criteria. Flow cytometry analyses of quantitative and semi-quantitative sperm human APN levels.
Main results and the role of chance: The obtained results proved that the most evolved and viable blastocysts were associated with low sperm APN levels. Expanding, expanded, hatching/hatched and viable blastocysts come from semen samples which showed lower APN levels than early blastocysts, blocked and non viable blastocyst. The cumulative probability of having more evolved blastyocysts increased 1.38-fold at day 5 and 1.98-fold at day 6 of embryo development as well as the likelihood of having viable embryo increased 1.48-fold when semen samples with low APN levels are used during the ICSI technique.
Limitations, reasons for caution: Data obtained from a single Fertility Clinic. A multi-centrum study will be required.
Wider implications of the findings: The human sperm APN has the potential to become new molecular prognostic biomarker for having high-quality embryos that could help to diagnose male infertility, especially when seminal parameters are close to the threshold values.
Trial registration number: Not applicable

O-149 Evaluation of structural problems in the application of strict criteria for sperm morphology assessment

L. Van Den Hoven[1], N. Van Vrouwerff[2], I. Dijkstra[2], J. Brinkman[3], A. Wetzels[1]

[1]Radboud University Medical Center, Obstetrics and Gynaecology, Nijmegen, The Netherlands ;
[2]St Antonius ziekenhuis, Clinical Chemistry, Nieuwegein, The Netherlands ;
[3]Ziekenhuis Sint Jansdal, Clinical Chemistry, Harderwijk, The Netherlands

Study question: Which criteria, described by WHO 2010, cause most problems during sperm morphology assessment and lead to outcome variation in a national external quality control program?
Summary answer: Assessment of head ovality, regularly contoured head, regularly contoured midpiece and alignment of major axis of midpiece and head lead to the most variation.
What is known already: Morphology assessment of spermatozoa is known as a rather difficult part of semen analysis. Over the past 40 years, morphological criteria became stricter and reference values changed significantly, leading to a 4% lower reference value for normal/typical morphology in 2010. This has consequences for the statistical power of the analysis. Moreover, many laboratories do not use the staining method as advised by the WHO and are getting stricter and stricter in the application of the criteria. Improvement of the assay is therefore necessary. In this study, as a first step, variation in the use of the strict criteria is evaluated.
Study design, size, duration: Data from the Dutch external quality control (EQC) program were evaluated in this retrospective study over the period 2015 – 2020. The program consists of four rounds per year and includes the assessment of three photos of Papanicolaou stained spermatozoa. These spermatozoa were dichotomously judged (normal/abnormal) on 14 morphological criteria (WHO manual, 2010). Consensus results of three experts served as reference. In total, variation over results of 72 photos (1008 values) was analysed.
Participants/materials, setting, methods: Participants were staff members from Dutch laboratories (1 member per lab per round) that perform semen analysis. The outcomes of the participants were tested for variation per criterion, both over the entire 6-year period and for trends during this period. To gain insight in the influence of "time", three photos were provided three times (in 2015/2018/2020) and six photos were provided twice (in 2016/2018 and 2018/2020). Setup was blinded to both participants and experts.
Main results and the role of chance: In the period 2015 – 2020, 88 – 103 laboratories participated in the EQC program. Of these laboratories, 40 – 60 took part in the photo evaluation. Variation per criterion was expressed in categories green, orange and red, with resp. >90%, 60-90% and <60% agreement between the participants. Overall, variation was in 57% in category green, 37% orange and 6% red. Head ovality, regularity of head contours, regularity of midpiece contours and alignment of the major axis of midpiece and head lead to the most variation. For these criteria, resp. 14, 17, 10 and 17% were in the category red and resp. 50, 47, 71 and 64% in category orange. Lowest variation was found for acrosomal vacuoles, excessive residual cytoplasm, tail thickness and tail length with resp. 76, 77, 94, 85% in category green. Trend analysis lead to similar conclusions: most criteria show a slightly positive trend, but head ovality and regularity of head and midpiece show a stable or declining trend. Three photos were used in three rounds and six photos in two rounds. In 26 (8.8%) cases, shifts towards higher (5) or lower (21) variation were found. Experts changed their opinion in 3 (1%) cases.
Limitations, reasons for caution: Results are dependent on the morphology of the spermatozoa (magnitude of abnormalities) and of the photo quality.
Wider implications of the findings: The definitions of the criteria need to be better explained and trained, especially for ovality of the head, regularity of the midpiece and overlap of the longitudinal axes of midpiece and head. Moreover, explanation of the criteria in the light of physiology will probably lead to better evaluations by participants.
Trial registration number: Not Applicable

O-150 Predicting the sperm retrieval of microsurgical testicular sperm extraction (mTESE) in infertile men with azoospermia on the day of TESE-ICSI

S.F. Kappes[1], S. Kliesch[1], F. Macke[1], V. Nordhoff[1]

[1]Centre of Reproductive Medicine and Andrology CeRA- University Hospital of Münster UKM, Department of Clinical and Surgical Andrology, Münster, Germany

Study question: Is the sperm retrieval rate of a small, pre-processed sample (PPS) of each TESE-biopsy representative for the sperm outcome on the day of ICSI?
Summary answer: The analysis of a PPS reliably reflects the probability of finding comparable numbers of sperm at time of TESE-ICSI.
What is known already: Azoospermia is defined as a condition where no spermatozoa are found in the ejaculate and is diagnosed in up to 15% among infertile men and in 11% of all patients attending our centre. The combination of testicular sperm extraction (TESE) and intracytoplasmic sperm injection (ICSI) has become the standard treatment of azoospermic patients. However, no validated standard procedure has been identified to predict the exact sperm outcome of the cryopreserved TESE samples prior to TESE-ICSI so far. For optimal management of TESE-biopsies and the respective ICSI treatment, we developed a stepwise approach for the analysis of tissue samples.
Study design, size, duration: We retrospectively analysed the outcome of 872 microsurgically retrieved testicular biopsies of 198 patients of legal age who had a TESE-ICSI at our department between 2009 and 2019. From all 872 mTESE biopsies the number of sperm extracted from a small, pre-processed sample (PPS) before freezing procedure were known. The PPS was then compared to the number of sperm retrieved from the corresponding thawed specimen on the day of TESE-ICSI.
Participants/materials, setting, methods: During micro-TESE eight samples per testis are retrieved, then 1/10 of each biopsy is removed, digested with collagenase and screened for spermatozoa (pre-processed sample, PPS). If less than 100 spermatozoa are detected the absolute sperm number is recorded, otherwise the result is displayed as the maximum value of 100 sperm. On the day of ICSI, one or more TESE biopsies are thawed and processed for TESE-ICSI; the absolute sperm number is counted again.
Main results and the role of chance: Comparing the sperm yield of 872 TESE samples at time of ICSI to its respective PPS showed a similar sperm outcome with a minor deviation of ±5 spermatozoa in 73.6% of all biopsies. However, 12.9% of the specimen had less and 13.4% had more spermatozoa. A negative sperm retrieval in the initial PPS was confirmed in 93.1% (268/288). PPS with 1-4 spermatozoa had a 27.2% (43/158) risk of complete absence of sperm on the day of ICSI, yet sperm detection (≥1 sperm) was positive in 72.8% (115/158) of the biopsies. With initially ≥5 spermatozoa present in the PPS, only 0.9% (4/426) of the biopsies had no sperm on the day of ICSI, vice versa 99.1% (422/426) were spermatozoa positive. A significant (p=0.01) and strong (rs= 0.926) correlation of the sperm retrieval rates of the PPS and the ICSI sample was found meaning that the PPS reflects very well the sperm retrieval rate of the cryopreserved mTESE biopsy thawed at time of TESE-ICSI. However, if ≤4 sperm are found in the PPS, there is a relevant risk for a negative sperm

retrieval on the day of ICSI and the couple should be carefully advised before start of treatment.
Limitations, reasons for caution: This analysis focussed on sperm prediction in cases of severe male factor infertility and therefore the sperm yield on the day of ICSI was chosen as primary outcome. The reproductive competence of the retrieved sperm in terms of pregnancy and birth rates should be subject to further investigation.
Wider implications of the findings: Treatment options for azoospermic patients are mostly related to the ability to find sperm on the day of ICSI. However, validated standards for sperm processing are missing. Therefore, a PPS seems to be a good option for prediction of sperm retrieval and improves counselling of the patients prior to TESE-ICSI.
Trial registration number: not applicable

O-151 Detailed characterization of infertile men with idiopathic versus unexplained infertility: a single-center experience

L. Boeri[1], L. Candela[1], E. Pozzi[1], F. Belladelli[1], P. Capogrosso[2], W. Cazzaniga[1], A. Costa[1], G. Fallara[1], N. Schifano[1], D. Cignoli[1], E. Ventimiglia[1], M. Alfano[1], C. Abbate[1], F. Montorsi[1], A. Salonia[1]

[1]Università Vita-Salute San Raffaele, Division of Experimental Oncology/Unit of Urology- URI- IRCCS Ospedale San Raffaele- Milan- Italy- University Vita-Salute San Raffaele- Milan- Italy., Milan, Italy ;
[2]Ospedale di Circolo and Macchi Foundation- Varese., Department of Urology and Andrology, Varese, Italy

Study question: We aimed to investigate the rate of and the clinical characteristics of men with idiopathic versus unexplained infertility from a cohort of white-European men.
Summary answer: Approximately 20% and 5% of men evaluated for primary couple's infertility depicted characteristics suggestive for idiopathic and unexplained infertility, respectively.
What is known already: Male factor infertility (MFI) can be associated with clinical, hormonal and genetic diseases, but MFI is idiopathic in almost 30% of cases.
Study design, size, duration: Data from 3098 infertile men (according to WHO definition) consecutively evaluated between 2003-2020 at a single academic centre were analysed and compared with those of 103 fertile controls. Health-significant comorbidities were scored with the Charlson Comorbidity Index (CCI). Idiopathic infertility was defined for pathological semen analysis but normal physical examination and endocrine, genetic and biochemical laboratory testing. Unexplained infertility is defined as infertility of unknown origin with normal sperm parameters.
Participants/materials, setting, methods: Testicular volume (TV) was assessed with a Prader's orchidometer. Serum hormones and sperm DNA fragmentation index (SDF) were measured in every patient. Vitamin D3 (VitD) deficiency was considered for vitD levels <20 ng/mL. Semen analyses were based on the 2010 WHO reference criteria. Health-significant comorbidities were scored with the Charlson Comorbidity Index (CCI).
Main results and the role of chance: Overall, 570 (18.5%) and 154 (5.0%) patients depicted criteria suggestive for either idiopathic or unexplained primary infertility, respectively. Groups were similar in terms of age, BMI, CCI, recreational habits, circulating serum hormones and SDF. Testicular volume was lower in men with idiopathic vs. unexplained infertility [median (IQR) 20 (15-25) vs. 20 (17-25); p<0.001]; more idiopathic than unexplained infertile men depicted TV <15ml (23.4% vs. 12%; p<0.01). Similarly, vitD levels were lower [22 (17-28) vs. 27 (21-42) ng/mL; p<0.001] in idiopathic vs. unexplained infertile men, with a higher rate of pathologic VitD levels in the same group (42.1% vs. 10%; p=0.04). When compared to fertile controls, groups were similar in terms of age, BMI, CCI and serum hormones values. TV was larger in fertile controls than idiopathic and unexplained infertile men (all p<0.01). At multivariable logistic regression analysis only vitD deficiency (OR 8.1, p=0.03) was found to be associated with idiopathic infertility after accounting for age, BMI, testosterone values and TV.
Limitations, reasons for caution: The small number of fertile controls may raise the possibility of biases.
Wider implications of the findings: Idiopathic and unexplained infertility were identified in approximately 20% and 5% of men evaluated, respectively. Idiopathic infertile men showed lower TV and lower vitD values compared to men with unexplained infertility. Future studies are needed to develop a more tailored management to these difficult MFI cases.

O-152 Investigation of the relationship of sperm motility and Kisspeptin in subfertile men

A. Kocaman[1], B. Ayas[2]

[1]Ondokuz Mayıs University- Faculty of Medicine, Histology and Embryology, Samsun, Turkey ;
[2]Ondokuz Mayıs University- Faculty of Medicine, IVF Center, Samsun, Turkey

Study question: Does kisspeptin administration affect the motility parameters in sperm samples of subfertile cases?
Summary answer: Kisspeptin administration significantly increased gene expression levels related with sperm motility as well as intracellular calcium concentrations.
What is known already: Sperm motility problems are among the most important causes of male infertility. In recent years, a peptide named kisspeptin has been discovered that may have effects on sperm motility. Kisspeptin is known to trigger calcium release in hypothalamic neurons. In addition, kisspeptin administration increased sperm progressive motility in studies conducted on normozoospermic individuals. Furthermore, it is suggested that kisspeptin protein in seminal plasma is positively associated with semen quality. However, there is no evidence that how kisspeptin can affect sperm in men with infertility problems.
Study design, size, duration: This basic research study was an in vitro experimental approach involving the use of semen samples from an infertil cases between September to December in 2020. 40 men were included in both control and experimental groups.
Participants/materials, setting, methods: All analyses were performed on semen samples from 10 normozoospermic (NZ), 10 asthenozoospermic (AZ), 10 oligoasthenozoospermic (OAZ) and 10 oligoastenoteratozoospermic (OATZ) men, aging between (21-40) years. Basal serum and seminal kisspeptin levels were analyzed by ELISA. Sperm were divided into two groups. Kisspeptin-13 administered *in vitro*. *KISS1, KISS1R, CATSPER1, AKAP4* gene expressions analyzed by qRT-PCR using $2^{-\Delta\Delta Ct}$ algorithm. Intracellular calcium concentration was determined with floresence spectroflurometer and laser scanning confocal microscope.
Main results and the role of chance: The serum kisspeptin level of NZ was significantly higher than other groups (p<0.05). The semen kisspeptin level was significantly higher than OAZ and OATZ (p<0.05), but not in NZ (p>0.05). Also, *KISS1* gene expression was higher in AZ compared to other groups (p<0.05). Biochemical and gene expression analysis of kisspeptin were consistent with each other. There was a significant increase in the expression of *CATSPER1* gene in AZ compared to other groups (p<0.05). Also, *AKAP4* gene expression was significantly higher in OATZ compared to other groups (p<0.05). No significant difference was documented for the expression of *KISS1R* (p>0.05). Intracellular calcium was significantly increased in AZ and NZ after kisspeptin administration. The intracellular calcium increase is consistent with increased *CATSPER1* gene expression levels in AZ. Kisspeptin administration may have a significant effect on sperm motility parameters.
Limitations, reasons for caution: The biochemical and gene expression levels of *KISS1* were consistent. However, gene expression was explored at the mRNA level for *CATSPER1* and *AKAP4*. The protein expression analyses of these genes may confirm the results. Also, using kisspeptin antagonists may strength the results of intracellular calcium analysis.
Wider implications of the findings: Kisspeptin treatment for individuals diagnosed with asthenozoospermia may have therapeutic results. KISS1 quantitation may be a determining factor for the subfertility in routine semen analysis.

O-153 Is paternal age associated with timing, stage, morphology, and implantation of the competent blastocyst: a multicenter cohort study

M. Buhl Borgstrøm[1], M.> Grøndahl[2], T. Wirenfeldt Klausen[3], A. Kjærgaard Danielsen[4], T. Thomsen[5], U. Schiøler Kesmodel[6]

[1]Herlev University Hospital and Aalborg University, fertility clinic, Herlev, Denmark ; [2]Herlev University Hospital, fertility clinic, Herlev, Denmark ; [3]Herlev University Hospital, Department of Hematology, Herlev, Denmark ; [4]Herlev University Hospital, Department of Gastroenterology, Herlev, Denmark ; [5]Herlev University Hospital, Department of Anaesthesiology, Herlev, Denmark ; [6]Aalborg University Hospital and Aalborg University, fertility clinic, Aalborg, Denmark

Study question: Is age of men undergoing assisted reproductive technology associated with timing, stage, morphology, and implantation of the competent blastocyst?
Summary answer: Advanced paternal age was associated with reduced development speed and level of hCG in the competent blastocysts in COS treatments.
What is known already: We have shown that for every one-year increase in women's age there is a 5% reduced probability that the competent blastocyst is in an advanced development stage. Likewise, we have shown that the initial hCG rise is associated with women's age with the youngest women having the lowest hCG level. It is unknown whether the age of men undergoing ART treatment is associated with the timing (day 5 or 6), the development stage, morphology, and the early implantation of the competent blastocyst.
Study design, size, duration: This is a multicenter historical cohort study based on data from 16 private and university-based public fertility clinics where 7246 men and women, between 2014 and 2018, underwent controlled ovarian stimulation (COS) or Frozen-thawed Embryo Transfer (FET) with a single blastocyst transfer resulting in a singleton pregnancy. These data were linked to the Danish Medical Birth Registry, resulting in inclusion of 4842 men with a partner giving birth.
Participants/materials, setting, methods: Exposure (age) and outcome data (blastocyst timing (day 5 or 6), development stage (3-6), inner cell mass (ICM)(A,B,C), trophectoderm (TE)(A,B,C) and hCG were collected from the database, Danish Medical Data Center. All COS cycles (IVF and ICSI) and FET cycles (natural and substituted), were included. Exclusion criteria were cycles with pre-implantation genetic testing, donated oocytes and semen. The analyses were adjusted for female age, female smoking, female BMI, diagnosis and clinic.
Main results and the role of chance: The adjusted association between paternal age and transfer day in COS treatments showed that for every increase of one year, men had a 6% increased probability that the competent blastocyst was transferred on day 6 compared to day 5 (OR 1.06, 95% CI (1.00;1.13). The mean difference in hCG values when comparing paternal age group 30-34, 35-39 and 40-45 with the age group 25-29 in those receiving COS treatment, all showed significantly lower adjusted values for older men. In FET treatments, none of the investigated associations reached statistical significance.
Limitations, reasons for caution: The blastocyst morphology was subjectively assessed, and information bias may have influenced the results. However, adjusting for clinic takes the potential influence of variation in embryo scoring between clinics into consideration.
Wider implications of the findings: We hypothesize that the later transfer (day 6) in female partners of older men is likely to be due to longer time spent by the oocyte to repair fragmented DNA of the sperm cells, which should be a focus of future research in men.
Trial registration number: "not applicable"

O-154 First mitotic spindle formation led by sperm centrosome-dependent microtubule organising centres may cause high incidence of zygotic division errors in humans

Y. Kai[1], H. Kawano[1], N. Yamashita[1]

[1]Yamashita Shonan Yume Clinic, Reproductive Medicine Research Center, Fujisawa, Japan

Study question: Why do multinucleated blastomeres appear at high frequency in two-cell-stage embryos in humans?
Summary answer: Failure in microtubule assembly during the first mitotic spindle body formation by sperm centrosome-dependent microtubule organising centres (MTOCs) may lead to chromosomal instability.
What is known already: Unlike that in mice, multinucleated blastomeres appear at high frequency in two-cell-stage embryos in humans. However, the underlying mechanism remains elusive. In mice, multiple acentriolar MTOCs appear around the male and female pronuclei after pronuclear disappearance and contribute to dual-spindle formation, engulfing each parental chromosome. This spindle formation may ensure an error-free division, keeping the chromosomes stable during the first cleavage, as observed in mice, but it is unclear whether a similar mechanism exists in humans.
Study design, size, duration: To examine how sperm centrosomes contribute to MTOC formation in humans, two types of 3PN zygotes derived fromeither conventional *in vitro* fertilization (c-IVF, n = 30) or intracytoplasmic sperm injection (ICSI, n = 10) were used. The zygotes were collected from October 2018 to January 2020. MTOC and mitotic spindle formation at consecutive stages of development during the first cleavage were analysed under static and dynamic conditions using immunofluorescence assay and fluorescent live-cell imaging.
Participants/materials, setting, methods: Under ethics approval, 3PN zygotes were donated by infertile couples undergoing c-IVF or ICSI cycles at the Yamashita Shonan Yume Clinic in Japan. All participants provided informed consent. Immunofluorescence assay was performed using antibodies against -tubulin, pericentrin, and H3K9me3 after fixation with MTSB-XF solution. Fluorescent live-cell imaging was performed using TagGFP2-H2B mRNA (chromosome marker) and FusionRed-MAP4 mRNA (microtubule marker).
Main results and the role of chance: Immunofluorescence revealed that while 3PN zygotes derived from c-IVF showed four pericentrin dots, those derived from ICSI exhibited two pericentrin dots. In pro-metaphase, an independent group of chromosomes derived from each pronucleus and MTOCs were formed by the sperm centrosome at the core. Microtubules from each MTOC extended toward the chromosomes in the early metaphase; a quadrupolar spindle was formed in the c-IVF-derived zygotes, and a bipolar spindle was formed in the ICSI-derived zygotes by the MTOCs at the zygote apex after chromosome alignment. In pro-metaphase, the microtubules extended from the MTOCs to the nearest chromosome. Since microtubule assembly was found on oocyte-derived chromosomes, we hypothesised that whether a chromosome is surrounded by microtubules depends on the location of the MTOCs, irrespective of its origin. Live-cell imaging of histone H2B and MAP4 revealed that four MTOCs appeared around the three pronuclei just before the disappearance of the pronuclear membrane; microtubules then extended from the MTOCs toward the chromosomes, beginning to form a mitotic spindle as the chromosomes moved to the centre of the oocyte. Interestingly, one of the three assembled chromosome groups showed no microtubule assembly in the pro-metaphase. Similar results were obtained in all six 3PN zygotes subjected.
Limitations, reasons for caution: We demonstrated the high risk of developing bare chromosomes not surrounded by microtubules during the formation of the first mitotic spindle, using human tripronuclear zygotes. However, owing to unavailability of normal fertilized oocytes for this study because of the clinical use, we were unable to confirm this in normal zygotes.
Wider implications of the findings: Although two sperm centrosome-dependent MTOCs are expected to be formed in normal fertilized oocytes, these MTOCs are not sufficient to completely enclose physically separated female and male chromosomes with the microtubules. This explains the high frequency of zygotic division errors that lead to unstable human chromosomes.
Trial registration number: not applicable

O-155 Dietary caloric normalization or restriction as preconception care strategies: impact on oocyte developmental competence and quality in high fat/high sugar-induced obese outbred mice

A. Smits[1], I. Pintelon[2], S. Thys[2], P.E.J. Bols[1], W.F.A. Marei[1], J.L.M.R. Leroy[1]

[1]University of Antwerp, Gamete Research Centre, Wilrijk, Belgium ; [2]University of Antwerp, Laboratory of Cell Biology & Histology, Wilrijk, Belgium

Study question: Can diet normalization or caloric restriction (CR) for two weeks be used as a preconception care intervention in obese Swiss mice to restore oocyte development and quality
Summary answer: Diet normalization or CR as short-term preconception care interventions in obese mice only partially restored oocyte quality but did improve overall developmental competence.

What is known already: Maternal metabolic disorders like obesity and metabolic syndrome may result in decreased oocyte and embryo quality, and thus reproductive failure. Overweight and obese patients are advised to lose weight before conception to increase the chance of a healthy pregnancy. However, as human studies show no univocal guidelines, more fundamental research might provide additional answers. In order to avoid interference with increased maternal age, the question remains if oocyte quality can be restored after only a short preconception care intervention (PCCI).
Study design, size, duration: Outbred mice were fed a control (CTRL) or high-fat/high-sugar (HF) diet for seven weeks. Afterwards, HF-mice were put on different PCCIs for two weeks, resulting in four treatment groups: control diet (9w; CTRL_CTRL), HF diet (9w; HF_HF), switch from HF (7w) to an *ad libitum* control diet for 2w (HF_CTRL) or to a 30% CR diet for 2w (HF_CR). Oocyte developmental competence (n=357) and quality (12-16 oocytes /treatment, scored blinded) were determined, using 6-8 mice/treatment.
Participants/materials, setting, methods: Body weight changes were recorded. *In vivo* matured oocytes were collected after superovulation and analysed for quality or *in vitro* fertilized and cultured. Oocyte quality was determined by staining for lipid content (Bodipy) and mitochondrial inner membrane potential and active mitochondria localization (JC-1). Oocyte developmental competence [cleavage (24h p.i.) and blastocyst rates (5 days p.i.)] was scored. Categorical and numerical data were analysed using binary logistic regression and ANOVA, respectively and corrected for multiple testing.
Main results and the role of chance: Compared to the CTRL group, HF diet increased body weight after 7 weeks by 24.19% ($P<0.001$). After the start of the PCCI, both HF_CTRL and HF_CR mice progressively lost weight and reached values similar to control mice after two weeks. HF_HF diet increased the intracellular lipid content in oocytes with 54.3% compared to the CTRL_CTRL group ($P<0.05$). This increased content was (partially) normalized in both preconception care intervention groups, even similar to the control levels in the HF_CTRL group. Both HF_HF and HF_CR oocytes showed a tendency to an increased ratio of active/total mitochondria when compared to the CTRL_CTRL group ($P=0.081$, $P=0.083$ respectively). In addition, active oocyte mitochondria in the HF_HF group were less pericortically distributed compared to controls. This was also the case in both preconception care intervention groups ($P<0.05$). After two weeks of PCCI, oocytes from HF_HF mice displayed lower cleavage rates than those from CTRL_CTRL mice (36.26% *vs.* 64.52%, $P<0.05$) but blastocyst rates (26.37% *vs.* 35.48%, $P>0.1$) were not different. HF_CR, but not HF_CTRL, oocytes showed higher cleavage rates (68.48%, $P<0.001$) compared with HF_HF oocytes. Moreover, both HF_CTRL (44.64%, $P<0.05$) and HF_CR (59.78%, $P<0.001$) oocytes showed improved blastocyst rates when compared to the HF_HF group (26.37%).
Limitations, reasons for caution: Although using a mouse model has several advantages, translating these results to the human setting is a limitation of this study. However, to improve this translatability, an outbred mouse model was used. Additional data will be collected to gain more information regarding the best preconception care intervention advice.
Wider implications of the findings: This research aims to provide fundamental insights in order to be able to formulate clear preconception guidelines to obese women planning for pregnancy. In addition, we aim to find the shortest possible intervention period to improve fertility.
Trial registration number: Not applicable

O-156 Fertilization rate as a novel indicator for cumulative live birth rate: multicenter retrospective cohort study of 9,394 complete IVF cycles

Study question: Does fertilization rate (FR) affect cumulative success rates in assisted reproduction cycles?
Summary answer: These data indicate a positive association between FR with CLBR suggesting the predictive clinical relevance of this parameter and its adoption as Key Performance Indicator(KPI).
What is known already: Numerous studies have aimed at characterizing outcome predictors. Maternal age is historically and correctly recognized as the single most important factor impacting on the clinical outcome of ART. More recently ovarian response has also gained interest in this respect. However, the quest for novel, more comprehensive predictive factors is not over; new relevant evidence is starting to emerge. FR is a noteworthy parameter because expressing a fundamental aspect of both oocyte and sperm developmental competence. In fact it has been adopted as a key performance indicator of the IVF laboratory, to assess laboratory, operator, and gamete competence.
Study design, size, duration: Reported data concern a retrospective cohort study carried out between 2015 to 2017 involving 7,968 couples undergoing 9,394 complete ICSI cycles, i.e. whose all embryos were transferred or disposed.All women aged between 18-42 years were included.We excluded from analysis: surgical sperm retrieval cases, cycles resulting in neither fresh or frozen–thawed embryo transfers,cycles in which live birth were not achieved, but with remaining cryopreserved embryos,cycles of PGT, cycle with fertilization failure and standard IVF cycles.
Participants/materials, setting, methods: The cohort was groupped according to fertilization rate intervals based on recommendations of the Vienna Consensus (<65% - Group 1; 65%-80% - Group 2; >80% - Group 3). Harnessing the large size of the original dataset, further cycle stratifications were carried out based on female age (<34, 35-38, 39-42 years) and number of oocytes retrieved (5-7, 8-10, >10 oocytes).
Main results and the role of chance: No significant difference in female age was observed between fertilization rate groups (p=0.640). CLBR was progressively higher in relation fertilization rate in Groups 1, 2 and 3 (20.1%, 34.7%, 41.3%, P<0.001, respectively). Number of recovered oocytes, embryo number per cycle, cumulative pregnancy rate followed the same trend (p<0.001). The decrease in CLBR with increasing female age was significantly correlated with fertilization rate and CLBR in all three female age groups (P<0.001). Finally, to further control for possible patient-specific confounding factors, maternal age, number of retrieved oocytes, percent of inseminated oocytes and fertilization rate were evaluated in a multivariate logistic regression analysis. From this assessment, fertilization rate emerged as a factor independently associated with cumulative live birth rate, to a degree equivalent or higher compared with the number or retrieved oocytes.
Limitations, reasons for caution: The study design is retrospective and requires further refinement to control for factors that may impact clinical outcome.
Wider implications of the findings: These data indicate a positive association of FR with CLBR, thereby suggesting that fertilization, in addition to representing an assay for gamete quality and laboratory performance,has an independent clinical significance.Irrespective of the number of retrieved oocytes and female age, we observed that, rates of FR are positively associated with CLBR.
Trial registration number: None

O-157 Micro-Computed Tomography of the adult mouse ovary: an in-silico 3D reconstruction of folliculogenesis

G. Fiorentino[1], A. Parrilli[2], S. Garagna[1], M. Zuccotti[1]

[1]Università di Pavia, Biologia e Biotecnologie Lazzaro Spallanzani, Pavia, Italy ;
[2]Swiss Federal Laboratories for Materials Science and Technology - Empa, Center for X-ray Analytics, Dübendorf, Switzerland

Study question: Which are the spatial dynamics of follicles recruitment and growth inside the ovary?
Summary answer: 3D micro-Computed Tomography (microCT) shows a simultaneous and homogeneous distribution of follicle recruitment all-over the cortex,and subsequent growth within the same ovarian region.
What is known already: In the mouse ovary, folliculogenesis progresses from the primordial type 1 (T1) to the fully-grown T8 follicle. Most of our knowledge of the folliculogenetic process has been obtained by disaggregating the ovary into its functional units (i.e., follicles and oocytes), thus losing the complexity of the whole histo-functional context.

To date, few studies employed 3D imaging approaches to gain information on the inside 3D ovary organisation. MicroCT is the only technique that combines a high spatial resolution (down to ~1 µm) with the production of a true 3D organ reconstruction, with cubic voxels and isotropic resolution.
Study design, size, duration: Three ovaries of three different adult mice were treated with the contrast agent and then imaged with microCT. A typical experiment required a total of 35 man/h from ovaries isolation to completion of X-ray scanning, and 24 man/h for follicles classification and mapping.
Participants/materials, setting, methods: Three ovaries of three different 8-week-old CD1 mice were fixed in 4% Paraformaldehyde and treated with Lugol's solution for 3 hr at RT. Ovaries were scanned with Skyscan 1172 (Bruker) using a 1.5 µm/pixel resolution. MicroCT sections were processed with Fiji ImageJ (NIH), and 3D rendering of follicles and blood vessels were obtained with Avizo-9 (Thermo Fisher Scientific). ANOVA and Bonferroni *post-hoc*statistical analyses were performed with RStudio, considering data significantly different when $p<0.05$.
Main results and the role of chance: Using microCT we built the first *in silico*3D reconstruction of the tiny mouse ovary, identifying, mapping and counting follicles,from pre-antral secondary T4 (53.2+12.7 µm in diameter) to fully-grown antral T8 (321.0+21.3 µm), and the *corpora lutea*.MicroCTbrought up the main functional compartments of the growing follicle, i.e., granulosa and cumulus cells, the antrum, the zona pellucida, and the oocyte with its nucleus. Instead, primordial and primary follicles (T1–T3) could not be observed, perhaps due to the reduced size of their enclosed oocyte and to the absence of a well-formed zona pellucida around the germ cell. In addition, our analysis allowed the visualisation and 3D modelling of the main ovarian vasculature, from the largest vessel that enters the organ at the hilum site (~150 µm size in diameter)to smaller branches present in the medulla region (~35 µm).

These results show that each of the eight ovarian sectors, virtually segmented along the dorsal-ventral axis,houses an equal number of each follicle type, suggesting a simultaneous and homogeneous distribution of follicle recruitment all-over the cortex,and subsequent growth within the same ovarian region.
Limitations, reasons for caution: To strengthen the results, the number of ovaries/individuals analysed should be increased.
Wider implications of the findings: This 3D mapping of follicles and vessels could contribute our understanding of folliculogenesis dynamics, not only under normal conditions, but also during ageing, after hormones or drugs administration, or in the presence of ovarian pathologies.
Trial registration number: not applicable

O-158 The effect of circadian rhythm disruption due to constant light on ovarian and oocyte aging through possible relationship between PER2 and mTOR signaling pathway

G. Bora[1], T. Onel[1], E. Yildirim[1], A. Yaba[1]

[1]*Yeditepe University School of Medicine, Histology and Embryology, İstanbul, Turkey*

Study question: Does circadian rhythm disruption by constant light affect the ovarian morphology and function, and cause ovarian and oocyte aging through possible relationship between PER2 and mTOR?
Summary answer: We demonstrated that circadian rhythm disruption by light may cause ovarian and oocyte aging.
What is known already: Circadian rhythm regulates multiple physiological processes and PER2 is one of the core circadian rhythm components. Changes in light conditions may cause circadian rhythm disruptions. Light exposure at night may cause attenuation in PER2 mRNA and protein levels. Circadian rhythm disruptions are thought to be associated with reproductive diseases. mTOR signaling pathway functions in folliculogenesis and oocyte maturation in ovary. Also, it is associated with ovarian and oocyte aging.
Study design, size, duration: A total of 32 female Balb/c mice which enter estrous cycle were used in the study. Mice were randomly assigned to one of two groups as 12:12h L:D and 12:12h L:L. During the experiment, 12:12h L:D (control group) was housed in a 12:12h light:dark cycle and 12:12h L:L (experiment group) was housed in a constant light conditions 12:12h light:light for 1 week.
Participants/materials, setting, methods: We housed 12:12h L:D group in standard lightening conditions and 12:12h L:L group in constant light for one week. We performed food intake and body weight change analysis. We evaluated ovarian morphology, follicle counting analysis. We evaluated ZP3 and nitrotyrosine (NTY) expression for oocyte aging markers. We performed western blot for PER2, mTOR, p-mTOR, p70 S6K, p-p70 S6K, and Caspase-3 protein levels.
Main results and the role of chance: We demonstrated that circadian rhythm disruption caused alteration in their food intake and decrease in primordial follicle numbers and increase in atretic follicles ($p<0.05$). It caused increase in oxidative stress and decrease in ZP3 expression in oocytes ($p<0.05$). We showed decreased protein levels of PER2, mTOR, p-mTOR and p70 S6K ($p<0.05$).
Limitations, reasons for caution: The explanation of molecular mechanism underlying the relationship between circadian rhythm disruptions by light and ovarian function may lead the usage of circadian rhythm-based or light-based therapies currently using to treat some diseases on female reproductive system related diseases.
Wider implications of the findings: We conclude that constant light may reduce follicle reserve, cause follicles to go rapidly atresia and disrupt the oocyte quality, thus it may be a risk factor for female reproductive diseases such as premature ovarian insufficiency and early menopause.

O-159 Prediction of weight loss and drop-out in a lifestyle intervention in women with pcos: A randomized controlled trial

G. Jiskoot[1], A. Dietz de Loos[1], R. Timman[2], A. Beerthuizen[2], J. Busschbach[2], J. Laven[1]

[1]*Erasmus Medical Center, Department of Reproductive medicine, Rotterdam, The Netherlands ;*
[2]*Erasmus Medical Center, Department of Medical Psychology, Rotterdam, The Netherlands*

Study question: Which patient related determinants contribute to a ≥5% weight loss and drop-out?
Summary answer: Participating in the lifestyle treatment and a worse body image at baseline were significantly associated with ≥5% weight loss.
What is known already: In general, three-component interventions including diet, exercise, and cognitive behavioral therapy have shown to be effective at the long-term to achieve weight loss. In a lifestyle program for infertile women, higher external eating behavior scores and not receiving previous support by a dietician were associated with weight loss. In a short term lifestyle program for women with PCOS, weight loss was associated with better quality of life scores and attendance of study appointments. Little has been published about the potential role of PCOS characteristics, psychological and behavioral variables on the ability to achieve weight loss in this group of women.
Study design, size, duration: The present study is a longitudinal RCT to study the effectiveness of a three component 1-year cognitive-behavioural lifestyle intervention on weight loss in overweight/obese women with PCOS. A total of 183 participants were randomly assigned to three groups: 1) CBT provided by the multidisciplinary team or; 2) CBT provided by the multidisciplinary team and Short Message Service (SMS) or; 3) usual care: women are encouraged to lose weight through publicly available services (control group).

Participants/materials, setting, methods: Women with menstrual cycle disorders are systematically screened using a standardised protocol. Data of 183 women diagnosed with PCOS according to the Rotterdam criteria, a Body Mass Index above 25 kg/m² were included. All variables were measured at start and at three, six, nine and twelve months.
Main results and the role of chance: The multivariable mixed-effect logistic regression model showed that participation in the lifestyle treatment (HR 2.3, P=0.012) and a worse body image (FNAE) (HR 0.95, P=0.023) at baseline were significantly associated with ≥5% weight loss. Drop-out was predicted by participation in the lifestyle treatment (OR 0.2 P=0.003), additional short message service (OR 3.7, P=0.008), smoking (OR 0.3, P=0.22), drinking alcohol (OR 2.4, P=0.04), higher levels of androstenedione (OR 1.2, P=0.047). Also, women who achieved spontaneous pregnancies were more likely to drop-out (OR 0.09, P=0.002).
Limitations, reasons for caution: A limitation of our study is the high discontinuation rate we observed especially after 3 months of the intervention. Therefore a statistical method was chosen that included all available data even if participants dropped out during the study period.
Wider implications of the findings: A three-component lifestyle intervention program for obese women with PCOS is effective for weight loss. The group of women with a more negative body image should receive additional treatment before entering such a lifestyle intervention to achieve better results.
Trial registration number: Registered at the Netherlands National Trial Register with number NTR2450 on August 2nd, 2010.

O-160 The effect of 6-month nutritional intervention on the anthropometric, biochemical, and reproductive profile of Lebanese women with Polycystic ovarian syndrome

C. Hmedeh[1], S. El Iskandarni[2], I. Tawfik[3]

[1]American University of Beirut, Obstetrics and Gynecology, Beirut, Lebanon ;
[2]American University of Beirut, Medicine, Beirut, Lebanon ;
[3]University of Westminster, Faculty of Science and Technology, London, United Kingdom

Study question: This study aims to assess the efficacy of, design, and implement a public health nutrition intervention designed to enhance healthy eating and life style management among PCOS patients.
Summary answer: After 6 months, this intervention decreased initial body weight by 5%-10%, increased pregnancy rate by 70%, and significantly improved psychological, metabolic and endocrine profiles.
What is known already: Polycystic ovary syndrome (PCOS) is a common endocrinopathy among women in their reproductive age and is characterized by imbalanced hormones, irregular menses, and fertility problems. PCOS has been linked to obesity and insulin resistance in many studies and this association suggests that a weight management intervention consisting of a lifestyle modification (LSM) program might improve the metabolic, reproductive and biochemical profiles of PCOS patients, especially that studies showed that weight loss among PCOS women reduces hyperandrogenism and thus improve ovulation.
Study design, size, duration: The study is a randomized control trial studying the effect of a 6 month weight management program with nutritional guidelines. 588 female participants attending the obstetrics/gynecology clinic, aged between 18 and 45 years old, were recruited. There were two obese/overweight (experimental and control) and two lean subgroups (experimental and control). Experimental groups received the intervention under study while the controls were given the usual programs (except for the non-PCOS lean group that received no intervention).
Participants/materials, setting, methods: Data on socio-demographic variables, nutritional status, physical activity, psychological and medical status were collected using a pre-validated questionnaire. Data on biochemical variables were collected from blood analysis. Data collection took place at baseline, after 3 and 6 months from intervention. Patients who were in the intervention groups were subject to nutritional education/counseling (following the proposed guidelines) as well as the structural weight loss program for obese patients.
Main results and the role of chance: After 6 months, PCOS women lost 8.2 kg (P=0.001), non-PCOS women lost 11.6kg among while controls gained weight. The biochemical, psychological and reproductive profile showed significant improvements among PCOS women. In fact, the percentage weight loss of 10% in the overweight/obese intervention group showed significant changes in some of the biochemical markers (total cholesterol FBS, CRP, LDL, and testosterone) (P<0.001). PCOS patients who got the intervention had a shorter time to ovulation, than those who didn't and had more average number of cycles during the 6 months study duration (P<0.001). Regarding the pregnancy rate for PCOS patients, it was shown that it increased significantly with intervention patients in all groups compared to controls (from 0% to 70% compared from 0% to 15 % respectively).
Limitations, reasons for caution: Limitations of the study includes inability to objectively assess patient compliance with innervation and inability to follow up with the participants for a longer period of time (12 months or more) for long term outcomes.
Wider implications of the findings: The findings of our study are in synchrony with previous studies that implied that nutritional and life style interventions improved PCOS outcome. This suggests the need for nutritional interventions and guidelines on additional to the traditioned gynecological treatment to improve PCOS outcome.
Trial registration number: Not applicable

O-161 Cumulative live birth rate after a freeze-all approach in women with polycystic ovaries: does the PCOS phenotype have an impact?

M. De Vos[1], P. Drakopoulos[2], M.F. Moeykens[1], L. Mostinckx[1], I. Segers[1], G. Verheyen[1], H. Tournaye[1], C. Blockeel[1], S. Mackens[1]

[1]Universitair Ziekenhuis Brussel / Vrije Universiteit Brussel, Centre for Reproductive Medicine, Brussel, Belgium ;
[2]Crete University- Crete- Greece, Department of Obstetrics and Gynecology, Heraklion, Greece

Study question: Do cumulative live birth rates (CLBR) differ between PCOS phenotypes when a freeze-all strategy is used to prevent OHSS after ovarian stimulation (OS)?
Summary answer: When conventional-dose OS resulted in high response, a CLBR of ~ 70% was observed after "freeze-all" in women with PCOS, irrespective of their phenotype.
What is known already: Previous observational studies have shown that CLBR in women with PCOS who undergo assisted reproductive technologies (ART) may depend on their phenotype. When OS was performed with caution to avoid ovarian hyperresponse, CLBR was lower in women with a hyperandrogenic PCOS phenotype. However, when women with PCOS do exhibit hyperresponse and a freeze-all strategy is used, the impact of the PCOS phenotype on the clinical outcome of the ART cycle is unclear.
Study design, size, duration: This is a single-centre, retrospective cohort study including 422 women with polycystic ovary syndrome (PCOS) as defined by Rotterdam criteria or PCO-like ovarian morphology-only (PCOM) in whom a freeze-all strategy was applied after GnRH agonist triggering in the context of hyperresponse defined as ³19 follicles of ³11mm in their first or second IVF-ICSI cycle between January 2015 and December 2019 in a tertiary referral hospital.
Participants/materials, setting, methods: PCOS phenotype was based on hyperandrogenism (H), ovulatory dysfunction (O) and PCO-like ovarian morphology (P). Ovarian stimulation was performed with rFSH or HPhMG, adjusted to BMI. The primary outcome was cumulative live birth rate (CLBR) resulting from the transfer of all cryopreserved embryos from the same IVF-ICSI cycle. Patient and cycle characteristics and laboratory and clinical data were analysed. Data were analysed by multivariate logistic regression adjusting for covariates.
Main results and the role of chance: In total, 91/422 (21.6%) patients had PCOS phenotype A (HOP); 33 (7.8%) had phenotype C (HP), 161/422 (38.2%) had phenotype D (OP) and 137/422 (32.5%) had PCOM (n= 137). BMI, AMH and AFC were significantly different between phenotype groups (p<0.001), and highest in PCOS phenotype A. The type of gonadotropin used, as well as the mean daily and total stimulation dose were comparable for all groups. The mean number of retrieved oocytes was comparable among groups (22.4±10.8 for phenotype A, 21.4±7.1 for phenotype C, 20.4±7.8 for phenotype D and 22.2±9.7 for PCOM; p= 0.46). The mean number of embryos available for vitrification differed significantly (4.4±3.7, 5.7±3.4, 5.7±3.4 and 5.2±3.6, respectively; p= 0.005). Following the first frozen embryo transfer, LBR was comparable among groups (41.5%, 43.3%, 49.3% and 38.5%, respectively; p=0.31). Unadjusted CLBR was also similar (69.2%, 69.7%, 79.5% and 67.9%, respectively; p= 0.11). The multivariate logistic regression model adjusting for age, BMI,

number of oocytes and embryo stage (cleavage vs. blastocyst stage) confirmed that the PCOS/PCOM phenotype did not have any impact on CLBR (OR 0.80, CI 0.28-2.29 (phenotype C); OR 1.40, CI 0.67-2.90 (phenotype D); OR 0.65, CI 0.31-1.34 (PCOM); p= 0.1, with phenotype A as reference).
Limitations, reasons for caution: These data should be interpreted with caution as the retrospective nature of the study holds the possibility of unmeasured confounding factors. The results cannot be generalised to all ART cycles in women with polycystic ovaries as they pertain to those cycles where OS leads to hyperresponse.
Wider implications of the findings: In subfertile women with PCOS eligible for ART, hyperresponse after OS confers excellent cumulative live birth rates when a freeze-all strategy is used, eliminating unfavourable clinical outcomes that had previously been observed in hyperandrogenic PCOS women after mild OS targeting normal ovarian response and fresh embryo transfer.
Trial registration number: not applicable

O-162 Metabolic syndrome prevalence and severity during a randomized controlled three-component lifestyle intervention in women with PCOS

A. Dietz de Loos[1], G. Jiskoot[1,2], A. Beerthuizen[2], J. Van Busschbach[2], J. Laven[1]

[1]Erasmus Medical Center, Obstetrics and Gynaecology- Division of Reproductive Endocrinology and Infertility, Rotterdam, The Netherlands ;
[2]Erasmus Medical Center, Psychiatry- Section Medical Psychology and Psychotherapy, Rotterdam, The Netherlands

Study question: What is the impact of a three-component lifestyle intervention on the prevalence and severity of metabolic syndrome (MetS) in women with polycystic ovary syndrome (PCOS)?
Summary answer: This three-component lifestyle intervention was more successful in improving metabolic health in reproductive-aged women with PCOS compared to minimal treatment.
What is known already: Women with PCOS have increased risk of MetS, and both PCOS and MetS are associated with excess weight. Moreover, obesity exacerbates many of the metabolic abnormalities associated with PCOS. Multicomponent lifestyle interventions are the first line treatment to improve weight. Previous studies in women with PCOS have described improvements in waist circumference, cholesterol, low-density lipoprotein and fasting insulin after (one-, or two-component) lifestyle interventions. However little is known about changes in the prevalence of MetS, continuous MetS severity z-score (cMetS z-score), different metabolic parameters and the effects of changes in weight per se after three-component lifestyle interventions.
Study design, size, duration: An randomized controlled trial (RCT) was performed and participants were either assigned to a one-year three-component (cognitive behavioural therapy, diet, exercise) lifestyle intervention (LSI), with or without additional short message service (SMS) support (SMS+ and SMS- respectively), both receiving 20 group sessions, or to care as usual (CAU, control) which consisted of advice to lose weight by methods of their own choosing. Overall, 183 women were included between August 2010 and March 2016.
Participants/materials, setting, methods: Women diagnosed with PCOS according to the Rotterdam 2003 criteria, aged 18-38 years, having a wish to conceive and a BMI >25 kg/m² were included at the Erasmus MC, The Netherlands. Outcome variables were evaluated every three months and included anthropometric measurements, ultrasound and an endocrine assessment. Multilevel linear and logistic regression was applied for longitudinal analyses.
Main results and the role of chance: The cMetS severity z-score decreased more in the SMS+ group vs CAU after one year (-0.39, p=0.015). MetS changed with -21.6% (p=0.037), -16.5% (p=0.190) and +7.0% (p=0.509) within the SMS-, SMS+ and CAU group respectively. Moreover, a post hoc analysis on the prevalence of MetS for both LSI groups combined vs CAU resulted in a difference of -25.9% (p=0.046) after one year in favour of the LSI groups. Weight loss per se resulted in significant favourable effects on all metabolic parameters.
Limitations, reasons for caution: Dropout during lifestyle interventions is unfortunately a common phenomenon, and our RCT also suffered from considerable discontinuation rates which is a limitation. Therefore, we selected a statistical method (multilevel regression modelling) specifically designed to deal with such missing values.
Wider implications of the findings: These findings confirm that three-component lifestyle interventions aiming at a 5-10% weight loss should be recommended for all women with PCOS in order to improve metabolic health during their reproductive lifespan.
Trial registration number: NTR2450

O-163 Hyperandrogenaemia in early adulthood is an independent risk factor for abnormal glucose metabolism in later life

K. Tuorila[1], M.M. Ollila[2], M.R. Järvelin[3], J. Tapanainen[4], S. Franks[5], K. Puukka[6], T. Piltonen[1], L. Morin-Papunen[1]

[4]University of Oulu and Oulu University Hospital- Medical Research Center-PEDEGO Research Unit- University of Helsinki and Helsinki University Hospital, Department of Obstetrics and Gynecology, Oulu, Finland ;
[5]Imperial College London, Institute of Reproductive and Developmental Biology, London, United Kingdom ;
[6]University of Oulu and Oulu University Hospital- Medical Research Center Oulu, NordLab Oulu- Department of Clinical Chemistry, Oulu, Finland

Study question: What is the role of androgen excess as a contributing factor to insulin resistance and abnormal glucose metabolism (AGM) in women?
Summary answer: There was a positive association between early adulthood hyperandrogenaemia with AGM. Serum SHBG levels could help identifying women at risk for disordered glucose metabolism.
What is known already: It is commonly recognised that insulin resistance induces compensatory hyperinsulinaemia which promotes ovarian androgen secretion. Studies in rodents have also suggested that testosterone causes prolonged activation of androgen receptor in pancreatic islet β-cells, inducing insulin hypersecretion and eventually secondary β-cell failure, thus predisposing to type 2 diabetes (T2D). However, the exact physiology behind the association between androgens, insulin resistance and T2D in women is not well understood. Many previously published studies are limited by cross-sectional study design, unrepresentative clinic populations, as well as variying steroid hormone measurement methods and definitions of androgen excess.
Study design, size, duration: A prospective longitudinal population-based cohort (n=5,889) to investigate whether serum levels of testosterone (T, measured using LC-MS/MS) and free androgen index (FAI) at ages 31 and 46 associated with AGM at age 46 years. After exclusion of pregnant women, users of hormonal intrauterine device, contraceptive pills, hormone therapy, minipills and statins, there were 4,421 women at age 31 and 4,457 women at age 46. At age 46 a two-hour OGTT was performed in 2,780 women.
Participants/materials, setting, methods: Serum fasting glucose and insulin, insulin resistance (HOMA–IR) and pancreatic β-cell function (HOMA–B) assessments were performed at ages 31 and 46. Elevated T levels (age 31: >2.3nmol/l; age 46: >1.7nmol/l) were defined according to the 97.5% percentile. T2D diagnoses were gathered from postal questionnaire at age 46, and verified and completed from the hospital discharge and national medication reimbursement registers. Impaired fasting glucose, impaired glucose tolerance or T2D were categorised as AGM.
Main results and the role of chance: At age 31, hyperandrogenic (HA) women displayed increased insulin resistance estimated by HOMA-IR (1.35±0.96 *vs.* 1.03±0.44, P=0.05), increased insulin secretion estimated by HOMA-B (115.05±34.67 *vs.* 99.25±25.47, P=0.006), and higher fasting insulin level (10.48±7.54 mU/l *vs.* 7.93±3.42 mU/l, P=0.034) compared with normoandrogenic (NA) women, after BMI adjustment. At age 46, HA women had comparable HOMA-B levels (98.04±60.03 *vs.* 96.27±65.89, P=0.93) but their fasting glucose (5.57±1.06 mmol/l *vs.* 5.37±0.77 mmol/, P=0.07) and glycated haemoglobin levels (37.47±7.83 mmol/mol *vs.* 36.18±4.99 mmol/mol, P=0.07) tended to be higher.
Women in the highest T quartile (Q4: odds ratio [OR]=1.77, 95%CI: [1.14–2.76]) and in the two highest FAI quartiles at age 31 (Q4: OR=3.61 [2.16–6.03] and Q3: OR=2.11 [1.24–3.59]) had increased risk for AGM at age

46, independently of BMI, when compared with women in the lowest quartile. Similarly, women in the two highest FAI quartiles at age 46 had increased risk for AGM (Q4: OR=2.91 [1.82–4.64]) when compared with women in the lowest quartile, after BMI adjustment. The three highest sex hormone-binding globulin (SHBG) quartiles inversely associated with AGM, both at ages 31 and 46, independently of BMI (at age 31: Q4: OR=0.38 [0.24–0.62], at age 46: Q4: OR=0.27 [0.17–0.44]).

Limitations, reasons for caution: We used only serum T as a marker of HA, even though other androgens, such as androstenedione and adrenal androgens have a place in the evaluation of androgenicity in women. Further studies of other large populations are needed to confirm our results.

Wider implications of the findings: This is the first longitudinal, general population based study to confirm a positive association between early adulthood hyperandrogenaemia with AGM in middle adulthood independently of confounding factors. Our results further suggest that SHBG levels could help to identify women at risk for AGM.

Trial registration number: NA

O-164 Associations between hypothyroidism and adverse obstetric and neonatal outcomes: a population study of 9.1 million births

R. Hizkiyahu[1], A. Badeghiesh[1], H. Baghlaf[1], M.H. Dahan[1]

[1]Department of Obstetrics and Gynecology- McGill University Health Centre-McGill University- Montreal- QC- Canada, Department of Obstetrics and Gynecology, Montreal, Canada

Study question: Does hypothyroidism confer an independent risk for adverse delivery and neonatal outcomes, based on analysis of the Healthcare Cost and Utilization Project-Nationwide Inpatient Sample database?

Summary answer: After controlling for confounders, women with hypothyroidism are at an increased risk of hypertensive disorders of pregnancy, preterm delivery, placental abruption, hemorrhage and caesarean section.

What is known already: Surprisingly, studies in the literature on maternal and neonatal complications of hypothyroidism in pregnancy are relatively small. The largest study to date included 184,611 pregnancies overall, with 7140 with hypothyroidism. Maternal hypothyroidism has been associated with multiple adverse pregnancy outcomes. These findings have not been confirmed in a large population database study.

Study design, size, duration: This is a retrospective study utilizing data from the Healthcare Cost and Utilization Project-Nationwide Inpatient Sample (HCUP-NIS). A cohort of all deliveries between 2004 and 2014 inclusively was created. Within this group, all deliveries to women with hypothyroidism formed the study group (n=185,073), and the remaining deliveries were categorized as non- hypothyroidism births and comprised the reference group (n=8,911,715). The main outcome measures were pregnancy and perinatal complications. Patients were included once per pregnancy.

Participants/materials, setting, methods: The HCUP-NIS is the largest inpatient sample database in the USA. It provides information relating to seven million inpatient stays per year, includes ~20% of hospital admissions, and represents over 96% of the American population. Multivariate logistic regression analysis, controlling for confounding effects, was conducted to explore associations between hypothyroidism and delivery and neonatal outcomes. According to Tri-Council Policy statement (2018), IRB approval was not required, given data was anonymous and publicly available.

Main results and the role of chance: Women with hypothyroidism were more likely to be older than 25 years, Caucasian, have higher household incomes, private insurance and deliver in an urban teaching hospital, as compared with the non-hypothyroidism obstetrical population (p<0.0001, all cases). After adjustment for all statistically significant confounders, women with hypothyroidism were more likely to suffer from gestational diabetes mellitus (aOR 1.43, 95%CI 1.38-1.47), hypertensive disorders of pregnancy: gestational hypertension (aOR 1.17, 95%CI 1.11-1.22) and preeclampsia (aOR 1.21, 95%CI 1.16-1.27) (all P<0.001)). They were more likely to experience PPROM (aOR 1.19, 95%CI 1.09-1.29) and preterm delivery (aOR 1.12 95%CI 1.08-1.17), and deliver by caesarean section (aOR 1.21, 95% CI 1.18-1.24 (all P<0.001)). Women with hypothyroidism more often developed chorioamnionitis (aOR 1.09, 95%CI 1.01-1.17, P=0.019), maternal infections (aOR 1.08, 95% CI 1.01-1.16, P=0.017), post-partum hemorrhage (aOR 1.07, 95%CI 1.01-1.13, P=0.012), disseminated intravascular coagulation (aOR 1.20, 95%CI 1.00-1.43, P=0.047), require blood transfusions (aOR 1.12, 95%CI 1.03-1.22, P=0.009), and hysterectomy (aOR 1.42, 95% CI 1.13-1.80, P=0.012) compared to the control group. [HB1] As for neonatal outcomes, small for gestational age and congenital anomalies were more likely to occur in the offspring of women with hypothyroidism (aOR 1.20, 95% CI 1.14-1.27 and aOR 1.34, 95% CI 1.22–1.48, both P<0.001).

Limitations, reasons for caution: This is a retrospective analysis utilizing an administrative database that relies on data coding accuracy and consistency.

Wider implications of the findings: Women with hypothyroidism were more likely to experience pregnancy, delivery and neonatal complications. We found an association between hypothyroidism and; hypertensive disorders, post-partum hemorrhage, transfusions, infections, preterm deliveries and hysterectomy, among other problems. This data from a population sized database confirmed the findings of the smaller studies in the literature.

Trial registration number: not applicable

Study question: How was the Logbook for the Nurses and Midwives Certification programme of the European Society of Human Reproduction and Embryology (ESHRE) developed?

Summary answer: The Logbook for the ESHRE Nurses and Midwives Certification programme, which questions 56 roles, was developed based on an extensive literature review and expert opinion.

What is known already: The ESHRE Executive Committee established the Nurses and Midwives Certification Committee (NMCC) in 2012. Since inception (2015), the certification programme has been delivered annually, with the exception of 2020 because of SARS-CoV-2. One-hundred-fourteen nurses/midwives have obtained ESHRE certification (passing rate=72%) and the programme is now accessible to nurses/midwives globally. The Certification program aims (i) to recognise the extended role of nurses/midwives delivering fertility care and (ii) to expand their theoretical background. The pre-requisites for certification are (i) being educated to a bachelor level of education and (ii) completing a practice based Logbook to demonstrate supervision of professional experience.

Study design, size, duration: Between 2012 and 2014, the NMCC completed a systematic literature search for papers relating to clinical, non-clinical and extended roles of nurses and midwives in fertility settings. In addition, the NMCC invited a larger expert panel of European senior nurses and midwives to a meeting to discuss their needs and preferences regarding the certification programme and to survey the diverse roles performed by nurses and midwives in their country.

Participants/materials, setting, methods: The NMCC comprised four nurses/midwives, one clinical embryologist, and one medical doctor (both in advisory capacity). The Medline database was searched by entering a search string in PubMed combining (MeSH) terms related to reproductive medicine and nursing or midwifery. Opinion and empirical papers relating to roles of nurses/midwives in fertility settings were included. The surveyed expert panel included twelve nurses/midwives, representing Belgium, Denmark, Finland, France, Norway, Slovenia, Sweden, Turkey, Ukraine, and the United Kingdom.
Main results and the role of chance: A total of 49 papers, of which 24 empirical papers, were identified with the search string (n=47) and snowball strategy (n=2). The papers originated from 13 countries spread across Asia, Oceania, Europe, and North America. All twelve European senior nurses and midwives responded to the survey. Finally, 56 different roles were included in the Logbook. Forty-four roles were performed by nurses/midwives working in fertility settings according to the surveyed expert panel (n=18), the literature (n=8), or both the surveyed expert panel and literature (n=18). An additional twelve observations of laboratory procedures were added by the NMCC. Substantial variation in roles and responsibilities existed across the countries from which the evidence originated. Whereas a considerate proportion of roles were performed in at least five countries (n=16/56), a minority of roles were only performed by nurses/midwives in some countries (n=7/56). Eight specialist roles (e.g. embryo transfer) were performed independently by nurses/midwives in some countries, whilst in other countries, nurses/midwives merely had an assisting role. In addition to completing the Logbook, participants were expected to write two ethical cases according to a guideline, testifying to their ability to reflect as a senior nurse/midwife. From 2015, the content of the Logbook was further developed.
Limitations, reasons for caution: This abstract relates to the development and content of the Logbook and not the curriculum/educational material required for the theoretical exam of the Nurses and Midwives Certification programme. The NMCC continuously improves the Logbook and elements have been added and removed since its creation.
Wider implications of the findings: The review and survey illustrated the variation in roles and responsibilities of nurses/midwives across the studied countries, further highlighting the opportunity for professional development within fertility care. Further research is required to elicit the experience of certified nurses/midwives with the programme and its impact on their professional and personal development.

O-166 A smartphone video clip on the patient journey to reduce patient's anxiety: a randomized controlled trial

L. Dias[1], P. De Loecker[2], T.M. D'Hooghe[1,3], K. Peeraer[1,4], E. Dancet[1,5]

[1]KU Leuven, Vrouw & Kind, Leuven, Belgium ;
[2]GZA Ziekenhuizen, Gynaecologie - Verloskunde - Fertiliteit, Wilrijk, Belgium ;
[3]Merck Healthcare KGaA, Global Medical Affairs Fertility, Darmstadt, Germany ;
[4]UZ Leuven, Leuvens Universitair Fertiliteitscentrum, Leuven, Belgium ;
[5]Research Foundation Flanders FWO, Postdoctoral Fellow, Brussel, Belgium

Study question: Can a smartphone video clip detailing the patient journey decrease the anxiety of women and men on the day of their first oocyte aspiration?
Summary answer: The video clip does not affect the anxiety of women but does reduce the anxiety of men on the day of couples' first oocyte aspiration.
What is known already: Infertility and in vitro fertilisation (IVF) decrease the personal wellbeing of women and men. Couples shared that this contributed to their IVF discontinuation despite a good prognosis and reimbursement of IVF. Previous longitudinal studies confirmed that pre-IVF anxiety is associated with IVF discontinuation. Limiting treatment anxiety is, therefore, relevant for fertility patients and clinics. Studies from the field of reproductive medicine examining the effect of preparatory information on anxiety suggest that focussed interventions seem more effective than complex interventions. Several randomized controlled trials (RCTs) found that preparatory information movies reduce anxiety for out-patient cardiology procedures in women and men.
Study design, size, duration: This monocentric RCT randomized (1:1 allocation; computerized) 190 heterosexual couples about to start their first IVF cycle between care as usual (i.e. preparatory information session 1-3 months before IVF) and care as usual combined with a novel intervention during a 24 months recruitment period (2018-2020). The novel intervention is a 5-minute smartphone video clip detailing the patient journey on the day of oocyte aspiration, which was sent to both partners the day before oocyte aspiration.
Participants/materials, setting, methods: Upon arrival at a private fertility clinic for their first oocyte aspiration women and men independently filled out the 'STAI-State anxiety inventory' and the 'infertility distress scale (IDS)' and evaluated the novel intervention, if applicable. A minority of randomized couples didn't comply with the standard IVF trajectory (n=27) or didn't fill out the questionnaires (n=8). The data of 155 couples (76-79/group, a-priori sample size calculation requested minimally 76/group) was subjected to a modified intention-to-treat analysis.
Main results and the role of chance: Women and men were on average 33 and 35 years old, respectively. Couples had a mean duration of infertility of 27 months and 63 of them (41%) had tried intrauterine insemination. The background variables were equally distributed between the intervention (IG) and control group (CG). The video clip did not affect women's anxiety on the day of oocyte aspiration (mean STAI-State score IG 42.7±8.1 vs CG 42.1±8.5, p=0.67). However, men who watched the video clip were significantly less anxious than men who did not watch it (mean STAI-State score IG 35.8±6.4 vs CG 38.2±7.6, p=0.04). Surprisingly, infertility-specific distress was higher among women and men who watched the video clip (mean IDS scores of 25.8±4.9 and 22.6±5.0, respectively), as compared to women (p=0.05) and men (p=0.02) who did not watch the video clip (mean IDS score 24.3±4.6 and 20.8±4.7, respectively). All women and men of the intervention group, except one woman, would recommend the video clip to friends and family going through IVF. The intervention and control group did not differ significantly regarding clinical pregnancy rate (31/76 vs. 29/79, p=0.60) or miscarriage rate (2/76 vs. 3/79, p=0.68) 12 weeks after their first oocyte aspiration.
Limitations, reasons for caution: Patients nor assessors were blinded and there was no attention control group. Selection bias is plausible although the participation rate was 89%. Assessing infertility-specific distress the day after watching the video clip was not optimal, as priming couples to feel infertility-specific distress short term is less problematic than longer term.
Wider implications of the findings: Providing additional procedural information is interesting for clinics as patients recommended the video clip and as it decreased men's anxiety. A follow-up study should examine whether the video clip's priming effect on infertility-specific distress lasts longer than only the day after and whether the video clip affects IVF discontinuation.
Trial registration number: NCT03717805

O-167 Sleep quality and affecting factors in women undergoing in vitro fertilization treatment

F. Yanık[1], M. Alus Tokat[1]

[1]Dokuz Eylul University Nursing Faculty, Obstetrics and Gynecology Nursing Department, Izmir, Turkey

Study question: Does in vitro fertilization (IVF) treatment affects the sleep quality of women and which factors reduce the sleep quality in different stages of this treatment?
Summary answer: The sleep quality decreased as the IVF treatment process progresses. Advanced age, prolonged treatment, economical concerns, stress ect. were factors that adversely affected women sleep.
What is known already: According to worldwide research, women receiving IVF treatment may suffer from physiological and psychological symptoms and even experience sleep disturbance. Sleep disturbances are thought to be frequent in women undergoing IVF despite minimal research of this hypothesis. The literature emphasizes the positive effect of quality sleep on oocyte health. Especially sleep hormone melatonin is effective in development of oocytes quality. During sleep, hormones such as melatonin and growth hormone can protect oocytes from the effects of harmful metabolites and improve oocyte quality. Routine evaluation of sleep quality and affecting factors may be an important issue in women receiving IVF treatment.
Study design, size, duration: It was longitudinal study with repeated measures. The sample consisted of 158 women from 218 eligible patients who received IVF treatment in two infertility centers in Izmir between December 2017 and March 2019. Treatment-related side effects, cancellation of embryo

transfer, and women could not be reached after embryo transfer were excludation reasons. According to the statistical analysis, the effect size was calculated as 0.496 and the statistical power as 100%.

Participants/materials, setting, methods: Data were collected via a structured questionnaires, "The Descriptive Data Form", "Pittsburgh Sleep Quality Index", "Visual Analog Stress Scale" and "Treatment Related Physical Symptoms List". The sleep quality and effecting factors were evaluated in three stages; the data related to pre-treatment period in beginning of IVF trial, in oocyte pick up (OPU) day induction-OPU process data and 1-2 days before pregnancy test, post embryo transfer data were collected.

Main results and the role of chance: The average sleep quality score was 6.96 in the pre-treatment period, 8.03 in the induction-oocyte pick up process, and 8.87 in the post embryo transfer ($p< 0.001$), the higher score it is evaluated as lower sleep quality. There was also a strong positive correlation between the stress scores and sleep quality before and during the treatment periods ($r=7.638$ $p< 0.001$, $r=0.672$ $p< 0.001$, $r=0.694$ $p< 0.001$). Among the descriptive features; advanced age, low education level, shift work, prolonged marriage duration, among infertility features; prolonged treatment, female and male factor, economic distress and sleep habit; such as being exposed to light were associated with poorer sleep quality ($p< 0.001$). Related to physical symptoms such as the abdominal distention, abdominal pain and breast fullness observed induction-OPU period ($t=4.79$ $p= .00$, $t=2.93$ $p= .00$, $t=2.77$ $p= .00$) and besides nausea and fatigue in post embryo transfer period where symptoms that significantly affect sleep quality ($t=9.38$ $p= .00$, $t=4.20$ $p= .00$, $t=4.06$ $p= .00$, $t=4.27$ $p= .00$, $t=4.33$ $p= .00$). According to results it was determined that women sleep quality decrease along with progress of IVF trial. Consequently health professionals should assess women's sleep quality and give support in most risky periods.

Limitations, reasons for caution: The fact that some women cannot be reached by phone after embryo transfer during the data collection process can be shown as the limitations of the study. At the same time, the subjective evaluation of sleep quality can be expressed as another limitation of the study.

Wider implications of the findings: There is a need for an experimental, randomized controlled study with objective evaluation of sleep outcomes. Therewithal examining the effect of sleep outcomes on the oocytes quality and pregnancy rates will guide clinical practise during IVF and other assisted reproductive treatments.

Trial registration number: There is no number

O-168 Chronic pelvic pain is the most troublesome endometriosis pain symptom for women's quality of life

P. Pijpops[1], S. Apers[2], C. Meuleman[3], C. Tomassetti[3], E. Dancet[1]

[1]Leuven University, Department for Development and Regeneration, Leuven, Belgium ;
[2]UZ Leuven, Women&Child, Leuven, Belgium ;
[3]KU Leuven, Department for Development and Regeneration, Leuven, Belgium

Study question: Which pre-operative endometriosis pain symptom is most troublesome for the quality-of-life of women assessed at different meta-levels?

Summary answer: Of five pain symptoms chronic pelvic pain is most troublesome or has the strongest correlation to women's overall quality-of-life and overall and endometriosis-specific health status.

What is known already: Endometriosis affects women's quality of life negatively, and its impact seems to depend more on women's symptoms than on their degree of endometriosis. Experts proposed to include 'the most troublesome symptom' and 'overall pain' as core outcomes but did not define how to assess these outcomes. It would be interesting to find out which pain symptom (i.e. assessed for presence and intensity) has most impact on women's quality-of-life assessed at different meta-levels, including: overall quality-of-life (depending on amongst others one's professional and relational life besides health), general health status and endometriosis-specific health status.

Study design, size, duration: A prospective survey addressed 277 adult women scheduled for diagnostic and/or therapeutic surgery in a University endometriosis clinic between October 2016 and November 2019. Women were reminded twice of our request to fill out the coded but anonymous questionnaire package assessing five pain symptoms (i.e. chronic pelvic pain, dysmenorrhea, dyspareunia, dysuria and dyschezia) and assessing quality-of-life at three different meta-levels.

Participants/materials, setting, methods: Women scored five endometriosis symptoms between 0 (no pain) and 10 (worst imaginable pain), combined into 'overall pain' (0-50). 'Overall quality-of-life' was assessed with the Linear Analogue Scale (LAS; the higher, the better). General and endometriosis-specific health status were assessed with the overall scores of the EuroQol-5D and the Endometriosis-Health-Profile-30 (the higher, the better). Pearson correlation coefficients between the six pain scores and three measures of quality-of-life were computed ($p=0.003$; 0.05/18 as Bonferroni correction).

Main results and the role of chance: A total of 227 women took part (participation rate=82%) and the data of 202 women (mean age 31±5 years old) with surgically confirmed endometriosis were analysed. In the previous six months, the majority of women reported chronic pelvic pain (56%), dyspareunia (55%), dysmenorrhea (56%) and/or dyschezia (58.4%), while only some reported dysuria (25%). Women's mean overall pain score was 20 (±12). Women's mean overall quality-of-life was 65 (±16). On average women rated their general health status to be 62 (±18) and their mean endometriosis-specific health status was 53 (±18). Only the pain symptom chronic pelvic pain was correlated ($p<0.001$) to assessments of quality-of-Life at all three meta-levels. The correlation for endometriosis-specific health status was large ($r= -0.574$), while the others were medium ($r= -0.343$ & $r= -0.324$). After taking account of the Bonferroni correction for multiple testing the remaining four pain symptoms only had a medium correlation ($p<0.001$) to endometriosis-specific health status ($r= -0.356$ – -0.265; $p<0.001$) and they were not correlated to overall quality-of-Life or general health status. Overall pain had a medium correlation ($p<0.001$) to Overall quality-of-Life ($r= -0.270$) and general health status ($r= -0.259$) and a strong correlation ($p<0.001$) to endometriosis-specific health status ($r= -0.529$).

Limitations, reasons for caution: The majority of patients (60%) of the recruiting University endometriosis clinic had severe endometriosis (AFS-IV) and this study could be repeated in another setting. Directly asking women which pain symptom is most troublesome to them would be interesting besides exploring correlations between pain symptoms and quality of life.

Wider implications of the findings: Nurses, midwives and other health care professionals should devote attention to chronic pelvic pain during the anamnesis and women-centred care as this pain symptom is most troublesome for women's quality of life. Whether surgery decreases chronic pelvic pain and overall pain is currently followed-up in the studied prospective cohort.

INVITED SESSION

SESSION 51: ENDOMETRIOSIS AND INFERTILITY. THE SILENT DISEASE

30 June 2021 Stream 2 11:45 - 12:45

O-057 The impact of diagnosis endometriosis as part of the fertility workup

J.A. Garcia-Velasco[1]

[1]IVI RMA -Madrid, Reproductive Endocrinology and Infertility, Madrid, Spain

Abstract text

The impact of diagnosis endometriosis as part of the Fertility workup

Endometriosis is a multifaceted disease that may go from completely asymptomatic to a debilitating condition with severe pelvic pain complicated infertility. In the last few years, how we approach fertility in women with endometriosis has clearly changed, postponing definitive/radical surgery till the patient has completed her family. As a clear association exists with endometriosis and infertility, during the fertility workup it is one of the diseases to investigate, as it may have been missed in previous annual gynecologic checkups. Here we may face two problems: a) the stigma of diagnosis a young women with the label "endometriosis", as she may be under the pressure of a progressive disease that may or may not affect her quality of life, and b) if the diagnosis of endometriosis is positive, how this may affect the decision making process during the fertility journey.

In this lecture we will discuss the difficulties of early diagnosis of endometriosis, why most of the previous test have failed, and the new opportunity that miRNAs seem to offer. Once endometriosis is diagnosed –early or late stages- how this may affect spontaneous chances of pregnancy, ovarian reserve, oocyte and embryo quality, endometrial receptivity, and last but not least, time to pregnancy. Obviously, the prognosis changes over time, and women's age will be conditioning most of our decisions. We will try to identify whom to treat, to increase the absolute pregnancy rate, and when to treat, to reduce the time to pregnancy. Finally, we will discuss the opportunity of fertility preservation in this particular subgroup of women. Being aware of the potential damage that endometriosis by itself, or the associated ovarian surgery, may inflict on ovarian reserve make these women more proactive for fertility preservation.

O-058 The impact of endometriosis on fertility treatment

E. Somigliana[1]

[1]*Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Obstet-Gynecol, Milano, Italy*

Abstract text

Endometriosis can affect natural fertility by distorting pelvic anatomy and by causing local pelvic inflammation that affects the quality of the oocytes, the function of the tubes and the sperm capacity to fertilize. Two approaches can be foreseen, either removing the disease with the aim of restoring normality (surgery) or overcoming the disease by retrieving oocytes in the ovary and allowing their fertilization in *in vitro* conditions (IVF). Both therapeutic approaches seem rational and wise. However, despite this apparently simple clinical scenario, management of endometriosis-related infertility has engendered long-lasting and burning debates over the last two decades and, to date, no consensus has been reached. Robust scientific evidence is scant, actually limited to the demonstration that laparoscopy modestly increases the chance of natural conception.

In this debate, it is noteworthy that chances of pregnancy do not represent the unique stake. Other factors can play a role and deserves consideration. Considering the choice of fertility treatment, he most relevant are the following: 1) the impact of ovarian endometriomas and their removal on ovarian responsiveness, 2) the impact of endometriomas and endometriosis in general on oocytes quality, 3) the additional risks of oocytes retrieval in the presence of endometriosis (infections in particular) 4) the detrimental effects of endometriosis-related hydrosalpinx, 5) the impact of endometriosis on uterine motility and endometrial receptivity, 5) the confounding effect of endometriosis-associated adenomyosis. Unfortunately, for the vast majority of these concerns, evidence is not definite and physicians have to take decisions based on their clinical commonsense.

INVITED SESSION

SESSION 52: THE END OF DONOR ANONYMITY. A MATTER OF FACT

30 June 2021 Stream 3 11:45 - 12:45

O-059 Direct to consumer genetic testing is the reason why

C. H. Howard[1]

[1]*Centre for Research Ethics and Bioethics, Uppsala University, Uppsala, Sweden*

O-060 Ethical implications of the direct to consumer genetic testing. What should donors and recipients know?

L. Frith[1]

[1]*Institute of Population Health, Health Services Research, Liverpool, United Kingdom*

Abstract text

The growth in the use of direct-to-consumer-genetic testing (DTCGT) is having a major impact on sperm, egg and embryo donor conception (hereafter donor conception). DTCGT services include family history sites, e.g. Ancestry.com, and medical testing sites, e.g.23andme. Despite the many different motivations people have for using these services, it is now easier to search and find donor relatives, with donor-conceived people, recipients of donor gametes and embryos, and donors all using these services to make hitherto unlikely connections. Some individuals have found large numbers of donor-siblings, while donors have been traced by their adult donor offspring. DTCGT can also reveal unexpected origins with the numbers of people finding out they are donor-conceived through DTCGT rapidly increasing. For example, one woman discovered she was donor conceived after using 23andme to assess her risk of breast cancer, an eventuality she had never anticipated when she decided to take th**at test.**

The increasing use of DTCGT has led to claims that donor anonymity is dead and we are entering a new era where the possibilities of finding our genetic relatives and extended family have dramatically expanded. These developments will produce new landscapes where different systems collide and interact, creating new ways of locating and finding donor relatives. In the UK for example, information on genetic relations, donors and donor siblings, is located within two very different systems: 'official' regulatory systems, such as central registers of information held by government bodies such as the Human Fertilisation and Embryology Authority's (HFEA) registers; and emerging digital online systems, of DTCGT.

This paper will explore how these new developments interact with existing ways of finding out information about donor relatives and consider the ethical and legal issues and challenges for fertility practice.

POSTER DISCUSSION

SESSION 53: ANDROLOGY POSTER DISCUSSIONS

30 June 2021 Stream 4 11:45 - 12:45

P-050 The effectiveness of the platelet-rich plasma treatment of men with severe oligoasthenoteratozoospermia

O. Somova[1], **H. Ivanova**[1], **N. Sotnyk**[2], **K. Kovalenko**[2], **I. Feskova**[1]

[1]*Centre of Human Reproduction Sana-Med Clinic of Professor Feskov O., IVF Deparrtment, Kharkiv, Ukraine ;*

[2]*Centre of Human Reproduction Sana-Med Clinic of Professor Feskov O., Biothechnology Department, Kharkiv, Ukraine*

Study question: To evaluate the effect of platelet-rich plasma (PRP) testicular injections on spermogram parameters of men with severe oligoasthenoteratozoospermia (OAT).

Summary answer: The PRP testicular injections have beneficial effects on spermatogenesis and enhance sperm concentration and motility in infertile men with OAT.

What is known already: The use of PRP therapy in assisted reproductive technologies is debatable. Despite the recent evidence of its positive effects in promoting endometrial and follicular growth, data from clinical studies are limited. There are only a few papers on the effectiveness of PRP therapy in the treatment of male infertility and sexual dysfunction. In more detail, the influence of PRP on spermatogenesis was carried out only on experimental animals. Although the mechanisms of its action have not yet been clarified, it is assumed that PRP, containing many biologically active molecules, realizes its effect through the tissue regeneration and cell proliferation.

Study design, size, duration: This prospective study included 68 men (34.6±5.2) years old with severe OAT (≤4 million/ml, motility ≤30%, normal sperm morphology ≤1%) receiving hormonal and antioxidant (AO) therapy during 6 months before in vitro fertilization cycles. 33 of them were injected once with autologous PRP (0.5 ml in each testicle). Spermogram and testosterone level were analyzed before the treatment and in 3, 4 and 6 months after it.

Participants/materials, setting, methods: Sperm concentration, motility and morphology in ejaculate of 33 men of PRP group were compared with those in the group of 35 men without PRP within 6 months of starting the treatment. Total and free testosterone level were measured in blood serum. PRP was prepared by centrifuging the patient's own blood in the anticoagulant-containing

tubes. The final concentration of platelets in the obtained sample was 950.000 – 1.250 000 cells in 1 ml.

Main results and the role of chance: 4 months after the PRP injection, sperm concentration and motility increased in 18 of 33 men of the PRP group compared with the baseline (before the treatment) – 4.2 (1.0;6.9) vs 1.4 (0.1;3.4) mln/ml ($p<0.05$) and 36.7 (30.6;45.8) vs 17.7 (6.7;28.2) % respectively ($p<0.05$). The maximum increase in sperm motility (but not in sperm concentration!) was observed in 24 men in 6 months – 49.6 (39.6;56.4) % ($p<0.05$). Percent of morphologically normal spermatozoa in ejaculate slightly increased only in 12 men in that time period from 0-1 % to 1-2%. The total testosterone level was 2.4 times higher than the baseline (31.6±7.2 vs 13.2±4.3 nmol/l, $p<0.05$), the free testosterone level was 1.8 times higher (14.5±3.5 vs 7.9±3.0 pgl/ml, $p<0.05$).

Unlike the PRP group, in the group of men without PRP treatment, the sperm parameters did not changed compared with the baseline in 4 months after the starting hormonal and AO treatment. A significant increase of sperin concentration was observed only in 17 of 35 patients in 6 months. Sperm motility and percent of morphologically normal spermatozoa after the treatment did not differ from the baseline. Changes in the testosterone levels were similar to changes in PRP group.

Limitations, reasons for caution: Only young and middle-aged men were considered in the study. Large randomized controlled studies are required to confirm the PRP therapy efficacy and safety of f various fertility disorders. There are also no standardized protocols for PRP preparation.

Wider implications of the findings: PRP therapy may have great potential for the treatment of male infertility and improving spermatogenesis. Optimization of methods of PRP preparation and dosage of testicular injections can enhance reproductive outcomes in assisted reproductive technologies.

Trial registration number: not applicable

P-054 Pre-selected for an award: Apoptosis related-microRNAs in Oligoasthenoteratozoospermia and Azoospermia men may reveal novel study of freezing damage

M. Ezzati[1], M. Pashaiasl[1]

[1]Faculty of Anatomical Sciences- Faculty of medicine- Tabriz University of medical sciences- Tabriz- Iran., Department of Anatomical sciences- Faculty of medicine- Tabriz University of medical sciences- Tabriz- Iran., Tabriz, Iran

Study question: Could choosing of non-apoptotic spermatozoa by biological biomarkers such as microRNAs promote post-thaw fertilization ability?

Summary answer: Biological alterations in correlation with apoptosis and oxidative stress markers such as microRNAs may preserve the function and fertility of spermatozoa during cryopreservation.

What is known already: Biological changes of cryopreserved spermatozoa such as microRNAs against cryo-injury were investigated. It was presented that several sperm parameters such as motility and abstinence period can impact the percentage of post-thaw sperm survival. Recent study, reported that microRNAs related to process of motility, sperm structure and apoptosis were associated with different expression after cryopreservation. More comprehensive study needed to fully mention the effect of microRNAs and their correlations with other biomarkers in cryopreservation.

Study design, size, duration: Our study was performed on 58 men who were 24-40 years old. Their ejaculated samples were classified as sever (concentrations less than 5 million sperm/mL) Oligoasthenoteratozoospermia (SOAT), mild (concentrations 5 million – 10 million sperm/ mL) Oligoastheno teratozoospermia (MOAT), obstructive azoospermai (OA), Non obstructive azoospermai (NOA) (absence of spermatozoa in the semen) and normal group (concentrations more than 15 million sperm/ mL). Then each sample was grouped into fresh and cryopreserved one.

Participants/materials, setting, methods: Density Gradient centrifugation (DGC) was performed to obtain high quality sperm without round cells after freeze-thawing. Biopsy of testicular tissue was prepared after Testicular Sperm Extraction (TESE) surgery. Then biological biomarkers were examined before and after cryopreservation including microRNA-122 (miR-122), miR-383, miR-15b, miR-184, miR-34c and target genes such as P53, Caspase9 and CYCLIN D1, using Quantitative real-time polymerase chain reaction (RT-PCR). Glutathione peroxidase (GPx), Superoxide dismutase (SOD) and malondialdehyde (MDA) using imaging multi-mode reader.

Main results and the role of chance: There was a significant reduction in sperm total motility and morphology in Cryopreserved-infertile groups (MOAT and SOAT) compared with the Fresh-infertile groups. Decreased level of GPx activity was associated with increased concentration of MDA during freeze-thawing procedure in oligoasthenoteratozoospermia. Also increasing levels of SOD, and DNA fragmentation were showed. Our data demonstrated that reduction of CYCLIN D1 in MOAT-Cryopreserved ($P=0.0174$) and NOA-Cryopreserved ($P=0.0001$) groups were considerable compared with their fresh ones. We observed high level of Capase9 and in cryopreserved groups ($P=0.01$).The expression of miR-34c was increased significantly in NOA-Cryo ($P=0.0064$), and OA-Cryo ($P=0.0441$) in comparison with their fresh groups. The expression of miR-184 ($P=0.0275$) was enhanced in NOA-Cryo as compared to NOA-Fresh. Quantitative RT-PCR demonstrated meaningful decrease level of miR-383 expression in SOAT-Cryopreserved as compared with SOAT-Fresh ($P=0.0223$). On the other hand, expression level of miR-383 was increased in NOA group significantly ($P= 0.0437$) and in OA group non-significantly during freezing. There was non-significant decrease of miR-122 and miR-15b in MOAT and SOAT-Cryopreserved groups in comparison to their Fresh groups. We observed reduced expression of miR-122 ($P=0.0109$) and miR-15b ($P=0.0322$) in OA group after freezing. Also, there was meaningful increased level of miR-15b ($P=0.0234$) in NOA-Cryo compared with Fresh.

Limitations, reasons for caution: Because of the ethical principle, we can not obtain testicular samples from normal groups. So, we analyzed NO and OA groups with each other.

Wider implications of the findings: Our study documented that total motility can be interfered by microRNAs. This phenomenon effects on the total motility of post-thaw spermatozoa. Also the increase level of MDA may disturb microRNAs regulation in the infertile cases. These non-coding RNAs may be known as fertility biomarker to development of freeze-thawing strategies.

Trial registration number: 60961

P-064 Application of an artificial intelligence model for morphologic prediction of fertilization-competent human spermatozoa

T.Y. Leung[1], C.L. Lee[1], P.C.N. Chiu[1]

[1]The University of Hong Kong, Department of Obstetrics and Gynecology, Hong Kong, Hong Kong

Study question: What is the role of artificial intelligence in selecting fertilization-competent human spermatozoa according to their morphological characteristics?

Summary answer: The established AI model in this study can be potentially used to select semen samples with superior fertilization potential in clinical settings.

What is known already: Defective spermatozoa-zona pellucida (ZP) interaction causes subfertility and is a major cause of low IVF fertilization rates. While ICSI benefits patients with defective spermatozoa-ZP binding, a standard method to identify such patients prior to conventional IVF is lacking. The application of artificial intelligence to sperm morphology analysis has become a topic of growing interest owing to the fact that the conventional assessment is highly subjective and time-consuming. Deep-learning, a core element of artificial intelligence (AI), incorporates the convolutional neural networks (CNN) to process all the data composing a digital image through successive layers to identify the underlying pattern.

Study design, size, duration: The fertilization-competent spermatozoa were isolated according to their binding ability to the ZP. The ZP-bound and -unbound spermatozoa were collected for functional assays and to establish an AI model for morphologic prediction of sperm fertilization potential. Human spermatozoa (n=289) were isolated from normozoospermic samples. Human oocytes (n=562) were collected from an assisted reproduction program in Hong Kong. Sample collection has been ongoing and will continue until the end of this study in November 2021.

Participants/materials, setting, methods: Sperm-ZP binding assay was employed to collect ZP-bound and -unbound spermatozoa. The fertilization potential and genetic quality of the collected spermatozoa were evaluated by our established protocols. Diff-Quik- stained images of ZP-bound and -unbound spermatozoa were collected respectively for the establishment of an AI model. A novel algorithm for sperm image transformation and segmentation was

developed to pre-process the images. CNN architecture was then applied on these pre-processed images for feature extraction and model training.
Main results and the role of chance: Our result showed that the sperm-ZP binding assay had no detrimental effect on sperm viability when compared with the raw samples and unbound-sperm subpopulations. ZP-bound spermatozoa were found with statistically higher acrosome reaction rates, improved DNA integrity, better morphology, lower protamine deficiency and higher methylation level when compared with the unbound spermatozoa. A deep-learning model was trained and validated by analyzing a total of 1,334 and 885 of ZP-bound/ unbound spermatozoa to evaluate the predictive power of sperm morphology for ZP binding ability. Our newly trained AI-based model showed initial success in classifying the ZP-bound/ unbound spermatozoa according to their morphological characteristics with high accuracy of 85% and low computational complexity.
Limitations, reasons for caution: This sperm selection method requires micromanipulation and relatively long processing time to recover ZP-bound spermatozoa. In addition to limited availability, the use of human materials may result in interassay variations affecting the reproducibility of this method among laboratories.
Wider implications of the findings: In light of current findings, AI-based sperm selection method may provide high predictive values of sperm fertilization potential for clinical purposes. This method is particularly applicable to patients who had poor fertilization outcomes after conventional IVF treatments or those with high degree of defective sperm-ZP binding ability.

P-117 Pre-selected for an award: Bioinformatic analysis of NRF2 in the study of association of NRF2 variant and male infertility related to smoking status

D. Aydos[1], O.S. Aydos[2], Y. Yukselten[2], A. Sunguroglu[2], K. Aydos[2]

[1]Ankara University Stem Cell Institute, Department of Stem Cells and Regenerative Medicine, Ankara, Turkey ;
[2]Ankara University Faculty of Medicine, Department of Medical Biology, Ankara, Turkey

Study question: Could *Nrf2* polymorphism (-617C>A; rs6721961) and oxidative stress (OS)-induced changes of signature seminal plasma (SP) miRNAs related to Nrf2 provide possible biomarkers of male infertility?
Summary answer: -617C>A SNP is associated with infertility through sperm OS DNA damage and miR-582-5p and miR-20a-5p, differentially represented between spermatozoa of smokers-non-smokers, might regulate Nrf2/ARE axis.
What is known already: As an extrinsic factor causing OS, smoking decreases male infertility by causing sperm membrane damage and DNA fragmentation. Expression of proteins related to the antioxidant defense system and phase 2 detoxifying enzymes controlled mainly by Nrf2/ARE pathway components is vital in managing OS-induced DNA damage. miRNAs, which multiple of are produced abundantly in male germ cells throughout spermatogenesis, have been detected in SP and contribute to multiple biological processes related to male reproductive events. miRNA-expression alterations may be induced in response to OS and without involving DNA sequence changes, miRNAs can provide additional mechanism of regulating the *Nrf2* gene expression.
Study design, size, duration: Wild-type (WT) and SNP (-617) alleles in the *Nrf2* gene were studied in 100 infertile cases and 100 controls and their associations with seminal parameters in relation to smoking status were assessed. In infertile cases, sperm DNA damage level was determined and compared among *Nrf2* genotypes. Interactions between differentially expressed miRNAs (DEMIs) in response to smoking and Nrf2/ARE pathway components were visualized on a miRNA-mRNA regulatory network using CluePedia (v1.5.7) plugin of Cytoscape software (v3.8.2).
Participants/materials, setting, methods: Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) was utilized to genotype the *Nrf2* SNP (-617). DNA damages were analyzed by Comet assay. DEMIs were identified by a comprehensive bioinformatics analysis using the miRNA expression dataset GSE44134 downloaded from the GEO database. Predicted targets of DEMIs in smokers were identified by mirDIP portal. Known interactions between Nrf2 and its first neighbors were visualized after selecting STRING-actions, miRTarBase and miRecords validated miRNA source files from CluePedia panel.
Main results and the role of chance: There was significant difference for *Nrf2* polymorphism between fertile and infertile males. The A allele was detected more frequently in the patient group; ($P = 0.001$). The frequencies of the C and A alleles of the *Nrf2* were 62% and 38% in patients, and 78% and 44% in control group. The AA genotype was higher in the infertiles; 14% vs. 3% ($P = 0.001$). In smokers, sperm quality decreased significantly in AA genotype. The risk of DNA damage was highest with 224.58 AU in the AA genotype group, whereas it is the lowest with 164.56 AU in those carrying the CC genotype ($P < 0.005$). 21 differentially expressed miRNAs (including 7 downregulated and 14 upregulated in smokers) were identified. Among the upregulated DEMIs, miR-582-5p, miR-20a-5p, miR-573, miR-186-5p, miR-499a-5p were found to target the *Nrf2* mRNA, suggesting their usage as biomarkers capable of indicating the antioxidant ability of the male reproductive system. The interrelations between Nrf2/Nrf2 direct interactors and DEMIs revealed the regulatory role of hsa-miR-20a-5p in SQSTM1/p62-Keap1-Nrf2 axis linked to selective autophagy. hsa-miR-582-5p was found to regulate the JNK/Jun/caspase-3 pathway, previously shown to be activated in response to OS, in which JUN can activate or suppress the *Nrf2* expression.
Limitations, reasons for caution: Small number of cases while evaluating the effect of smoking weakens our ability to generalize the results. Including other coexisting factors and larger patient groups carrying other functional variants of *Nrf2* as well as confirming the results at the protein level would further strengthen the results of the study.
Wider implications of the findings: This study is the first to report -617C>A polymorphism in the *Nrf2* gene in the Turkish population and such a SNP may cause impaired fertility in men, especially in smokers, through oxidative metabolism. Considering these data may be valuable in determining risk groups.

O-062 In vitro maturation of oocytes in connection with ovarian tissue cryopreservation

M. De Vos[1]

[1]Vrije Universiteit Brussel, Centre for Reproductive Medicine- Universitair Ziekenhuis Brussel, Brussel, Belgium

Abstract text

Discussing fertility preservation (FP) in young cancer patients has become a key component of routine oncological health care. Although ovarian stimulation followed by oocyte cryopreservation has been recommended in cases where two to three weeks are available before the start of chemotherapy, ovarian tissue cryopreservation (OTC) is the preferred option when this timeframe is not available and when the potential gonadotoxic impact of cancer therapy is deemed moderate or severe, or in prepubertal girls. During ovarian tissue processing in the laboratory, cumulus-oocyte complexes can be identified. In vitro maturation and further vitrification of oocytes retrieved in ex vivo from the extracted ovarian tissue (ovarian tissue oocytes in vitro maturation; OTO-IVM) can be attempted to enhance the future reproductive options of the patient. Although the number of reported live births after OTO-IVM are limited, this experimental FP procedure has potential to become a standard appended procedure in conjunction with OTC. In cancer patients with haematological tumours and ovarian invasion, or patients with primary tumours of the ovary, ovarian tissue grafting may be contraindicated because of the risk of reintroducing malignant cells. Utilisation of vitrified oocytes after OTO-IVM may be the only hope for genetic offspring for these patients. Moreover, exogenous hormonal pretreatment is not required and COC can be recovered during

ovarian tissue processing in the majority of patients who undergo partial or total unilateral oophorectomy. Nevertheless, maturation rates after OTO-IVM vary and are generally lower compared to IVM of transvaginally harvested IVM oocytes; currently available IVM systems registered for clinical use will have to be adapted to accommodate the *in vitro* requirements of oocytes derived from extracorporeal ovarian tissue, and follow-up data are needed to assess the success rate and safety of this novel approach.

O-063 PGT-M, for multi-system genetic diseases

J. Xu[1]

[1]*The First Affiliated Hospital of Zhengzhou University, Reproductive Medical Center, Zhengzhou, China*

Abstract text
Reciprocal translocations (RecT) and Robertsonian translocations (RobT) are among the most common chromosomal abnormalities that cause infertility and birth defects. In 2017, the Reproductive Medicine Center of the first affiliated Hospital of Zhengzhou University reported a method named "Mapping Allele with Resolved Carrier Status" (MaReCs), which enables chromosomal ploidy screening and resolution of the translocation carrier status of the same embryo. Meanwhile, the first international healthy baby, where the chromosomal balanced translocation that can be transmitted to offspring was precisely blocked by "MaReCS ", was born in our center . Roche translocation can also delivery healthy babies. Therefore, MaReCs accurately enables the selection of translocation-free embryos from patients carrying chromosomal translocations.In addition, with regard to the monogenic disorders and relative cases, our center used Karyomapping-SNP and NGS technology for preimplantation genetic diagnosis, completed the first Huntington's disease patient in China and delivered a healthy embryos. NGS/Karyomapping PGD can be used to assist pregnancy for all genetic diseases with clear genetic patterns and pathogenic genes.

O-064 Artificial intelligence in embryo selection of IVF

X. Zhang[1]

[1]*Chongqing Reproductive and Genetics Institute- Chongqing Obstetrics and Gynecolo, s, Chongqing, China*

Abstract text
Some studies have discussed the use of artificial intelligence and machine learning in the assessment and selection of embryos for in vitro fertilization. Complete artificial intelligence acquired using CNN's dark box algorithm could be highly useful in assessing in embryos, though it could be difficult to perform the external validation necessary to confirm its value. But due to the inherent drawbacks in complete artificial intelligence assessing in vitro developmental embryos, such as lacking results of discard embryos, dislocations between computer scientist and embryologist, low explanatory values in dark box algorithm, here, we suggest training computers to recognize the target region (internal pellucid zone region) and the features of embryos, then continuously score the embryos starting at in vitro fertilization through the zygote to the blastocyst stage. Parameters suitable for use with various endpoints in treatment sequence could be found by AI. Further clinical studies should be performed to validate the parameters and AI needed.

O-242 Metabolic coupling and spermatogenesis

Y. Bing[1]

[1]*University Medical School, The department of Reproduction of Nanjing Jinling Hospital affiliated to Nanjing, Nanjing, China*

Abstract text
The microenvironment of spermatogenesis mainly consists of Sertoli cells, Leydig cells, and peritubular cells. The traditional theory considers that spermatogenesis is regulated by hypothalamus-pituitary gland- gonadal axis. In the hypothalamus-pituitary gland- gonadal axis, the microenvironmental cells are mainly regulated by the hormones, which are secreted by the hypothalamus or/and pituitary gland. Meanwhile, Sertoli cells and Leydig cells also secrete related factors to feedback the functions of the hypothalamus and pituitary gland. With the development of research, it has found that metabolic disorders are closely related to the spermatogenesis. Some components involving in lipid metabolism pathways, including saturated fatty acids, cholesterol, and triglycerides, etc. affect the functions of Sertoli and Leydig cells through metabolic coupling pathway. The disorder function of Sertoli and Leydig impairs the microenvironment of spermatogenesis, which finally leads to spermatogenic failure. Current studies have found that the imbalance of lipid metabolism can affect the intestinal flora, which induces the changes of related metabolites, and finally leads to the occurrence of male infertility. Based on the current research, we regulated the lipid metabolism by Omega-3 and metformin in clinic, the activity of spermatogenesis can be remolded.

O-169 Conventional ovarian stimulation with gonadotropins depletes the developmental proteome of mouse oocytes, reducing their size and compromising their fetal yield.

Study question: Does conventional ovarian stimulation with gonadotropins alter the molecular composition, size, and developmental fitness of superovulated mouse oocytes?
Summary answer: Ovarian stimulation perturbs 31% of developmental proteome vs. 2% of transcriptome, yielding smaller oocytes that form blastocysts with less primitive endoderm and diminished fetal yield.
What is known already: Prior mouse studies aimed to assess the impact of superovulation on oocyte and embryo quality provided variable results. Aberrations were observed in some studies but not in others, and were associated with a variable time spent in the oviduct until retrieval for *in vitro* culture. Although the natural ovarian cycle lasts 4 days in mice, the conventional stimulation protocol time spans 2 days. No genome-wide studies have been devoted yet to the global gene expression of superovulated mouse oocytes and derivative embryos, to determine if gene products accumulate to the same extent as in natural cycles.

Study design, size, duration: Approx. 1100 female mice were injected, half with serial equine and human chorionic gonadotropin, eCG and hCG, to induce superovulation; the other half were injected with saline as control. Both groups were mated to vasectomized or fertile males to obtain, respectively, metaphase II and fertilized oocytes. These were removed from the oviducts, and followed up *in vitro* to blastocyst, or *in vivo* to term after surgical transfer to naturally cycling females.
Participants/materials, setting, methods: B6C3F1 oocytes (n= ~16000) from superovulation (10 I.U. eCG+hCG) or natural ovulation were measured for diameter, and upon fertilization, they were cultured in KSOM(aa) to collect preimplantation stages for analyses (mass spectrometry; RNA sequencing; immunofluorescence for counting of trophectoderm, epiblast, and primitive endoderm cells). Embryos at the 4-cell stage were transplanted to naturally cycling females (8/female, 45 recipients). Results were compared between natural ovulation and superovulation with 48h (conventional) or 72h interval of eCG-hCG stimulation.
Main results and the role of chance: Preimplantation embryos of superovulated oocytes were affected in 31% of the proteins (893 / 2855) vs. 2% of the transcripts (482 / 21784), compared to natural counterparts (adj.P<0.05, Wilcoxon test). Gene set enrichment analysis of the perturbed proteome returned the top-terms 'thin zona pellucida' (ZP1, ZP2, ZP3) and 'abnormal inner cell mass apoptosis' (DAB2, STAT3). Microscope measurements verified a thinner zona pellucida (p = 0.077, Wilcoxon test) along with a smaller diameter (p<0.0001, Wilcoxon test) of superovulated oocytes, which gave rise to blastocysts deficient in primitive endoderm (p<0.013, Fisher's exact test). Since 529 of the 893 differently expressed proteins were depleted, we considered that ovarian stimulation provided insufficient time for protein accumulation. Increasing the eCG-hCG interval from 48 h (conventional) to 72 h restored oocytes' diameters, and improved their fetal output from 25% to 59%, compared to 54% of natural ovulation (15 embryo transfers per group). Conversely, oocytes lost part of their developmental potential to the micromanipulation-assisted reduction of their volume. This study provides evidence of an additional novel effect of exposure to gonadotropins on mouse oocyte quality, whose mechanism is mediated not by the stimulated genital tract, but by the time-dependent accumulation of proteins in oocytes.
Limitations, reasons for caution: This is an animal model study based on one mouse strain. Ovarian stimulation protocols differ between mice and humans. There can be yet other, more subtle or long-term differences between superovulated and naturally ovulated oocytes, than those described here. Proteome and transcriptome analysis cover much, but not everything.
Wider implications of the findings: There is a trade-off between oocyte quantity and quality in mice subjected to superovulation. Cytological and molecular deficits define a 'small oocyte syndrome'. Problematic is not so much the gonadotropin treatment, rather its timing. An evidence-based protocol for superovulation may be different from that used currently in mice.

O-170 Predictive value of cytoplasmic granulation patterns during IVF in MII oocytes from young donors

J. Hu[1], E. Molinari[1], S. Darmon[2], D.F. Albertini[1,3], D.H. Barad[4,5], N. Gleicher[3,4,5,6]

[1]Center for Human Reproduction, Embryology Lab, New York, U.S.A. ;
[2]Center for Human Reproduction, Statistics, New York, U.S.A. ;
[3]The Rockefeller Uiversity, Stem Cell Biology and Molecular Embryology Laboratory, New York, U.S.A. ;
[4]Center for Human Reproduction, Clinical Research, New York, U.S.A. ;
[5]Foundation for Reproductive Medicine, Clinical Research, New York, U.S.A. ;
[6]Vienna University School of Medicine, Department of Obstetrics and Gynecology, Vienna, Austria

Study question: Do ooplasm granulation patterns of donor MII oocytes have similar predictive values for in vitro fertilization (IVF) outcomes as they have in older infertile women?
Summary answer: Ooplasm granulation patterns of donor MII oocytes are predictive for IVF outcomes in young oocyte donors even more pronounced than in older poor prognosis patients.
What is known already: Cytoplasmic granules had been noticed for years, with data mostly focused on central granulation. Dispersed granulations were mentioned but lacked analysis.
Study design, size, duration: A retrospective cohort study during 2017-2020.
Participants/materials, setting, methods: We investigated 776 fresh and 381 vitrified-thawed MII oocytes from carefully selected young donors (mean, 26.7±2.7; range, 21-35 years) and determined cytoplasmic granulation patterns during intracytoplasmic sperm injection as fine, central, uneven, dispersed and peripheral (see only in thawed oocytes). Fertilization, pregnancy and live-birth rates in fresh and thawed donor oocytes were analyzed
Main results and the role of chance: In fresh donor oocytes: 2PN rates significantly trended down from 96.3% to 90.7%, 89.2%, 66.7% from fine to central, uneven, dispersed granulations; overall pregnancy rates trended down from 48.8% to 29.0%, 19.0% and 6.4%, as did live birth rates (42.1%, 21.6%, 12.5%, 6.4%), from fine to uneven, central and dispersed granulations. Known-pregnancy and known-live-birth analyses showed similar findings. Thawed donor oocytes demonstrated similar trends, though with significantly worse outcomes than fresh oocytes. Peripheral granulation, unique to vitrification and thawing, always demonstrated the worst IVF outcomes. Interestingly, granulation patterns were mostly disassociated from morphologic embryo grades in fresh and thawed donor oocytes.
Limitations, reasons for caution: As a retrospective cohort study, some cases had to be excluded for lack of information. The scoring system may have diluted the real contribution of an oocyte when two or more embryos were transferred.
Wider implications of the findings: Ooplasm granulation patterns have predictive values for fertilization, pregnancy and live birth in IVF cycles, supporting integration of them into embryo selection, and suggesting that ooplasm granulation patterns reflect intrinsic features of oocytes that relate to oocyte quality, cytoplasmic maturity and developmental competence, but are largely independent of clinical co-variables.
Trial registration number: NA

O-171 Altered meiotic spindle morphology and composition in in vitro matured oocytes

P. Karamtzioti[1], G. Tiscornia[2], D. Garcia[2], A. Rodriguez[2], I. Vernos[3,4], R. Vassena[2]

[1]Eugin, Pompeu Fabra University, Barcelona, Spain ;
[2]Eugin, Eugin, Barcelona, Spain ;
[3]Centre for Genomic Regulation CRG- Barcelona Institute of Science and Technology, Research, Barcelona, Spain ;
[4]Institució Catalana de Recerca I Estudis Avançats ICREA, research, Barcelona, Spain

Study question: How does the meiotic spindle tubulin PTMs of MII oocytes matured *in vitro* compare to that of MII oocytes matured *in vivo*?
Summary answer: MII cultured *in vitro* present detyrosinated tubulin in the spindle microtubules, while MII oocytes matured *in vivo* do not.
What is known already: A functional spindle is required for chromosomal segregation during meiosis, but the role of tubulin post-translational modifications (PTMs) in spindle meiotic dynamics remains poorly characterized. In contrast with GVs matured *in vitro* within the cumulus oophorous, *in vitro* maturation of denuded GVs to the MII stage (GV-MII) is associated with spindle abnormalities, chromosome misalignment and compromised developmental potential. Although aneuploidy rates in GV-MII are not higher than in vivo matured MII, disorganized chromosomes may contribute to compromised developmental potential. However, to date, spindle PTMs morphology of GV-MII has not been compared to that of *in vivo* cultured MII oocytes.
Study design, size, duration: GV (n=125), and MII oocytes (n=24) were retrieved from hormonally stimulated women, aged 20 to 35 years old. GVs were matured to the MII stage *in vitro* in G-2 PLUS medium for 30h; the maturation rate was 68,2%; the 46 GV-MII oocytes obtained were vitrified, stored, and warmed before fixing and subjecting to immunofluorescent analysis. *In vivo* matured MII oocytes donated to research were used as controls.
Participants/materials, setting, methods: Women were stimulated using a GnRH antagonist protocol, with GnRH agonist trigger. Trigger criterion was ≥2 follicles ≥18mm; oocytes were harvested 36h later. Spindle microtubules were incubated with antibodies against alpha tubulin and tubulin PTMs (acetylation, tyrosination, polyglutamylation, Δ2-tubulin, and detyrosination); chromosomes were stained with Hoechst 33342 and samples subjected to confocal

immunofluorescence microscopy (ZEISS LSM780), with ImageJ software analysis. Differences in spindle morphometric parameters were assessed by non-parametric Kruskal–Wallis and Fisher's exact tests.

Main results and the role of chance: Qualitatively, Δ2-tubulin, tyrosination and polyglutamylation were similar for both groups. Acetylation was also present in both groups, albeit in different patterns: while *in vivo* matured MII oocytes showed acetylation at the poles, GV-MII showed a symmetrical distribution of signal intensity, but discontinuous signal on individual microtubule tracts, suggesting apparent islands of acetylation. In contrast, detyrosination was detected in *in vivo* matured MII oocytes but was absent from GV-MII. Regarding spindle pole morphology, of the four possible phenotypes described in the literature (double flattened and double focused; flattened-focused, focused-flattened, with the first word characterizing the cortex side of the spindle), we observed double flat shaped spindle poles in 86% of GV-MII oocytes (25/29) as opposed to 40.5% (15/37) for the in vivo matured MII oocytes (p=0.0004, Fisher's exact test). Further morphometric analysis of the spindle size (maximum projection, major and minor axis length) and the metaphase plate position (proximal to distal ratio, angle) revealed decreased spindle size in GV-MII oocytes (p=0.019, non parametric Kruskal- Wallis test).

Limitations, reasons for caution: Oocytes retrieved from hyperstimulation cycles could be intrinsically impaired since they failed to mature *in vivo*. Our conclusions should not be extrapolated to IVM in non-stimulated cycles, as in this model, the cumulus oophorus is a major factor in oocyte maturation and correlation with spindle dynamics has been inferred.

Wider implications of the findings: The metaphase II spindle stability compared to the mitotic or metaphase I meiotic one justifies the presence of PTMs such as acetylation and glutamylation, which are found in stable, long-lived microtubules. The significance of the absence of detyrosinated microtubules in the MII-GV group remains to be determined

Trial registration number: not applicable

O-172 Metabolic imaging of cumulus cells to predict embryo implantation potential

M. Venturas[1,2], K. Kumar[3], X. Yang[1], D. Wells[3,4], C. Racowsky[5,6], D. Needleman[1]

[1]Harvard University, Molecular and Cellular Biology and School of Engineering and Applied Sciences, Cambridge, U.S.A. ;
[2]Universitat Autònoma de Barcelona, Department de Biologia Cel·lular- Fisiologia i Immunologia, Cerdanyola, Spain ;

[4]Juno Genetics, Oxford Science Park, Oxford, United Kingdom ;
[5]Brigham and Women's Hospital, Department of Obstetrics and Gynecology, Boston, U.S.A. ;
[6]Hospital Foch, Department of Obstetrics and Gynecology and Reproductive Medicine, Suresnes, France

Study question: Can non-invasive metabolic imaging detect variations in cumulus cell metabolic parameters associated with a viable pregnancy of the corresponding embryo?

Summary answer: Noninvasive metabolic imaging can detect differences in the cumulus cell metabolic signatures between embryos that led to a viable pregnancy and those that did not.

What is known already: Bidirectional metabolic cooperativity between the human oocyte and its surrounding cumulus cells is essential for the oocyte to acquire full developmental competency. However, the relationship between cumulus cell metabolism and oocyte viability is not well established. Metabolic imaging uses Fluorescence Lifetime Imaging Microscopy (FLIM) to non-invasively measure autofluorescence of the endogenous molecules, NADH and FAD+, which are essential coenzymes for cellular respiration and glycolysis. This technique enables quantitative information for these coenzyme concentrations and regarding metabolite enzyme engagement. We have previously shown that this technique is an effective tool for quantitatively measuring metabolic state of mouse embryos.

Study design, size, duration: Cumulus cell clusters (n=617 from 193 patients) were dissected from cumulus-oocyte complexes prior to insemination or ICSI, vitrified, warmed and their metabolic function assessed. We conducted a prospective observational study to evaluate to what extent cumulus cells from an oocyte that led to a viable pregnancy (presence of a viable fetus >7 weeks gestation) after transfer of the corresponding embryo metabolically differed from those that did not. We also evaluated the associations with embryo morphology.

Participants/materials, setting, methods: Cumulus cell metabolism was assessed non-invasively using FLIM to measure the autofluorescence of NADH and FAD+. Overall a single FLIM measurement provides a total of 8 metabolic parameters (4 for NADH and 4 for FAD+). An additional parameter, the Redox Ratio was also acquired (NADH intensity / FAD+ intensity). We used multilevel models to investigate the association of cumulus cell metabolic parameters with the morphology of the corresponding embryo and clinical outcome.

Main results and the role of chance: Of the cumulus samples analyzed, 75 corresponded to embryos that did not result in a viable pregnancy, and 24 that did so. Significant associations were observed between cumulus cell FAD+ fraction bound to enzyme (p =0.007), FAD+ long lifetime (p= 0.01) and FAD+ short lifetime (p <0.001) and the clinical outcome of the corresponding embryo. These significant associations held up after controlling for age. We used a support vector machine algorithm to distinguish between embryos that led to a viable pregnancy and those that did not. The optimum hyperplane derived from a support vector machine algorithm predicted whether a sample with random cumulus cell metabolic parameters will lead to a viable pregnancy or not with an accuracy of 80%. Embryo morphological assessments were stratified as excellent, good, fair and poor. We found no significant associations between cumulus cell metabolic signatures and embryo morphology evaluated on day 3. Significant associations of FAD+ short lifetime (p <0.001) and day 5 embryo morphology were found. However, these associations were not significant after controlling for age.

Limitations, reasons for caution: Although we observed significant variations in metabolic parameters, further studies with larger sample sizes are required. Despite our validation studies showing no significant effect of vitrification on cumulus cell metabolic parameters, analyses with fresh clusters are needed to confirm our results.

Wider implications of the findings: Noninvasive FLIM imaging detects metabolic variations of cumulus masses and their association with embryo viability. The ability to correlate metabolic measurements of cumulus clusters, in combination with embryo morphology assessments and patient clinical characteristics, with embryo fate paves the way for this approach to be used in a clinical setting.

SESSION 57: THE ART OF MANAGING LOW OVARIAN RESERVE - TOO LITTLE TOO LATE?

30 June 2021 Stream 4 14:00 - 15:00

O-173 Decline in anti-Müllerian hormone (AMH) concentrations following radioactive iodine (RAI) treatment in women with differentiated thyroid cancer (DTC): a systematic review and meta-analysis

J. Bosdou[1], P. Anagnostis[2], P. Florou[2], I. Iakovou[3], G. Grimbizis[1,2], D. Goulis[2], E. Kolibianakis[1]

[1]Aristotle University of Thessaloniki- Medical School, 1st Department of Obstetrics and Gynecology- Unit for Human Reproduction, Thessaloniki, Greece ;
[2]Aristotle University of Thessaloniki- Medical School, 1st Department of Obstetrics and Gynecology- Unit of Reproductive Endocrinology, Thessaloniki, Greece ;
[3]Aristotle University of Thessaloniki- Medical School, Academic Department of Nuclear Medicine, Thessaloniki, Greece

Study question: Does radioactive iodine (RAI) treatment in premenopausal women with differentiated thyroid cancer (DTC) affects ovarian reserve, as

evaluated by anti-Müllerian hormone (AMH), antral follicle count (AFC) and follicle-stimulating hormone (FSH)?

Summary answer: AMH concentrations decreased at three, six and 12 months following RAI treatment in women with DTC, whereas no difference was observed regarding FSH.

What is known already: Thyroid cancer is the third most common type of female malignancy and DTC is the most common histopathological type. Thyroidectomy constitutes the mainstay of treatment for DTC, followed by administration of RAI, which acts as an adjuvant therapy to destroy residual cancerous thyroid tissue. However, the effect of RAI on ovarian reserve of these women, as assessed by AMH, AFC and FSH, remains controversial.

Study design, size, duration: A systematic review and meta-analysis was performed aiming to identify studies evaluating the effect of RAI treatment on ovarian reserve in women with DTC. For this purpose, a literature search in the electronic databases PubMed, Scopus and CENTRAL was carried out until 06/12/2020. The primary outcome measure was the effect of RAI on ovarian reserve, as evaluated by AMH, AFC and FSH.

Participants/materials, setting, methods: Studies were eligible if they included premenopausal women with DTC, treated with a single RAI dose and assessed for at least one marker of ovarian reserve repeatedly within 12 months post-RAI.Meta-analysis of weighted data was performed using random effects model. Results were reported as weighted mean difference (WMD) with 95% confidence interval (CI).

Main results and the role of chance: Four prospective eligible studies, published between 2005 and 2020, were eligible for the meta-analysis, evaluating a total of 154 women. The number of participants ranged from 24 to 50. The single dose of RAI used to treat DTC ranged from 50 to 150 mCi. AMH concentrations decreased at three (WMD -1.66 ng/ml, 95% CI -2.42 to -0.91, p<0.0001; I2 0%), six (WMD -1.58 ng/ml, 95% CI -2.63 to -0.52, p=0.003; I2 54.7%) and 12 months (WMD -1.62 ng/ml, 95% CI -2.02 to -1.22, p<0.0001; I2 15.5%) following a single RAI dose compared with baseline (three studies; n=104). With respect to FSH concentrations, no difference was observed at six (WMD +3.29 IU/l, 95% CI -1.12 to +7.70, p=0.14; I2 96.8%) and 12 months (WMD +0.13 IU/l, 95% CI -1.06 to +1.32, p=0.83; I2 55.2%) post-RAI compared with baseline (two studies; n=83). No data on AFC was available.

Limitations, reasons for caution: The small number of studies and patients included, as well as the lack of data on AFC may have compromised the validity of the conclusions drawn. Moreover, subgroup analysis according to female age was not feasible, due to the lack of relevant data.

Wider implications of the findings: The negative effect of RAI on ovarian reserve in premenopausal women with DTC, as indicated by the decreased AMH, should be confirmed by data on AFC, which are currently not available. These findings necessitate close monitoring of ovarian reserve in such women, counselling them regarding the need for fertility preservation.

Trial registration number: N/A

O-174 Individualized versus standard FSH dosing in predicted poor responders: an RCT

X. Liu[1], W. Wen[1], W. Tao[1], T. Li[1], L. Na[1], S. Ting[1], W. Ting[1], Z. Hanying[1], Z. Na[1], S. Juanzi[1]

[1]Northwest women's and children's hospital, assisted reproduction center, Xi'an, China

Study question: Is there a difference in fertility outcomes between individualized or standard FSH dosing in women scheduled for IVF with an expected poor response?

Summary answer: In predicted poor responders (AFC<10) undergoing IVF/ICSI, individualized FSH dosing does not improve ongoing pregnancy rates as compared to a standard FSH dose.

What is known already: Poor responders usually lead to many detrimental effects on IVF outcomes due to low oocyte number and quality which in turn result in low pregnancy outcomes and an increased chance of cycle cancellation. Clinicians often individualize the FSH dose using ovarian reserve tests (ORT), including antral follicle count (AFC), basal FSH (bFSH), and anti-Mullerian hormone (AMH). However, it is unclear whether individualized FSH dosing improves clinical outcomes.

Study design, size, duration: Between March 2019 and April 2020, we performed a single-center, parallel, open-label RCT in women with an AFC<10. A total of 661 women were randomized either to start FSH dosing at 300IU/225IU or 150IU. The primary outcome was live birth attributable to the first ART cycle within 18 months of randomization. In this abstract, we report ongoing pregnancy rates. Live birth date will be available at the meeting.

Participants/materials, setting, methods: Women referred for their first IVF/ICSI cycle, <43 years of age, AFC<10 were approached. A total of 328 women were allocated to the individualized group and 333 women were allocated to the standard group. In the individualized group, women with AFC 1-6 were assigned to 300IU/day (n=122), while women with AFC 7-9 were assigned to 225IU/day (n=206). In the standard group, women were assigned 150IU/day. Outcomes were evaluated from an intention-to-treat perspective.

Main results and the role of chance: For ongoing pregnancy rate attributable to the first ART cycle for individualized versus standard dosing was comparable [52.44% vs 46.25%, relative risk (RR): 1.29 (95%CI, 0.94-1.74), P=0.11]. Biochemical pregnancy rate [62.50% vs 62.16%, RR: 1.01 (95%CI, 0.74-1.39), P=0.929], clinical pregnancy rate [59.45% vs 58.86%, RR: 1.02 (95%CI, 0.75-1.40), P=0.877] and multiple pregnancy rate [5.18% vs 5.12%, RR: 1.01 (95%CI, 0.51-2.02), P=0.971] also did not differ between individualized and standard dosing. There are 24 women who are ongoing pregnancy but do not reach live birth in the completed embryo transfer cycle. The individualized group reported less poor response (31.1% vs 48.7%: P<0.001), more obtained oocytes (6.80 ± 3.85 vs 5.28 ± 3.22; P <0.001), less embryos (3.76 ± 2.70 vs 3.16 ± 2.42; P=0.004), and less good quality embryos (2.61 ± 2.29 vs 2.21 ± 2.05; P=0.018). When outcomes were compared over the first embryo transfer, ongoing pregnancy rates were 39.0% (128/328) versus 37.2% (124/333), respectively [RR:1.08 (95%CI, 0.79-1.48), P=0.636], without differences in the other outcomes. There are 7 women who are ongoing pregnancy but do not reach live birth in the first embryo transfer cycle.

Limitations, reasons for caution: Due to the open-label character, potential selective canceling and small dose adjustments of standard dosing were allowed. This abstract reports on ongoing pregnancy. At the meeting, we will present live birth rates.

Wider implications of the findings: In women with predicted poor response, an increased dose does not increase ongoing pregnancy rates. A standard dose of 150IU/day is recommended in these women.

Trial registration number: ChiCTR1900021944

O-175 Impact of female chromosomal polymorphic variants on ovarian reserve markers and fertility treatments prognosis.

L. Luque[1], N. Ruíz[2], Á. Linares[2], J. Bartolomé[2], J.A. Ortíz[3], A. Fabregat[3], E. García-Hernández[3], J. Ten[4], R. Bernabéu[5]

[1].Instituto Bernabeu Albacete, Reproductive Medicine, ALBACETE, Spain ;
[2]Instituto Bernabeu Albacete, Embryology, Albacete, Spain ;
[3]Instituto Bernabeu, Biotech, Alicante, Spain ;
[4]Instituto Bernabeu, Embryology, Alicante, Spain ;
[5]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: Could the presence of chromosomal polymorphisms in women undergoing fertility treatments influence ovarian reserve, oocyte preservation or IVF clinical outcomes?

Summary answer: Polymorphic variants of chromosomes seem to adversely influence the Anti-Müllerian Hormone (AMH) serum levels and the post-thawing oocyte survival rate.

What is known already: Infertile couples have been reported to have a higher incidence of karyotype abnormalities than the general population, which could lead to lower fertility rates. However, few studies have demonstrated the controversial relationship between these karyotype alterations in women and the specific involvement of these variants and their combinations in an IVF cycle.

Therefore, there is a growing interest in categorizing chromosomal polymorphic variants and relating them to the subsequent evolution in ART cycles.

Study design, size, duration: Retrospective evaluation of a cohort of women undergoing IVF cycles in a private fertility center. The sample included 280 cycles performed between July 2017 and December 2020. The study explored the correlation between karyotype polymorphisms and IVF outcomes in terms of: Anti-Müllerian Hormone (AMH) level, Antral Follicle Count (AFC), Oocyte Maturity (MII), Oocyte Survival after Thawing (TS), Fertilization (FZ), Useful Embryos (UE), Biochemical (BP) and Clinical Pregnancy (CP), Miscarriage (M) and Live Birth (LB) rates.

Participants/materials, setting, methods: Women with karyotype performed before an IVF cycle. Chromosome analysis was carried out according to the International System for Human Cytogenetic Nomenclature guidelines (ISCN).

Only own eggs cycles were included, and testicular sperm cycles were excluded.

The normality of the distribution of the variables was assessed using the Shapiro-Wilk test. The association between IVF cycle parameters and the presence of polymorphisms was assessed by T-Student (parametric) or U-Mann-Whitney (non-parametric).

Main results and the role of chance: From a total of 280 IVF cycles, 198 met the inclusion criteria: Control Group (CG) with normal karyotype (94) and Study Group (SG) with presence of polymorphisms (104) were analyzed. Cycles with fresh (136) and warmed (62) oocytes were included. Mean female age was 37.66 ± 3.99 (CG) and 36.61 ± 3.72 (SG). The overall outcome rates were: 75.82% MII, 81.39% TS, 72.78% FZ, 49.07% UE on day 5, 21.82% BP, 78.18% CP, 14.53% M and 63.65% LB.

Statistically significant differences were found between the presence of polymorphisms and mean AMH serum level between CG (2.36 ng/mL) and SG (1.74 ng/mL) (p=0.04), especially when the type "qh+" was detected (1.01 ng/mL) (p=0.02). Furthermore, statistically significant differences were found regarding oocyte thawing survival rate, which decreased in the SG (78.94%) compared to the CG (93.69%) (p=0.02), mainly when the type "ps+" was detected (75.13%) (p<0.01).

No statistically significant differences were found between the presence of polymorphism and the AFC (p=0.25), MII (p=0.10), FZ (p=0.93) or UE (p=0.52) rate on day 5. In the same way, from 106 embryo transfers (ET) performed, no significant differences were found for BP, CP, M and LB rates (p>0.05).

Limitations, reasons for caution: Larger prospective studies including homogeneous cohorts are needed in order to corroborate our initial results.

Wider implications of the findings: Our findings may represent a practical tool in order to advise these patients about their reproductive success, especially, in terms of post-thawing oocyte survival prognosis. Therefore, it could be provided more personalized prognostic information before embarking on IVF treatments.

Trial registration number: Not Applicable

O-176 Secondary ovarian insufficiency (SOI) - a new infertility diagnosis

N. Gleicher[1,2,3,4], S.K. Darmon[5], D.F. Albertini[4,6], D.H. Barad[1,3]

[1]Center for Human Reproduction, IVF/ Reproductive Medicine, New York- NY, U.S.A. ;
[2]Vienna University School of Medicine, Obstetrics and Gynecology, Vienna, Austria ;
[3]Foundation for Reproductive Medicine, Clinical Research, New York, U.S.A. ;
[4]The Rockefeller University, Stem Cell Biology and Molecular Embryology Labratory, New York, U.S.A. ;
[5]Center for Human Reproduction, Statistics, New York- NY, U.S.A. ;
[6]Center for Human Reproduction, Clinical Research, New York- NY, U.S.A.

Study question: Can, in contrast to primary ovarian insufficiency (POI), ovarian insufficiency also be caused as a secondary event (SOI)?**Summary answer:** Adrenal hypo-androgenism, caused by insufficiency in androgen production by the zona reticularis, may mimic POI in clinical presentation.

What is known already: A variety of small and large animal models have, especially at small growing follicle stages, conclusively demonstrated the dependence of normal follicle maturation on adequate testosterone levels, a process mediated via the androgen receptor on granulosa cells. Increasing clinical evidence, moreover, has demonstrated clinical improvements in oocyte numbers and oocyte quality following androgen supplementation at these stages in hypo-androgenic women with premature ovarian aging (POA). Whether adrenal hypo-androgenism in extreme cases can, however, also lead to complete ovarian insufficiency mimicking POI, is unknown.

Study design, size, duration: Based on FSH levels >40.0 mIU/mL and amenorrhea, we searched our center's electronic research data bank for patients who between 2016-2018 presented with a diagnosis of presumed POI.

Participants/materials, setting, methods: Among 78 POIs, 13 demonstrated low DHEAS (< 100 ug/dL), i.e., adrenal hypo-androgenism, 6 rejected egg donation and received DHEA (Fertinatal®, 25mg TID, Fertility Nutraceuticals, LLC, New York, N.Y., USA) and Coq10 (Ovoenergen®, 333mg TID,same manufacturer) before stimulation with 450IU FSH and 150 IU hMG (different manufacturers). All women were < age 41, demonstrated menopausal FSH (>40.0 mIU/mL), undetectable AMH, amenorrhea, > prior cycle cancellation, elevated SHBG, low total testosterone and low DHEAS (high DHEA/DHEAS).

Main results and the role of chance: Out of the 6 patients so stimulated, 5 demonstrated follicular responses following DHEA supplementation and 2/6 conceived spontaneously and delivered healthy offspring. One of these two is currently in treatment for another child.

Limitations, reasons for caution: To better understand adrenal control of ovaries via androgen production, further elucidation of endocrine signaling between adrenals and ovaries is required, including detection of unknown, though increasingly likely, feedback loops, considering that adrenals and ovaries share a primordium.

Wider implications of the findings: We confirmed existence of SOI due to adrenal hypoandrogenism, defined its phenotype, demonstrating that some patients with alleged POI actually exhibit SOI. Better pregnancy chances with adrenal SOI than POI, reemphasize the importance of correct differential diagnoses to avoid premature referrals of women into third-party egg donations

Trial registration number: N/A

POSTER DISCUSSION

SESSION 58: NURSING AND MIDWIFERY POSTER DISCUSSIONS

30 June 2021 Stream 1 15:15 - 16:30

P-467 Emotions, Thoughts, and Coping Strategies of Women with Infertility Problems on Changes in Treatment during Covid-19 Pandemic: A Qualitative Study

E. Arbag[1], M. Aluş Tokat[2], S. Fata[3]

[1]M2021-00379, Nursing department, karşıyaka/Örnekköy, Turkey ;
[2]Dokuz Eylul University DEU, Nursing Faculty-, Izmir, Turkey ;
[3]Dokuz Eylul University DEU, Nursing Faculty, Izmir, Turkey

Study question: What are the emotions, thoughts and coping strategies of women with infertility problems on changes in treatment during the COVID-19 pandemic?

Summary answer: Treatment-related procedures keep changing directions, exposing the women to high level of uncertainty. Changes in treatments may be perceived as threats to achieving parenting goals.

What is known already: Both infertility and the treatment process constitute a stressful experience. Literature reports that couples describe infertility as the most difficult challenge to overcome in their lives. In addition, it has been reported that women experience more anxiety, stress, and depression than men during this period. Societies and individuals affected by large-scale disasters, such as global pandemics, can develop stress-related disorders. Current data indicate that closure of fertility clinic during the COVID-19 pandemic was associated with a sharp increase in the prevalence of anxiety and depression among patients undergoing fertility treatments and was perceived as an uncontrollable and stressful event.

Study design, size, duration: The research was designed as a qualitative study. The data were collected from two Internet forums between October - December 2020. Blogs most frequently used by women with infertility in Turkey were simultaneously selected. The comments of 30 women were included.

Participants/materials, setting, methods: Data were screened by using the directed qualitative content analysis. After selecting the blog, emotions, thoughts, and coping strategies expressed by 30 women whose treatment was canceled due to the Covid-19 pandemic or who continued treatment during this period were included in the analysis. The themes created were adapted to Lazarus and Folkman's Transactional Model of Stress and Coping.

Main results and the role of chance: The thematic analysis of the expression of women with infertility problems in accordance with the Transactional Model of Stress and Coping stages of Lazarus and Folkman resulted in 4 themes: psychological changes, cognitive changes, changes in social life, and coping

strategies. Some women perceived changes in treatments positively, and stopping the treatments due to the uncertainty of the pandemic and its effect on pregnancy and the baby made them feel safe. The majority of women appraised the closure of fertility clinics negatively impacted their lives. They experienced despair, uncertainty, disappointment, anxiety, anger, sadness, and exhaustion from waiting. Also, some participants did not find it right to delay the treatments and felt that the healthcare personnel postponed the treatments to avoid infection. Women experienced feelings of anger, distrust, and threats toward the health authorities. Moreover, the women in our study stated that they were always at home due to the pandemic, far from friends and family, and therefore did did not feel need for self-care and considered themselves ugly. The expressions of women mostly include emotion-based coping strategies. They used activities such as praying, exercising, distracting, noticing the positive side of postponing, and stopping treatments during the pandemic, accepting, and meditating.

Limitations, reasons for caution: Clinics closed due to the pandemic or limited procedures caused fewer women to come to the clinics. At the same time, it is not accepted for anyone other than working in the clinic to come to the clinics for scientific studies. Therefore, comments of women have been reached through blogs.

Wider implications of the findings: It is believed that approaches based on Lazarus and Folkman's model helped the health professionals to determine potential stressors for women with infertility during the pandemic, and identified areas that required strengthening and improved personal coping strategies.

Trial registration number: not applicable

P-469 Period Tracker Applications – are they giving women accurate menstrual cycle information?

L. Worsfold[1], L. Marriott[2], S. Johnson[3], J. Harper[1]

[1]Institute for Women's Health, University College London, London, United Kingdom ;
[2]SPD Development Company Ltd, Statistics and Data Managment, Bedford, United Kingdom ;
[3]SPD Development Company Ltd, Clinical and Regulatory Affairs, Bedford, United Kingdom

Study question: Are period trackers giving women accurate information about their periods and ovulation?

Summary answer: The top 10 period trackers gave conflicting information on period dates, ovulation day and the fertile window.

What is known already: Period tracking applications allow women to track their menstrual cycles and receive a prediction for their periods. The majority of applications also provide predictions of day of ovulation and the fertile window. Previous research indicates applications are basing predictions on assuming women undergo a textbook 28-day cycle with ovulation occurring on day 14 and a fertile window between days 10 and 17.

Study design, size, duration: An audit of menstrual cycle apps was conducted on the Apple app store using menstrual cycle tracker/period tracker as the search terms. The top ten apps that followed the inclusion and exclusion criteria were analysed and used for this study. All apps had the ability to allow retrospective data entry giving future cycle predictions and fertile window, and nine of the apps predicted a day of ovulation.

Participants/materials, setting, methods: Five women's profiles for 6 menstrual cycles were created and entered into each app. Cycle length (CL) and ovulation day (OD) for the 6th cycle were; Woman 1 – Constant 28 day CL, 0D 16, Woman 2 – Average 23 day CL, OD 13, Woman 3 – Average 28 day CL, OD 17, Woman 4 – Average 33 day CL, OD 20 and Woman 5 – Irregular, average 31 day CL, OD 14.

Main results and the role of chance: For cycle length, the apps all predicted woman 1's cycles correctly but for women 2-5, the apps predicted 0 to 8 days shorter or longer than expected. For day of ovulation; for woman 1, no apps predicted this correctly; the apps ranged from day 13-15. For woman 2, 1 app was correct and overall the apps showed a lot of variation from day 8 to 13. For woman 3, no apps got it right, with a range of day 13-16. For woman 4, 2 apps got it right, but the apps ranged from day 13-20. For woman 5, no apps got right; the apps ranged from day 13-21. Irrespective of cycle length, 7 apps predicted a fertile window of 7 days in almost all cases; except 1 app that predicted 6 days for woman 2 and a different app which predicted 8 days for woman 4. For the remaining 3 apps, one always predicted a 10 day fertile window. One app predicted an 11 day fertile window in 4/5 women. One app predicted a 12 day fertile window in 4/5 women.

Limitations, reasons for caution: The five profiles created spanned a range of observed cycle characteristics, but many permutations are possible. A Monte Carlo type analysis could be conducted to examine these possibilities to provide more precise assessment of app performance, but as data had to be added manually into apps, this was not possible.

Wider implications of the findings: The apps do not use the same algorithm and show variation. The information given by these apps is not 100% accurate, especially for the day of ovulation and the fertile window which can only be predicted if using a marker of ovulation, such as basal body temperature or ovulation sticks.

Trial registration number: not applicable

P-470 Sex in the time of Covid-19: Examining the sexual behavior and sexual desire of female adults in Hong Kong

D. Khoo[1], G. So[1], C. Chan[1]

[1]The University of Hong Kong, Social Work and Social Administration, Hong Kong, Hong Kong

Study question: How are sexual behavior and sexual desire of Hong Kong women affected during the Covid-19 pandemic?

Summary answer: The Covid-19 pandemic has a negative impact on the sexual life of adult women, in particular, single women who do not have a live-in partner.

What is known already: Since the beginning of the Covid-19 pandemic, there have been ongoing debates on whether lockdown measures would do more harm on individuals or families who are already living in fear of virus infection. Some studies have shown that despite social distancing and measures that limit contact and interaction, women, particularly those who are either married or have a stable partner, were found to be sexually more active and reported stronger emotional bonding with their partners during lockdown. This study attempts to examine any significant changes in sexual behavior and sexual desire of adult females in Hong Kong during the pandemic.

Study design, size, duration: This is a cross-sectional online study examining the sexual behaviors among female adults. The survey was conducted in Hong Kong between July and August 2020, in which the city has been locked down.

Participants/materials, setting, methods: Six hundred and two Chinese female adults (mean age = 32±7.09) were recruited through social media and community networks. Respondents completed the Desire Domain of the Female Sexual Function Index and self-reported frequency of sexual behavior before and during the Covid-19 pandemic. T-tests and ANOVAs were used to compare sexual behavior and sexual desire across demographic groups. Linear regression was conducted with sexual behavior and sexual desire as criterion variable and demographic characteristics as predictors.

Main results and the role of chance: Women reported significantly lower frequency of sexual behavior during the Covid-19 pandemic compared to previously ($t = 8.25$, $P < .001$). Less often did women feel sexual desire or interest during the pandemic ($t = 7.05$, $P < .001$) and a lower degree of sexual desire or interest was reported ($t = 11.16$, $P < .001$). During the pandemic, women who were married or cohabitated reported significantly more frequent sexual behavior than did single women with partners ($P < .01$), while the two groups were comparable in terms of the frequency and intensity of having sexual desire. Linear regression analyses showed a statistically significant reduction in frequency of sexual intercourse during Covid-19 with increasing age ($B = -.19$, $P < .001$), and being single with ($B = -.26$, $P < .001$) or without partner ($B = -.40$, $P < .001$), taking into account all other demographic characteristics. Single women reported significantly less often did they feel sexual desire or interest during Covid-19, while age ($B = -.26$, $P < .001$) and being single without a partner ($B = -.22$, $P < .001$) predicted significantly lower intensity of sexual desire during Covid-19.

Limitations, reasons for caution: Women with either primary or secondary education level are not adequately represented as recruitment was carried out via community network and social media platform, which are more likely to be more accessible by a population who is more tech-savvy and has more access to email.

Wider implications of the findings: We are still in the middle of the pandemic and there is still paucity of data illustrating its impact on sexual life. Current

findings could give insight to stakeholders to develop sexual health counselling services that address the negative effect on sexual intimacy arising from sexual behavioral change.
Trial registration number: Not applicable

P-472 Single mothers by choice - experiences of single women seeking treatment at a public fertility clinic in Denmark: A pilot study.

M.L. Steenberg[1], R. Sylvest[1], E. Koert[1], L. Schmidt[1]

[1]Copenhagen University, Public Health, Copenhagen, Denmark

Study question: Are single women in fertility treatment stigmatised and what do they experience?
Summary answer: The women did not feel stigmatised. They experienced self-blame and negative thoughts about themselves, despite experiencing empowerment and receiving positive reactions from families and friends.
What is known already: Since 2007, medical doctors in Denmark have been permitted to offer medically assisted reproduction (MAR) also to single women. Denmark is a welfare state with a public health care sector providing MAR free of charge, 240 days of paid parental leave, and public full-time day-care. There has been an increase in the number of single women deciding to have children through the use of MAR. These women are referred to as 'single mothers by choice' (SMC), and they have been criticised for being selfish when raising a child without a father. Previous studies have shown how SMC can feel stigmatised.
Study design, size, duration: Semi-structured qualitative interviews at a public fertility clinic in Copenhagen, Denmark. Data collection took place between September and October 2020.
Participants/materials, setting, methods: The participants were single and childless women (N=6) undergoing MAR at the Fertility Clinic, Rigshospitalet in Copenhagen, Denmark. Five women received IVF and one received IUI. The women were between 30 and 40 years old and were all residents in the Capital Region of Denmark. The interviews were audiotaped, anonymised, and transcribed in full. Data were analysed using qualitative content analysis.
Main results and the role of chance: Single women did not differ from cohabiting women seeking MAR in relation to their experiences and attitudes towards motherhood. Four main themes were identified; (1) Experiences of single women seeking fertility treatment, (2) Emotions associated with becoming a single mother by choice, (3) The decision of becoming a single mother by choice, and (4) Family formation – a social interaction. The women would have preferred to have a child in a relationship with a partner and the shattered dream about the nuclear family has caused a wide range of experiences and emotions. The women did not feel stigmatised but they all had an awareness of the prejudices other people might have towards single mothers by choice. Hence, they were ready to defend their choice if necessary. On the other hand, they had received positive reactions and the process of becoming a single mother by choice was influenced by their social relations with family and friends. Despite their dream of the nuclear family the women choose to become SMC because motherhood was of such importance and they feared they would otherwise become too old to have children – the biological clock was ticking.
Limitations, reasons for caution: The participants were recruited from a public fertility clinic in the Capital Region of Denmark and may not be representative of all single women seeking MAR. Results might not be transferable to other countries with a different cultural context regarding the societal acceptance of different ways to establish a family.
Wider implications of the findings: This study contributes to the understanding of the experiences of single women seeking fertility treatment in a welfare state where there are no differences in the possibilities for different social classes to seek MAR in the public health care sector.
Trial registration number: N/A

P-473 Should couples be educated on how to try to conceive (TTC) before an infertility diagnosis? A comparative study of fertile, subfertile and infertile couples

M. Martins, M.Sc.- Ph.D.[1,2], J. Fernandes[1], J. Pedro[2,3], A. Barros[3,4], P. Xavier[5,6]

[1]University of Porto, Faculty of Psychology and Education Sciences, Porto, Portugal ;
[2]University of Porto, Centre for Psychology at University of Porto, Porto, Portugal ;
[3]Centre for Reproductive Genetics A. Barros, n.a., Porto, Portugal ;
[4]University of Porto, Faculty of Medicine., Porto, Portugal ;
[5]University of Porto, Faculty of Medicine, Porto, Portugal ;
[6]Porto Clínica, Reproductive Medicine, Porto, Portugal

Study question: What sexual strategies do individuals TTC with different fertility status use?; What are the predictors of sexual dysfunction(SD) and frequency of intercourse(IF) when TTC?
Summary answer: TTC strategies with no evidence of effectiveness are the most used. Poor marital quality predicted SD, and female SD was a significant predictor of IF.
What is known already: It is well known that couples TTC have low fecundity knowledge. Previous evidence showed that after 12 months the frequency of intercourse decreases. After seeing a fertility specialist couples report a feeling of waiting time by attempting natural conception, which can be associated to evidence of an overestimation and excessive confidence in the success of fertility treatments. Existing guidelines recommend intercourse every other day, but no comparative studies exist up to date on what sexual strategies are used in different fertility status and what are the predictors of sexual frequency and sexual dysfunction when trying to conceive.
Study design, size, duration: This study is part of a randomized controlled trial on the effects of timed intercourse in psychosocial outcomes. Data was collected between July 2016 and November 2019 via an advertising strategy and obstetrics/gynecology centers. Inclusion criteria were: i) adult in a marital/cohabitation heterosexual relationship >1 year; ii) not knowing of any condition that can prevent pregnancy; iii) being actively TTC; iv) female age >22<42 years old; v) no previous children. Measurements were carried out online.
Participants/materials, setting, methods: Our final sample had 399 subjects (252 women). Participants rated the use of the following strategies: intercourse every other day (EOD), fertile week (FW), basal temperature, cervical mucus monitoring (CMM), ovulation predictor kits (OPK), and keeping legs elevated afterwards (EL). We also accessed psychological adjustment, relationship quality, SD and IF. Comparisons between groups were made by analysis of variance (ANOVA) and Chi-square tests, and logistic regression was used to determine predictors of SD and IF.
Main results and the role of chance: Participants were highly educated (72,8%), in the relationship for 9 years (±5.2), cohabitating for 5 (±3.6), and TTC for 2,5 years (range 0-16). Women were 33 years old (±4.4) and men 36 (±5.5). Regarding fertility status, 22.6% of participants were TTC <12 months, 22.8% >12 months but not diagnosed, 23.6% had a diagnosis but no treatment, and 31.1% had ART.

The most reported female strategy in all groups was EL, and the most never used was OPK. Differences were found in EOD, with significantly more women TTC <12 months that never used it, and more women with previous ART using it. Women who had ART are the ones who more frequently use FW and CMM comparing to other women (P>.05). In all groups, the majority reported IF once or twice/week. SD was found in 17.5% of women and 10,9% of men. Age (OR 0.91, 95%CI 0.85-0.97) and SD (OR 2.47, 95%CI 1.02-6.02) were the only predictors of low IF for women, with no significant findings for men. Poor relationship quality increased the risk of SD for both men (OR 0.11, 95%CI 0.03-0.40) and women (OR 0.46, 95%CI 0.03-0.40), and depression increased the risk of female SD (OR 1.24, 95%CI 1.06-0.46).
Limitations, reasons for caution: The cross-sectional nature of this study does not allow causal relationships to be determined. Further cohort studies allowing to assess differences as couples cross different fertility status are warranted. There are important predictors of SD that were not considered, specifically the comorbidity of diseases and pain.
Wider implications of the findings: Findings indicate that individuals TTC are misinformed, and that those using evidence-based sexual strategies are fertility patients. SD should be screened in patients TTC given that it might be an important predictor of IF. Couples might benefit from counselling to improve marital quality and consequently sexual functioning.
Trial registration number: NCT028140069

POSTER DISCUSSION
SESSION 59: EMBRYOLOGY POSTER DISCUSSIONS
30 June 2021 Stream 2 15:15 - 16:30

P-180 Bisphenols are present in culture media used for ART and cell culture

C. Vignault[1], A. Togola[2], A. Desmarchais[3], O. Téteau[3], V. Maillard[3], S. Bristeau[2], A. Binet[4], F. Guérif[1], S. Elis[3]

[1]CHRU de Tours, Médecine et Biologie de la Reproduction, Tours, France ; [2]Bureau de Recherches Géologiques et Minières, Chemistry, Orléans, France ; [3]INRAE, Physiologie de la Reproduction et du Comportement, Nouzilly, France ; [4]CHRU de Tours, Chirurgie pédiatrique, Tours, France

Study question: Do plastic laboratory consumables and cell culture media used in human ART contain bisphenols?
Summary answer: Human embryo development media contained bisphenols close to the nanomolar concentration range while no release of bisphenols by plastic consumables was detected under routine conditions.
What is known already: The deleterious effect of the endocrine disruptor bisphenol A (BPA) on female fertility raised concerns regarding ART outcome. BPA was detected neither in media nor in the majority of plastic consumables used in ART, however it might have already been replaced by its structural analogs, including bisphenol S (BPS).
Study design, size, duration: Seventeen plastic consumables and 18 cell culture and ART media were assessed for the presence of bisphenols.
Participants/materials, setting, methods: Ten different bisphenols (bisphenol A, S, AF, AP, B, C, E, F, P, and Z) were measured using an isotopic dilution according to an on-line solid phase extraction / liquid chromatography/mass spectrometry method.
Main results and the role of chance: While all the plastic consumables of this study did contain bisphenols, none of them did release bisphenols under routine conditions. Moreover, 16 of the 18 cell culture and ART media assessed contained bisphenols, including 8 among the 10 media used in human ART. Five human ART media exhibited bisphenol concentrations higher than 0.8 nM and reached up to 3.2 nM (799 ng/L).
Limitations, reasons for caution: Further studies are required to investigate a greater number of ART media to identify less potentially harmful ones, in terms of bisphenol content.
Wider implications of the findings: As BPS has already been reported to impair oocyte quality at nanomolar concentrations, its presence in ART media, at a similar concentration range, could contribute to a decrease in the ART success rate. Thus far, there has been no regulation of these compounds in the ART context.
Trial registration number: Not applicable

P-181 Morphine regulates BMP4 growth factor and is involved in in-vitro early embryo development and PGCs formation.

I. Muñoa[1], M. Araolaza-Lasa[1], I. Urizar-Arenaza[1], M. Gianzo Citores[1], N. Subiran Ciudad[1]

[1]University of the Basque Country, Physiology in the Faculty of Medicine and Dentistry, Leioa, Spain

Study question: To elucidate if morphine can alter embryo development.
Summary answer: Chronic morphine treatment regulates BMP4 growth factor, in terms of gene expression and H3K27me3 enrichment and promotes *in-vitro* blastocysts development and PGC formation.
What is known already: BMP4 is a member of the bone morphogenetic protein family, which acts mainly through SMAD dependent pathway, to play an important role in early embryo development. Indeed, BMP4 enhances pluripotency in mouse embryonic stem cells (mESCs) and, specifically, is involved in blastocysts formation and primordial germ cells (PGCs) generation. Although, external morphine influence has been previously reported on the early embryo development, focus on implantation and uterus function, there is a big concern in understanding how environmental factors can cause stable epigenetic changes, which could be maintained during development and lead to health problems.
Study design, size, duration: First, OCT4-reported mESCs were chronically treated with morphine during 24h, 10^{-5}mM. After morphine removal, mESCs were collected for RNA-seq and H3K27me3 ChIP-seq study. To elucidate the role of morphine in early embryo development, two cell- embryos stage were chronically treated with morphine for 24h and *in-vitro* cultured up to the blastocyst stage in the absence of morphine. Furthermore, after morphine treatment mESCs were differentiated to PGCs, to elucidate the role of morphine in PGC differentiation.
Participants/materials, setting, methods: Transcriptomic analyses and H3K27me3 genome wide distribution were carried out by RNA-Sequencing and Chip-Sequencing respectively. Validations were performed by RNA-RT-qPCR and Chip-RT-qPCR.
Main results and the role of chance: Dynamic transcriptional analyses identified a total of 932 differentially expressed genes (DEGs) after morphine treatment on mESCs, providing strong evidence of a transcriptional epigenetic effect induced by morphine. High-throughput screening approaches showed up *Bmp4* as one of the main morphine targets on mESCs. Morphine caused an up-regulation of *Bmp4* gene expression together with a decrease of H3K27me3 enrichment at promoter level. However, no significant differences were observed on gene expression and H3K27me3 enrichment on BMP4 signaling pathway components (such as *Smad1*, *Smad4*, *Smad5*, *Smad7*, *Prdm1* and *Prmd14*) after morphine treatment. On the other hand, the *Bmp4* gene expression was also up-regulated in *in-vitro* morphine treated blastocyst and *in-vitro* morphine treated PGCs. These results were consistent with the increase in blastocyst rate and PGC transformation rate observed after morphine chronic treatment.
Limitations, reasons for caution: To perform the *in-vitro* analysis. Further studies are needed to describe the whole signaling pathways underlying BMP4 epigenetic regulation after morphine treatment.
Wider implications of the findings: Our findings confirmed that mESCs and two-cell embryos are able to memorize morphine exposure and promote both blastocyst development and PGCs formation through potentially BMP4 epigenetic regulation. These results provide insights understanding how environmental factors can cause epigenetic changes during the embryo development, leading to alterations and producing health problems/diseases.
Trial registration number: not applicable

P-186 Volumetric imaging provides insight into the 3D ultrastructural organization of maturing human oocytes

Z. Trebichalská[1], J. Javůrek[2], D. Kyjovská[3], M. Tatíčková[1], S. Kloudová[3], P. Otevřel[3], A. Hampl[1], Z. Holubcova[1]

[1]Masaryk University- Faculty of Medicine, Department of Histology and Embryology, Brno, Czech Republic ; [2]TESCAN ORSAY HOLDING- a.s, Applications - Life Science, Brno, Czech Republic ; [3]Reprofit International, Clinic of Reproductive Medicine, Brno, Czech Republic

Study question: Is volume electron microscopy suitable for high-resolution oocyte imaging in three dimensions (3D)?
Summary answer: Focused Ion Bean Scanning Electron Microscopy (FIB-SEM) allows 3D visualization and quantitative analysis of ultrastructural features in the large human oocyte volume.
What is known already: Transmission electron microscopy (TEM) has been traditionally used to study the fine morphology of female gametes. However, 2D micrographs provide only limited information about the topology of subcellular structures. Volumetric studies are needed to elucidate the 3D organization of complex oocyte cytoplasm.
Study design, size, duration: An academic study conducted in collaboration with an IVF clinic. Advanced 3D - ultrastructural analysis was performed on 9 human oocytes representing 3 stages of maturation (3 germinal vesicle (GV), 3 metaphase I (MI), 3 metaphase (MII) oocytes) collected from February 2018 to November 2019.
Participants/materials, setting, methods: Spare IVF oocytes, donated by 9 young egg donors (22-29 years), were cultured in vitro until they reached a defined developmental stage. Each oocyte´s meiotic status was determined based on the presence/absence of a prophase nucleus, a polar body, and a non-invasively detectable MI/MII spindle. Following standard TEM preparation, individual oocyte-containing resin blocks were coated with a thin carbon layer[JJ1] , mounted on the microscope stage, and subjected to FIB-SEM imaging.
Main results and the role of chance: FIB-SEM tomography provided an unprecedented view of the oocyte´s intracellular morphology. Automated serial scanning of newly exposed sample surface generated large stacks (120-1294 slices) of ultrastructural images with 40-100 nm z-resolution. The tomographic reconstruction of acquired datasets revealed the spatial arrangement of inner oocytes´ structures. The imaging protocol was optimized to ensure sufficient

image detail, minimal noisiness, and time-efficiency of large volume scanning. Comparison of oocytes fixed at different maturation stages confirmed previous TEM observations that the cortical region of GV oocytes is deprived of membraneous structures, and major organelle redistribution occurs during the MI phase. Semi-automated 3D image segmentation was employed to distinguish distinct organelle populations and evaluated their abundance. Subsequent quantitative analysis of volumetric data showed that the mitochondrion occupies ~ 5.27 % of MII oocyte volume. In conclusion, the volumetric imaging, followed by advanced image analysis, maximizes the amount of morphological data obtained from a single human oocyte.

Limitations, reasons for caution: The imaging procedure was pioneered on a small number of hormonally-primed oocytes, which failed to complete development in vivo. There is a trade-off between resolution, the size of the 3D volume, and imaging time. Block-face ion milling during FIB-SEM imaging inevitably results in sample destruction.

Wider implications of the findings: This proof-of-concept study opens up new possibilities to study the delicate architecture of scarce human oocytes. Enhancing our knowledge of the spatial organization of ooplasm is pivotal for developing experimental and therapeutical strategies involving oocyte microsurgery.

Trial registration number: not applicable

P-203 Applying artificial intelligence for ploidy prediction: The concentration of IL-6 in spent culture medium, blastocyst morphological grade and embryo morphokinetics as variables under consideration.

B. Aparicio Ruiz[1], L. Bori[1], E. Paya[1], M.A. Valera[1], A. Quiñonero[2], F. Dominguez[2], M. Meseguer[1]

[1]IVIRMA Valencia, FIV Laboratory, Valencia, Spain ;
[2]IVI Foundation, Research Department, Valencia, Spain

Study question: Would it be possible to predict embryo ploidy by taking into account conventional morphological and morphokinetic parameters together with IL-6 concentration in spent culture medium?

Summary answer: Our artificial neural network (ANN) trained with blastocyst morphology, embryo morphokinetics and IL-6 concentration distinguished between euploid/aneuploid embryos in 65% of the testing dataset.

What is known already: The analysis of spent embryo culture media represents the protein and metabolic state of the embryo and could be a non-invasive method of obtaining information about embryo quality. The impact of the presence/absence of several proteins in embryo culture samples over clinical results has been widely studied. The IL-6 is one of the most mentioned protein for its effect on embryo development, implantation and likelihood of achieving a live birth. In this initial attempt, we examined the predictive value for euploidy of a model that took into account the concentration of IL-6 in the spent culture medium.

Study design, size, duration: This prospective study included 319 embryos with PGT-A results. Out of the total, 127 were euploid and 192 aneuploid embryos. Concentration of IL-6 in spent embryo culture media (collected on the day of trophectoderm biopsy-fifth/sixth day of development), morphokinetic parameters (division time to 2 cells-t2; to 3 cells-t3, to 4 cells-t4; to 5 cells-t5 and time of blastocyst formation-tB) and blastocyst morphological grade (according to ASEBIR criteria) were considered to predict the embryo ploidy.

Participants/materials, setting, methods: Embryos were cultured in EmbryoScope. The chromosome analysis was performed using next-generation sequence technology. The concentration of IL-6 was measured in 20µL of spent embryo culture media with ELISA kits. Morphokinetic parameters were automatically annotated and the blastocyst morphology was evaluated by senior embryologists based on blastocele expansion, inner cell mass and trophectoderm quality. All the embryos were divided into 70% for training, 15% for validating and 15% for testing our ANN model with MatLab®.

Main results and the role of chance: The general description for the euploid embryo population was the following: 2% of the embryos were graded as A, 71% were graded as B and 28% were graded as C; the means and standard deviations were 25.32±2.97 hours (h) for t2, 35.33±5.15h for t3, 37.30±5.43h for t4, 48.24±6.62h for t5 and 103.93±12.8h for tB; and the average of IL-6 concentration was 1.51±0.70 pg/ml. The general description for the aneuploid embryo population was the following: 1% of the embryos were graded as A, 48% were graded as B and 51% were graded as C; the means and standard deviations were 26.13±3.51h for t2, 36.70±4.29h for t3, 38.20±4.24h for t4, 49.86±6.89h for t5 and 107.10±8.29h for tB; and the average of IL-6 concentration was 1.47±0.71 pg/ml. Our ANN model showed a higher general success rate as we increased the variables considered in the final prediction of euploid embryos. The accuracy, sensitivity and specificity for the testing dataset were: 0.60, 0.12 and 0.87 with morphokinetic parameters; 0.63, 0.24 and 0.93 with morphokinetics and IL-6 concentration; and 0.65, 0.16 and 0.96 with morphokinetics, IL-6 concentration and blastocyst morphological grade.

Limitations, reasons for caution: The low sensitivity and high specificity achieved in our models indicated that they were more capable of detecting aneuploid than euploid embryos. As this was a preliminary study, the small number of embryos included in the test (n=48) was also a limitation.

Wider implications of the findings: The results showed that our model tended to classify the embryos as aneuploid. More euploid embryos would be necessary to train our model and achieve better results in the prediction of chromosomally normal embryos. Further studies with large number of embryos and additional variables could improve the non-invasive ploidy prediction.

Trial registration number: not applicable

P-240 Human extracellular vesicles (EVs) secreted by aneuploid embryos potentiate development of non-invasive PGT-A RNA biomarkers and stimulate MUC1 up-regulation in primary endometrial stromal cells (ESCs).

S. Makieva[1], G.M. Scotti[2], D. Lazarevic[2], E. Giacomini[1], J. Ottolina[3], L. Bartiromo[4], M. Schimberni[4], A. Alteri[3], V. Pavone[1], S. Minetto[3], E. Papaleo[3], M. Morelli[2], G. Tonon[2], P. Viganò[1]

[2]IRCCS San Raffaele Scientific Institute, Center for Omics Sciences, Milan, Italy ;
[3]IRCCS San Raffaele Scientific Institute, Centro Scienze della Natalità, Milan, Italy ;
[4]IRCCS San Raffaele Scientific Institute, Department of Obstetrics and Gynecology, Milan, Italy

Study question: Could EVs secreted by aneuploid embryos a) serve for development of RNA biomarkers for PGT-A and b) elicit a relevant transcriptomic response in decidualised ESCs?

Summary answer: Aneuploid embryo EVs a) contain *PPM1J*, *LINC00561*, ANKRD34C and TMED10 in differential abundance from euploid EVs and b) induce up-regulation of *MUC1* in decidualised ESCs.

What is known already: Embryo aneuploidy accounts for approximately 50% of all recurrent implantation failures in women >35 years old. PGT-A identifies euploid embryos to increase implantation probability but the technology is controversial as it requires an invasive embryo biopsy with an elusive long-term biosafety. The development of non-invasive methods to screen out aneuploid embryos is paramount. It is also critical to decode the embryo-endometrial dialog underlying implantation failure. We have previously reported that IVF embryos secrete EVs that can be internalised by ESCs, conceptualising that successful implantation to the endometrium is facilitated by EVs, which may additionally serve as biomarkers of ploidy status.

Study design, size, duration: Embryos destined for biopsy on days 5-7 for PGT-A were grown under standard conditions. Spent media (30µl) were collected from euploid (n=175) and aneuploid embryos (n=145) at both cleavage (days 1-3) and blastocyst (days 3-5) stage. Media samples from n=35 cleavage embryos were pooled in order to obtain five euploid and four aneuploidy pools. Blastocyst media were pooled to create one euploid and one aneuploid pool. ESCs were obtained from five women undergoing diagnostic laparoscopy.

Participants/materials, setting, methods: The study was realised at a research hospital. EVs were isolated from euploid and aneuploid Day3 pools with differential ultracentrifugation and EV-RNA sequencing was performed following the SMARTer Stranded Total RNA-Seq approach. ESCs were decidualised (E2:10nM, P4:1uM, cAMP:0.5 mM twice every 48 hours) and treated for 24 hours with 50 ng/ml euploid or aneuploid EVs extracted from blastocyst media. RNA sequencing was performed on ESCs following the Truseq RNAseq protocol.

Main results and the role of chance: Aneuploid cleavage stage embryos (n=4) secreted EVs that were less abundant in RNA fragments originating from the genes *PPM1J* (log2fc=-5.13, p=0.011), *LINC00561* (log2fc=-7.87, p=0.010)

and *ANKRD34C* (log2fc=-7.30, p=0.017) and more abundant in *TMED10* (log2fc=1.63 p=0.025) compared to EVs (n=5) from euploid embryos. Decidualisation *per se* induced downregulation of *MUC1* (log2FC=-0.54, p=0.0028) in ESCs as prerequisite for the establishment of receptive endometrium. The expression of *MUC1* transcript in decidualised ESCs was significantly increased following treatment with aneuploid compared to euploid embryo-secreted EVs (log2FC=0.85, p=0.0201).

Limitations, reasons for caution: The findings of the study may require validation utilising a second cohort of EVs samples.

Wider implications of the findings: This discovery that the RNA cargo of EVs secreted from aneuploid cleavage stage embryos is diverse from that of euploid embryos potentiates the development of non-invasive methodology for PGT-A. The upregulation of *MUC1* in decidualised ESCs following aneuploid embryo EV treatment proposes a new mechanism underlying implantation failure.

Trial registration number: NA

POSTER DISCUSSION

SESSION 60: IMPLANTATION AND EARLY PREGNANCY POSTER DISCUSSIONS

30 June 2021 Stream 3 15:15 - 16:30

P-365 Pre-selected for an award: Altered endometrial oestrogen-responsiveness and aberrant expression of cell-fate markers may contribute to the aetiology of recurrent pregnancy loss

H. Al-Lamee[1,2], N. Tempest[1,2], J. Drury[1], A. Drakeley[2], D. Hapangama[1]

[1]University of Liverpool, Liverpool Women's Hospital- Department of Women's and Children's Health, Liverpool, United Kingdom ;
[2]Liverpool Women's NHS Foundation Trust, The Hewitt Fertility Centre, Liverpool, United Kingdom

Study question: Do women with recurrent pregnancy loss (RPL) have an aberrant expression of oestrogen receptor- (ER) and cell-fate markers during the window of implantation (WOI) endometrium?

Summary answer: Women with RPL are found to have significantly altered levels of ER and Ki-67 in the WOI endometrium, possibly resulting in anti-proliferative and anti-angiogenic effects.

What is known already: RPL affects 1% of all women and has been associated with altered endometrial angiogenesis and proliferation when compared with the endometrium of healthy fertile women. RPL can be subcategorised into recurrent loss of anembryonic pregnancy, fetal loss (following evidence of a fetal heartbeat) and recurrent implantation failure (RIF). ER is the only oestrogen-receptor (ER) known to be expressed in the vascular endothelium of the endometrium and is the dominant ER during the WOI. It has an important role in endometrial regeneration and is proposed to regulate the angiogenic and vascular changes that occur in embryo implantation.

Study design, size, duration: This pilot case-control study took place at the Liverpool Women's Hospital and included 38 women; 29 who suffered RPL and 9 controls with proven fertility (≥2 healthy pregnancies). Of the RPL group, 9 had recurrent loss of anembryonic pregnancy, 10 had recurrent fetal loss and 10 had RIF. Endometrial samples were collected during the WOI (cycle day 22+/-2).

Participants/materials, setting, methods: To determine whether markers of endometrial cell proliferation and oestrogen-responsiveness are associated with RPL, we assessed the immuno-staining for ER , progesterone receptor (PR) and cell-fate marker Ki-67 in endometrial biopsies during the WOI using immunohistochemistry. A semi-quantitative immuno-staining score was used to assess the endometrial glands, stroma, luminal epithelium, perivascular and vascular endothelium compartments separately. Statistical differences between groups were calculated by non-parametric tests and significance level set at p<0.05.

Main results and the role of chance: During the WOI, the endometrial epithelium of women with RIF and recurrent anembryonic pregnancy loss showed significantly higher levels of ER when compared with fertile controls (p=0.01 and p=0.01, respectively). This may indicate an anti-proliferative process occurring at the site of implantation with very early pregnancy losses. In contrast, with women with recurrent fetal loss, a significantly lower level of ER was found within the vascular endothelium when compared with the fertile controls (p<0.01). This supports the theory that increased oxygen levels may compromise trophoblastic invasion, thereby leading to fetal loss.

The presence of Ki-67 (a marker of proliferation) was significantly lower within the vascular endothelium of all types of RPL: recurrent anembryonic loss (p=0.02), RIF (p=0.02) and recurrent fetal loss (p<0.01). These findings suggest ineffective endometrial angiogenesis in RPL, resulting in a suboptimal endometrial microenvironment.

PR was found to be significantly reduced (p<0.01) in the perivascular area of women with RIF versus fertile controls. Since decidualisation and preparation of the endometrium for a successful implantation is controlled by critical target genes downstream of PR, this alteration in PR may be an important feature of their defective endometrial phenotype.

Limitations, reasons for caution: Samples analysed were taken from the functional endometrium and therefore the results do not reflect the basalis. The WOI was identified using history and histological appearance, rather than timing with ovulation. Although we detected statistical significance, generalisation of the results requires further studies with larger sample size.

Wider implications of the findings: This data provides novel insight into the biological correlates of clinical types of RPL and suggests that specific alterations in the regulation of endometrial cell fate and oestrogen- responsiveness are associated with different types of RPL. This highlights possible new therapies for RPL, such as selective oestrogen receptor modulators (SERMs).

Trial registration number: Not applicable

P-377 Association between antinuclear antibodies and pregnancy prognosis in recurrent pregnancy loss patients

H. Yoshihara[1], M. Sugiura-Ogasawara[1], T. Kitaori[1], S. Goto[1]

[1]Nagoya City University Graduate School of Medical Sciences, Obstetrics and Gynecology, Nagoya, Japan

Study question: Can antinuclear antibody (ANA) affect the subsequent live birth rate in patients with recurrent pregnancy loss (RPL) who have no antiphospholipid antibodies (aPLs)?

Summary answer: ANA did not affect the pregnancy prognosis of RPL women.

What is known already: The prevalence of ANA is well-known to be higher in RPL patients. Our previous study found no difference in the live birth rates of ANA-positive and -negative patients who had no aPLs. Higher miscarriage rates were also reported in ANA-positive patients compared to ANA-negative patients with RPL. The RPL guidelines of the ESHRE state that "ANA testing can be considered for explanatory purposes." However, there have been a limited number of studies on this issue and sample sizes have been small, and the impact of ANA on the pregnancy prognosis is unclear.

Study design, size, duration: An observational cohort study was conducted at Nagoya City University Hospital between 2006 and 2019. The study included 1,108 patients with a history of 2 or more pregnancy losses.

Participants/materials, setting, methods: 4D-Ultrasound, hysterosalpingography, chromosome analysis for both partners, aPLs and blood tests for ANA and diabetes mellitus were performed before a subsequent pregnancy. ANAs were measured by indirect immunofluorescence. The cutoff dilution used was 1:40. In addition, patients were classified according to the ANA pattern on immunofluorescence staining. Live birth rates were compared between ANA-positive and ANA-negative patients after excluding patients with antiphospholipid syndrome, an abnormal chromosome in either partner and a uterine anomaly.

Main results and the role of chance: The 994 patients were analyzed after excluding 40 with a uterine anomaly, 43 with a chromosome abnormality in either partner and 32 with APS. The rate of ANA-positive patients was 39.2 % (390/994) when the 1: 40 dilution result was positive. With a 1:160 dilution, the rate of ANA-positive patients was 3.62 % (36/994). The live birth rate was calculated for 798 patients, excluding 196 patients with unexplained RPL who had been treated with any medication.

With the use of the 1: 40 dilution, the subsequent live birth rates were 71.34 % (219/307) for the ANA-positive group and 70.67 % (347/491) for the ANA-negative group (OR, 95%CI; 0.968, 0.707-1.326). After excluding miscarriages

with embryonic aneuploidy, chemical pregnancies and ectopic pregnancies, live birth rates were 92.41 % (219/237) for the ANA-positive group and 92.04 % (347/377) for the ANA-negative group (0.951, 0.517-1.747).

Using the 1:160 dilution, the subsequent live birth rates were 84.62 % (22/26) for the ANA-positive group, and 70.47 % (544/772) for the ANA-negative group (0.434, 0.148-1.273).

Subgroup analyses were performed for each pattern on immunofluorescence staining, but there was no significant difference in the live birth rate between the two groups.

Limitations, reasons for caution: The effectiveness of immunotherapies could not be evaluated. However, the results of this study suggest that it is not necessary.

Wider implications of the findings: The measurement of ANA might not be necessary for the screening of patients with RPL who have no features of collagen disease.

Trial registration number: not applicable

P-382 Pre-selected for an award: Association of extended culture to blastocyst and gestational trophoblastic disease risk following IVF/ICSI assisted reproduction cycles: An analysis of large UK National database

I. Bambaranda[1], R. Bomiriya[2], M. Choudhary[1]

[1]Newcastle Fertility Centre at Life- Newcastle upon Tyne Hospitals NHS Foundation Trust- UK, Department of Reproductive Medicine, Newcastle upon Tyne, United Kingdom ;
[2]R S Metrics Asia Holdings Private Limited, Data Science, Battaramulla, Sri Lanka

Study question: Is there any association between stage of embryo at transfer based on extended in vitro culture and gestational trophoblastic disease risk during assisted reproduction?

Summary answer: No significant association between stages of embryo transfer from zygote stage to blastocyst stage was found after analysing 540376 cycles of IVF and ICSI.

What is known already: Gestational trophoblastic disease (GTD), commonly referred to as molar pregnancy, results from abnormal proliferation of the trophoblast with a reported incidence of ~1 in 700 in the UK. Despite technological advances such as ICSI, PGT and selection of normally fertilised (2PN) embryos, there are reported cases of GTD following assisted reproduction. Blastocyst transfer is associated with higher pregnancy and live birth rates but evidence is lacking whether extended embryo culture to blastocyst stage influences implantation of an abnormal embryo or abnormal trophoblastic proliferation leading to GTD.

Study design, size, duration: A retrospective study was carried out using Human Fertilisation and Embryology Authority (HFEA) anonymised register data from 1999 to 2016. HFEA holds the longest running register for fertility treatment data in the world and is the national database for fertility treatment data in UK. A total of 540376 fresh IVF or ICSI assisted reproduction cycles were analysed.

Participants/materials, setting, methods: There were 1033588 treatment cycles during the study period but only 540376 cycles met the inclusion criteria of fresh IVF or ICSI. Cycles with incomplete data, frozen embryo transfers, donor treatment or surrogacy were excluded. A subgroup analysis of those with primary subfertility was performed after excluding subjects with secondary infertility in order to exclude an effect of a previous molar pregnancy. Multivariate regression analysis was used to adjust for possible confounders.

Main results and the role of chance: 78 molar pregnancies were reported in the original sample giving a prevalence of 4/10000 live births (78/228461), much lower than the prevalence given with natural pregnancies. Prevalence of molar pregnancy amongst the study population after meeting exclusion criteria was 4 /10000 livebirths (53/156683). Incidence of molar pregnancy was not statistically different between treatment type (0.0001 vs 0.00009).

Significantly higher incidence of GTD was seen in the 40 to 42 age category compared to 18-34 category(OR 1.86(95% CI 8.7-3.75)),in par with known higher GTD risk in women above 40 in the general population. Of interesting note, although the incidence of molar pregnancy was significantly lower in women undergoing assisted reproduction increased risk with advancing age is not totally eliminated with treatment. There was no significant association between the occurrence of molar pregnancy with the type and cause for infertility and number of embryos transferred.

Crude (1.06 (95% CI 0.852-1.31)) and adjusted odds ratios (1.07 (95% CI (0.857-1.32)) did not show any association between day of embryo transfer and molar pregnancy even after adjusting for age and excluding secondary infertility. Selection of blastocyst stage embryo after extended culture did not alter the likelihood of having a GTD compared to cleavage stage embryo.

Limitations, reasons for caution: The retrospective analysis of anonymised HFEA data limited adjustments for confounders such as smoking, previous history of GTD, ethnicity etc that predispose to GTD. Caution needs to be exercised for under-reporting of GTD to HFEA and lack of information on type of GTD identified.

Wider implications of the findings: Though GTD cannot be prevented by IVF/ICSI, the incidence is significantly low and extended culture is not associated with higher risk of abnormal trophoblastic proliferation or GTD occurrence with IVF/ ICSI treatment. These findings would aid informed implications counselling and reassurance of patients during assisted reproduction treatments.

Trial registration number: not applicable

P-388 Pre-selected for an award: Endometrial extracellular vesicles from recurrent implantation failure patients inhibited embryonic growth and implantation via miR-6131/PAK2 pathway

C. Liu[1]

[1]Tongji Hospital- Tongji Medical College- Huazhong University of Science and Tech, Reproductive Medicine Center, Wuhan, China

Study question: Could endometrial extracellular vesicles from recurrent implantation failure patients (RIF-EVs) attenuate the growth and implantation potentials of embryos and what are the mechanisms?

Summary answer: RIF-EVs inhibited embryonic growth and decreased the trophoblast functions via miR-6131/PAK2 pathway.

What is known already: Recurrent implantation failure (RIF) is characterized by repeated embryo transfers without pregnancy. To date, the etiology of RIF remains poorly understood. Recent evidence indicated that extracellular vesicles (EVs) secreted by endometrial cells, played a crucial role in the implantation by regulating the development and implantation of embryos.

Study design, size, duration: Endometrial cells isolated from endometrial tissues of RIF patients (n=25) and fertile women (n=16) were cultured and modulated via hormones. Endometrial EVs from RIF patients (RIF-EVs) or fertile women (FER-EVs) were isolated from the conditioned medium. The influence of EVs on embryonic development and implantation was investigated by co-culture models of EVs and 2-cell murine embryos or HTR8/SVneo cells, respectively. High-through put sequencing was performed to identify the miRNA profile in the RIF-EVs.

Participants/materials, setting, methods: RIF-EVs and FER-EVs were characterized using western blotting, nanoparticle tracking analysis, and transmission electron microscopy. After co-culture with EVs, embryonic blastocyst rate and hatching rate were calculated. Besides, the proliferation, migration, and invasion of EV-treated trophoblast cells were evaluated by CCK-8, wound healing, and transwell invasion assays. miRNA expression profiles were compared between RIF-EVs and FER-EVs, and the regulatory role of significantly upregulated miR-6131 in RIF-EVs was investigated in the trophoblast cells.

Main results and the role of chance: RIF-EVs and FER-EVs are round bilayer vesicles, ranging mainly at 100 nm and enriched in TSG101, Alix, and CD9. Both RIF-EVs and FER-EVs entered embryonic or trophoblast cytoplasm. The blastocyst rate in the RIF-EV groups was significantly decreased compared to that in the FER-EV groups, at concentrations of 5, 10, and 20 μg/ml. The hatching rate was decreased significantly in embryos treated with 10 or 20 μg/ml RIF-EVs compared to those treated with FER-EVs at the same concentration ($p<0.05$). The proliferation, migration, and invasion of trophoblasts were significantly decreased in the RIF-EV group at 20 μg/mL. A total of 11 differently expressed (fold change >2 and $p< 0.05$) miRNAs were found in the RIF-EVs, and two of them were validated in a larger set of EV samples using RT-PCR. The most significantly different miRNA, 6131, was increased in the RIF-EV-treated HTR8/SVneo cells. The up-regulation of miR-6131 inhibited the growth and invasion of HTR8/SVneo. Bioinformatics coupled with luciferase and western blot assays revealed that PAK2 is a direct target of miR-6131, and the overexpression of PAK2 can rescue the phenotype changes induced by miR-6131 overexpression.

Limitations, reasons for caution: Our study indicated miRNA in the RIF-EVs dysregulating the growth and function of embryonic cells. However, EVs contained a wide spectrum of bioactive molecules, including proteins, mRNAs, and DNA, which may play an important role in the implantation. Further studies are required to investigate the mechanisms.
Wider implications of the findings: This work indicates an important role of EVs from women with RIF in embryonic implantation, potentially providing a novel insight to understand the pathophysiology of RIF.
Trial registration number: not applicable

P-420 Pre-selected for an award: Uncomplicated oocyte donation pregnancies display elevated CD163 positive type 2 macrophage load in the decidua, which is associated with fetal-maternal HLA class II mismatches

X. Tian[1], K.T.S. Aiyer[2], H.M. Kapsenberg[2], D.L. Roelen[2], M.L.V.D. Hoorn[1], M. Eikmans[2]

[1]Leiden University Medical Center, Gynecology and Obstetrics, Leiden, The Netherlands ;
[2]Leiden University Medical Center, Immunology, Leiden, The Netherlands

Study question: Do quantity and composition of decidual macrophages differ between uncomplicated oocyte donation (OD) pregnancies and non-OD in vitro fertilization (IVF) pregnancies?
Summary answer: OD placentas show higher decidual CD163 positive fraction within the total macrophage population compared to non-OD IVF placentas.
What is known already: The embryo of an OD pregnancy is completely allogeneic to the mother, which may lead to a bigger challenge for the maternal immune system to tolerize the fetus compared to autologous pregnancies. Placental macrophages may be essential in maintaining a healthy pregnancy. Macrophages can be classified into different categories based on phenotype and characteristics, in which type 2 macrophages are thought to exhibit immune suppressive activity.
Study design, size, duration: This retrospective case-control study included patients who delivered in the Leiden University Medical Center between January 1st 2006 and July 1st 2016. A total of 42 pregnancies were enrolled in this study, conceived by uncomplicated singleton OD pregnancies (n=25) or non-OD IVF pregnancies (n=17). Medical records were reviewed and clinical data were collected. Placental tissue samples were collected for immunohistochemical staining and blood samples were collected for HLA typing.
Participants/materials, setting, methods: Placentas were collected and immunohistochemically stained for CD14 (pan-macrophage marker) and CD163 (type 2 macrophage marker). The extent of staining was quantitated by digital image analysis software. To assess mismatching, maternal and fetal DNA was typed for HLA-A, -B, C, -DRB1, and -DQB1.
Main results and the role of chance: A significantly lower percentage of CD14 positive staining was observed in the decidua basalis of OD pregnancies compared to non-OD IVF pregnancies (p=0.030). Consequently, the CD163/CD14 ratio in OD group was higher than in non-OD IVF group (p=0.243). In the parietalis, OD pregnancies demonstrated a significantly higher percentage of CD163+ staining (p=0.040) and a significantly higher CD163/CD14 ratio (p=0.032) compared to non-OD IVF group. The reproducibility of this quantitative analysis was found to be high. OD group was separated into a syngeneic group (number of mismatches lower than half of the antigens per HLA locus) and an allogeneic group (number of mismatches higher than half of the antigens per HLA locus). Significant differences of CD163+ and CD163/CD14 ratio were found in the decidua parietalis when comparing the HLA-classII-allogeneic OD group with the non-OD IVF group (p=0.047). This difference was not found for the HLA-class-II-syngeneic OD group.
Limitations, reasons for caution: Our study only focused on decidua basalis and parietalis, no other locations in the placentas. Larger sample size might be needed to verify the association between macrophages and HLA mismatches.
Wider implications of the findings: To our knowledge, this study is the first to quantify a higher CD163 positive M2 macrophages load within the total decidual macrophages of uncomplicated OD pregnancy compared to non-OD IVF pregnancies.
Trial registration number: not applicable

POSTER DISCUSSION

SESSION 61: ENDOMETRIOSIS, ENDOMETRIUM AND FALLOPIAN TUBE POSTER DISCUSSIONS

30 June 2021 Stream 4 15:15 - 16:30

P-295 Does endometriosis affect oocyte quality? An analysis of 13 627 donor oocyte recipient and autologous IVF cycles.

M.S. Kamath[1], B. Antonisamy[2], S.K. Sunkara[3]

[1]Christian Medical College and Hospital, Department of Reproductive Medicine, Vellore, India ;
[2]Christian Medical College- Vellore, Department of Biostatistics, Vellore, India ;
[3]King's College London, Division of Women's Health- Faculty of Life Sciences and Medicine, London, United Kingdom

Study question: Does endometriosis affect live birth following donor oocyte recipient versus autologous in vitro fertilisation (IVF) cycle.
Summary answer: There was no significant difference in the live birth rate (LBR) in women with endometriosis undergoing donor oocyte recipient versus autologous IVF cycle.
What is known already: For infertile women with endometriosis, IVF is often considered as a treatment option. Lower implantation and pregnancy rates have been observed following IVF in women with endometriosis when compared to tubal factor infertility. It has been debated that lower pregnancy rates following IVF in endometriosis is due to both oocyte quality and the endometrium. To delineate whether endometriosis affects oocyte quality or the endometrium, we planned a study using donor oocyte recipient model where the recipient were women with endometriosis. We compared the LBR after oocyte recipient cycle with autologous IVF in women with endometriosis
Study design, size, duration: We obtained anonymised dataset of all the IVF cycles performed in the UK since 19991 from the Human Fertilization and Embryology Authority (HFEA). Data from 1996 to 2016 comprising a total of 13 627 donor oocyte recipient and autologous IVF cycles with endometriosis and no other cause of infertility were analysed.
Participants/materials, setting, methods: Data on all women with endometriosis undergoing fresh or frozen IVF treatment cycles were analysed to compare the LBR between donor oocyte recipient and autologous treatment cycles. Logistic regression analysis was performed adjusting for number of previous IVF cycles, previous live birth, period of treatment, day of embryo transfer, number of embryo transferred, fresh and frozen cycle.
Main results and the role of chance: There was no significant difference in the LBR in women with endometriosis undergoing donor oocyte recipient fresh cycles compared to women undergoing fresh autologous IVF cycles (31.6% vs. 31.0%; odds ratio, OR 1.03, 99% CI 0.79 – 1.35). After adjusting for confounders listed above, there was no significant difference in LBR in women undergoing donor oocyte recipient fresh cycles versus fresh autologous ART cycles (aOR 1.06, 99% CI 0.79 – 1.42).

There was no significant difference in the LBR in women with endometriosis undergoing frozen donor oocyte recipient cycles compared to women undergoing autologous frozen embryo transfer cycles (19.6% vs. 24.0%; OR 0.77, 99% CI 0.47 - 1.25). After adjusting for potential confounders, there was no significant difference in the LBR in women undergoing frozen donor oocyte recipient cycles compared with autologous frozen embryo transfer cycles (aOR 0.84, 99% CI 0.50 - 1.41).
Limitations, reasons for caution: Although the analysis was adjusted for several potential confounders, there was no information on classification of endometriosis to allow adjustment.
Wider implications of the findings: The current study design does not indicate endometriosis has an impact on oocyte quality given that the outcomes in donor oocyte recipient cycles are comparable with autologous IVF cycles. These findings need to be further studied and validated.
Trial registration number: Not applicable

P-296 Examining the link between environmental toxin exposure and uterine leiomyoma: a systematic review

J. Sodhi[1], L. Chan[4], R. Chow[3], I. Chen[2]

[1]University of Ottawa, Biology, Ottawa, Canada ;
[2]The Ottawa Hospital Research Institute- University of Ottawa, Clinical Epidemiology Program- Obstetrics and Gynecology, Ottawa, Canada ;
[3]University of Ottawa, Faculty of Medicine, Ottawa, Canada ;
[4]University of Ottawa, Biology- Toxicology and Environmental Health, Ottawa, Canada

Study question: Is there an association between exposure to certain environmental toxins and the prevalence of uterine leiomyoma in women?
Summary answer: Some evidence was obtained to suggest an association between phthalate esters, bisphenol A, heavy metals, persistent organic pollutants and the prevalence of uterine fibroids.
What is known already: Environmental toxins are naturally occurring, or human made chemicals that can act as endocrine disrupting chemicals (EDCs) by binding and activating estrogen receptors in the body. Uterine fibroids, often called leiomyoma are non-cancerous growths occurring in the uterus. Though often asymptomatic, they can cause pain, infertility, pregnancy complications and are a leading cause for hysterectomy. The aetiology of leiomyoma is not fully understood but both estrogen and progesterone have been implicated in their growth. We aimed to investigate the epidemiological evidence for the association between EDCs and the prevalence of fibroids.
Study design, size, duration: We undertook a systematic review and in keeping with PRISMA guidelines, a structured search of Medline, Embase, Scopus, and Web of Science was conducted (to October 2020). Case-control, cross-sectional, cohort and experimental studies were included.
Participants/materials, setting, methods: The included studies analyzed the association between one or more toxins and the occurrence, or growth of leiomyoma in humans, including human cell lines. The types of toxins, patient characteristics, association and outcome, body concentration of toxin and confounding variables were extracted and analyzed. Quality assessment was performed using the Newcastle-Ottawa Scale.
Main results and the role of chance: In total, 34 studies were included. The majority (76%) of studies revealed a significant association between the exposure studied and the prevalence of uterine leiomyoma. In examining body burden in cases vs controls, phthalate esters showed an association with increased odds of uterine leiomyoma, except in one case where a negative association was observed. In vitro experimental studies examining the effect of alkyl-phenols such as bisphenol A (BPA), octylphenol (OP) and nonylphenol (NP) demonstrated that these environmental estrogens can act to promote the proliferation of leiomyoma cells through a number of mechanisms, typically including the estrogen receptor alpha (ERa) signalling pathway. There were conflicting results for the association between alkyl-phenols and fibroids in case-control studies. A positive association between cadmium was demonstrated in only two studies. There were conflicting results for the association between lead, mercury, arsenic and uterine fibroids. Several metabolites of organophosphate esters, alternative plasticizers, and persistent organic pollutants were associated with an increased risk of uterine fibroids.
Limitations, reasons for caution: Separating these exposures from the multiple other factors that could affect the outcome of leiomyoma is challenging, but an important issue for future research.
Wider implications of the findings: The link between some environmental toxins and uterine fibroids discussed is in agreement with previous literature. However, our review provides a more in depth analysis on specific dosage effects, odds ratios, and potential gene mechanisms of the exposures. This information could contribute to more accurate preventative measures.
Trial registration number: not applicable

P-307 Fatty acid degradation during in vitro decidualization of human endometrial stromal cells

A.C. Mestre Citrinovitz[1], J. Jauckus[1], J. Hauke[2], C.D. Langhans[2], K. Schwarz[2], M. Zorn[3], T. Strowitzki[1], J.G. Okun[2], A. Germeyer[1]

[1]Heidelberg University - Women's Hospital, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany ;
[2]Metabolic laboratory and newborn screening- Dietmar-Hopp-Metabolic Center, University Children´s Hospital- Heidelberg University Hospital, Heidelberg, Germany ;
[3]Central laboratory, Heidelberg University Hospital, Heidelberg, Germany

Study question: Is the activity of the β-oxidation pathway, involved in the degradation of fatty acids, modified during *in vitro* decidualization of human endometrial stromal cells (HESC)?
Summary answer: The level of expression of fatty acid´s transporters suggests that the activity of the mitochondrial β-oxidation pathway is increased during *in vitro* decidualization of HESC.
What is known already: The differentiation of endometrial stromal cells (ESC), named decidualization, is essential for the proper formation of the materno-fetal interphase. One important feature of decidualization is the increased glucose consumption. In the endometrium, glucose is incorporated into ESC by glucose-transporters (GLUT). Fatty acids are another important energy source in living cells. Fatty acids are transported into mitochondria by the carnitine-palmitoyl-transferases 1 and 2 (CPT1 and 2) and are degraded there through the β-oxidation pathway. It has been described that the inhibition of CPT1 affects ESC decidualization. However, it is unknown whether the turn-over of fatty acids degradation is modified during decidualization.
Study design, size, duration: This study was performed using primary HESC. Endometrial biopsies (mid-late proliferative-phase) were obtained from healthy-regularly-cycling women (33.6±2.2 years-old) after written informed consent was obtained (protocol approved by Ethics committee no. S-239/2005). HESC were decidualized (D) *in vitro* with a decidualization-cocktail (containing: medroxyprogesterone acetate, estradiol and 8-Bromo-cyclic adenosine monophosphate) for 6 days. Non-decidualized (ND) controls were treated with vehicle solutions. Cell-culture supernatant and cell extracts were collected for the evaluation of protein/gene expression and metabolite content.
Participants/materials, setting, methods: Decidualization was evaluated by measuring prolactin (PRL) protein levels in cell-culture supernatant (mU/l). Changes in mRNA expression levels of *GLUT1*, *CPT1A* and *CPT2* were evaluated by real-time polymerase chain reaction (RT-PCR). Analysis was performed by the ΔΔCt method (internal control: *RPLP0*) (fold change -FC- in D compared to ND cells). Contents of acylcarnitines were evaluated by Electrospray Ionization-Tandem Mass Spectrometry (ESI-MS/MS) (nmol/mg of total protein). N=5, mean±SEM. Paired Student's t-test was used for statistical analysis.
Main results and the role of chance: PRL protein levels in cell-culture supernatant were significative increased in HESC treated with the decidualization-cocktail compared to ND cells (ND 16.80±0.73 mU/l; D 684.20±219.80 mU/l, *p<0.05). This result confirmed the decidualized state of HESC upon *in vitro* treatment with the decidualization-cocktail. Additionally, the mRNA expression level of *GLUT1* was highly upregulated in D compared to ND cells (FC 10.02±2.90, ***p<0.001), consistent with the increase in glucose consumption characteristic of decidualization. Once confirmed the decidualized state of HESC, the mRNA expression levels of *CPTA1* and *CPT2* were evaluated. The mRNA expression levels of both fatty acid´s transporters were upregulated in D compared to ND cells (*CPTA1*: FC 1.84±0.44, **p<0.01; *CPT2*: FC 2.04±0.49, **p<0.01). Finally, the content levels of different acylcarnitines, intermediate metabolites of the β-oxidation degradation of fatty acids, were evaluated. The concentrations of acetyl- (C2) and butyryl- (C4) acylcarnites were decreased in D compared to ND cells [(C2: ND 1.37±0.10 nmol/mg of total protein; D 1.06±0.20 nmol/mg of total protein, *p<0.05), (C4: ND 0.03±0.01 nmol/mg of total protein; D 0.01±0.00 nmol/mg of total protein, *p<0.05)]. The content levels of other intermediate acylcarnitines measured from cell extracts had no differences between D and ND cells (p>0,05).
Limitations, reasons for caution: This study was performed *in vitro* using primary HESC treated with a decidualization-cocktail. The interconnection of different metabolic pathways within a living cell is very complex. Further studies are necessary to define whether the different intermediate metabolites of the mitochondrial β-oxidation pathway are being used by related-metabolic pathways during decidualization.
Wider implications of the findings: The regulation of the energy metabolism and its interconnection with other important intra-cellular metabolic pathways is of great importance for cellular function. Our results contribute to highlight the importance of the regulation of fatty acids degradation during decidualization. Further insights into HESC metabolism could facilitate the improvement of women´s health.
Trial registration number: not applicable

P-321 The impact of endometrioma and ovarian cystectomy in patients with major indications for IVF/ICSI with endometriosis

J.C. Chang[1], C. Ming-Jer[1]

[1]Taichung Veterans General Hospital- Taiwan, Division of Reproductive Endocrinology and Infertility- Department of Obstetrics and Gynecology and Womens' Health-, Taichung, Taiwan R.O.C.

Study question: Does presence of endometrioma has worse IVF/ICSI outcome than endometriosis per se? What about the impact of cystectomy of endometrioma on IVF/ICSI outcomes?
Summary answer: IVF/ICSI outcome of patients with endometrioma is comparable than with endometriosis. Cystectomy for endometrioma did not alter IVF/ICSI outcomes if ovarian reserve is comparable.
What is known already: Previous studies revealed women with endometrioma undergoing IVF/ICSI had similar reproductive outcomes compared with those without. Most of the comparisons are between women with endometrioma and women without endometriosis. However, endometrioma per se, different from endometriosis may have specific impact on IVF/ICSI outcomes. There is now molecular, histological and morphological evidence to suggest endometrioma is detrimental to the ovaries. Studies comparing IVF/ICSI outcomes between women with endometrioma and women with endometriosis are few.

Cystectomy of endometrioma may worse ovarian reserve, and subsequently adversely affect IVF/ICSI outcomes. But there are possible complications associated with the persistence of endometrioma during IVF/ICSI.
Study design, size, duration: Retrospective analysis of 2153 IVF/ICSI cases during Jan/01/2014 to Dec/31/2018 in VGHTC. We included women who received ART due to endometriosis(n=208). Exclusion criteria including patients >40 years-old, simulation day < 5 days, severe male factor, uterine factor (including adenomyosis) and immunological factors. Patients whose embryos were not completely transferred back or who received embryo transfer from different OPU cycles are excluded. We followed up these patients till 2020/6. The primary outcome is cumulative LBR
Participants/materials, setting, methods: For first analysis, we divided 208 cases to patients with endometrioma during IVF/ICSI(n=89), and patients only diagnosed of endometriosis (n=119). Second analysis on the effect of cystectomy of endometrioma on IVF/ICSI outcomes. Patients with endometrioma (n=89) during IVF/ICSI were further divided to patients with primary endometrioma (n=70) and patients with recurrent endometrioma (n=19, ever received cystectomy for endometrioma). Another group is patients without endometrioma during IVF/ICSI, but ever received cystectomy before (n=40)
Main results and the role of chance: For the first analysis, age, BMI and AMH were comparable in endometrioma (n=89) and endometriosis group(n=119). The usage gonadotropin dose was significantly higher in the endometrioma group (FSH 3619IU vs 3471IU, p=0.001. LH 1224 IU vs 941 IU, p=0.009). The Blastocyst formation rate is lower in the endometrioma group (49.4% vs. 57.7% p=0.005). The OPU number, LBR and cumulative LBR were comparable in both groups (10.3 vs 12.4 p=0.131, 33.3% vs 37%, p=0.687, 49.4% vs 60.5%, endometrioma vs endometriosis). For the second analysis, when comparing cystectomy before IVF/ICSI group with primary endometrioma group, cystectomy group were younger (32.8 vs 34.8 p=0.006). AMH level were comparable. The BC formation rate was significantly higher in the cystectomy group (61.5% vs 50.4% 0= 0.007). The LBR and cumulative LBR were comparable in both groups (43.5% vs 28.1%, 60% vs 48% in cystectomy vs primary endometrioma group). As for the recurrent endometrioma group, the age and AMH level were comparable with cystectomy group, but the usage gonadotropin dose was significantly higher than other two groups. The BC formation rate was also lower than cystectomy group (47.8% vs 61.5% p=0.042). The LBR and cumulative LBR were comparable with other two groups (55.6%, 57.9%).
Limitations, reasons for caution: This is a retrospective study, and the sample size is limit. We did not analysis the size of endometrioma nor the unilateral or bilateral endometrioma.
Wider implications of the findings: Cystectomy for endometrioma must be carefully selected since it did not alter IVF/ICSI outcome only if the ovarian reserve is not affected. Recurrent endometriomas do not have a worse impact on IVF/ICSI outcome than primary endometrioma. If there is recurrent endometrioma, IVF/ICSI may be the first priority.
Trial registration number: not applicable

P-322 Addressing progesterone and cAMP signalling pathways for decidualization induction of endometrial stromal cells of patients with endometriosis

J. Moyer[1], D. Dunja Baston-Buest[2], G. Wennemuth[1], A. Bielfeld[2], R. Grümmer[1]

[1]University Hospital Essen Germany, Institute of Anatomy, Essen, Germany ; [2]Medical Center University of Düsseldorf, Department for OB/GYN and REI UniKiD, Düsseld0rf, Germany

Study question: Which compounds/compound combinations are most effective in decidualization induction of endometrial stromal cells (ESCs) of patients with and without endometriosis?
Summary answer: Combination of compounds addressing different steps in the signalling cascade of decidualization induce decidualization more effectively than application of the individual compounds alone.
What is known already: Decidualization is the monthly recurring differentiation process of the ESCs in preparation for embryo implantation in human. Undifferentiated ESCs reveal an increased potential to proliferate and invade after retrograde menstruation. This may lead to the formation of ectopic lesions and the manifestation of the chronic gynaecological disease of endometriosis due to an impairment of the decidualization process.
Study design, size, duration: Compounds and compound combinations addressing the progesterone receptor- or the cAMP-mediated pathway were evaluated with regard to their own and their synergistic potential to induce decidualization of ESCs from women with (n=10) and without (n=10) endometriosis during a 6-day treatment.
Participants/materials, setting, methods: Human primary ESCs were isolated via enzymatic-mechanic digestion from eutopic endometrium from women with and without endometriosis and treated for 6 days in vitro with different progestins (progesterone, medoxyprogesterone acetate (MPA)), 8-Br-cAMP, forskolin, or phosphodiesterase (PDE)-inhibitor (Rolipram) alone or in combination. The degree of decidualization induction was quantified by morphological, biochemical (prolactin) and molecular (HAND2, FOXO1) parameters by means of ELISA, flow cytometric analysis, Realtime PCR and Western blot analysis.
Main results and the role of chance: After 6 days of treatment, decidualization was induced by forskolin as well as by 8-Br-cAMP whereas progestins or PDE alone hardly induced prolactin secretion by ESCs as a marker of decidualization. A change of morphology from undifferentiated fibroblast-like cells to rounded cells could be observed in parallel with the secretion of prolactin. Forskolin and 8-Br-cAMP-induced decidualization was significantly enhanced by MPA but not by progesterone. These effects were similar in ESCs from women with and without endometriosis. Moreover, forskolin-induced decidualization was significantly enhanced by simultaneous application of PDE. Interestingly, this effect was higher in cells of patients with endometriosis. An induction of decidualization in ESCs was associated with a parallel increase of the process-associated transcription factors HAND2 and FOXO1. This rise of transcription was markedly increased in combination with MPA but not with progesterone.
Limitations, reasons for caution: Endometrial tissue was obtained from women undergoing infertility treatment and thus may differ from the endometrium of fertile women. Results obtained from primary cells in vitro may not cover the in vivo situation in all respects.
Wider implications of the findings: The results of this study provide baseline data for the development of a possible therapeutical approach to induce decidualization as a treatment option for endometriosis. Further research is required to determine the effectiveness of the in vitro tested compound combinations in an in vivo model.
Trial registration number: not applicable

SELECTED ORAL COMMUNICATIONS

SESSION 62: MALE AND FEMALE FERTILITY PRESERVATION: INDICATIONS AND OUTCOME

30 June 2021 Stream 1 17:00 - 18:00

O-177 Long-term follow up to assess criteria for ovarian tissue cryopreservation for fertility preservation in young women and girls with cancer

R. Howie[1], K. Duffin[2], T. Kelsey[3], W.H.B. Wallace[4], R.A. Anderson[5]

[1]NHS Lothian, Edinburgh Fertility Centre, Edinburgh, United Kingdom ; [2]University of Edinburgh, Biomedical Sciences, Edinburgh, United Kingdom ; [3]University of St Andrews, School of Computer Science, St Andrews, United Kingdom ; [4]NHS Lothian, Royal Hospital for Sick Children, Edinburgh, United Kingdom ; [5]University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

Study question: Do the Edinburgh selection criteria correctly identify females, diagnosed with cancer under 18 years old, at high risk of future premature ovarian insufficiency (POI)?

Summary answer: Patient assessment using these criteria accurately identifies those at risk of POI. Ovarian tissue cryopreservation with future transplantation can be offered, providing future fertility options.

What is known already: Cancer treatments can be gonadotoxic and future fertility and reproductive health should be considered at the time of diagnosis and treatment planning. Correct identification of patients at high risk allows appropriate discussion of fertility preservation with ovarian tissue cryopreservation (OTC) and future transplantation. The Edinburgh selection criteria have been proposed as a tool to identify those patients at high risk.

However, the surgical procedure is not without risk and reproductive outcomes remain uncertain in girls. Therefore, long-term follow up of reproductive function is crucial to ensure that this treatment strategy is offered appropriately.

Study design, size, duration: All females diagnosed with cancer less than 18 years old, in South East Scotland, between 01/01/96 and 30/10/20 were included. They were assessed using the Edinburgh selection criteria and offered OTC, if appropriate. Ongoing long-term follow up of reproductive outcomes has been undertaken for the whole patient cohort to detect those who develop POI.

Participants/materials, setting, methods: A total of 639 eligible patients were identified from the Cancer registry and their electronic records reviewed. Reproductive function was assessed by the presence of menstruation, pregnancy, hormonal measurements, evidence of puberty or diagnosis of POI. Patients on hormonal contraception (other than for the treatment of POI) were considered unsuitable for analysis.

Data were analysed using the Kaplan Meier method, with POI as the event, and the Cox proportional hazards model to calculate hazard ratios.

Main results and the role of chance: Of the 639 patients diagnosed with cancer during the study period, those deceased before age 12 years old (n=73) or under 12 years old (n=134) at the date of analysis were excluded; also excluding those on hormonal contraception (n=9) gave a study population of 423.

Data were analysed including those with unknown reproductive outcomes (n=143), assuming they did not have POI. A subgroup analysis excluding these patients was also performed.

Mean age at diagnosis and analysis was 8.8 years and 22.5 years respectively.

OTC was offered to 37 patients, 26 of whom underwent the procedure. Nine patients developed POI (24.3%). Of the 386 not offered OTC, 11 developed POI (2.85%). The hazard ratio for developing POI was 8.8 (CI 3.6-21).

Excluding the patients with unknown outcomes (n=143) left a study population of 280. Within this group, 9 of 29 offered OTC developed POI (31.0%) versus 11 of 251 not offered OTC (4.4%); hazard ratio 8.2 (CI 3.4-20).

In the group offered OTC, all cases of POI developed after the primary treatment. In those not offered OTC, POI developed after secondary treatment for disease relapse in 5 patients (45.5%).

Limitations, reasons for caution: A significant number of patients had unknown reproductive outcomes; this is likely to reflect a lack of recording of normal menstrual function in oncology/haematology clinics but may have biased the analysis. The duration of follow up is also short for some patients, highlighting the need for further follow up.

Wider implications of the findings: The overall prevalence of POI after childhood cancer is low, but the Edinburgh selection criteria are a robust tool for selecting those at high risk at the time of diagnosis, who can be offered OTC. However, many patients had incomplete information on current reproductive status, which should be assessed routinely.

Trial registration number: N/A

O-178 Reproductive and endocrine outcomes after fresh and frozen-thawed ovarian tissue transplantation based on age and anti-cancer therapy: A systematic review and individual patient data meta-analysis

H. Khattak[1], R. Malhas[2], L. Craciunas[1], Y. Afifi[3], S. Fishel[4], C. Amorim[5], I. Gallos[1], A. Coomarasamy[1]

[1]University of Birmingham, Institute of Metabolism and Systems Research, Birmingham, United Kingdom ; [2]New Cross Hospital, Maternity, Wolverhampton, United Kingdom ; [3]Birmingham Women's and Children's NHS Foundation Trust, Gynaecology, Birmingham, United Kingdom ; [4]Care Fertility Group, Research and Development, Nottingham, United Kingdom ; [5]University of Louvain, GYNE- Professor, Brussels, Belgium

Study question: Do reproductive and endocrine outcomes from fresh and frozen-thawed ovarian transplants differ based on age and anti-cancer therapy before cryopreservation?

Summary answer: There was a significant difference in reproductive outcomes of women who have their tissue cryopreserved before or at the age of 35 years.

What is known already: Ovarian tissue cryopreservation (OTC) and transplantation is emerging as a new fertility preservation method. Despite being available for two decades, there is a marked variation in the delivery of this procedure worldwide. Most of the data are based on case reports from specialised centres with expertise in providing this procedure, but there are many unreported cases. Through this review, we aim to collate reproductive and endocrine outcomes from ovarian tissue transplantation. In particular the outcomes in women based on age at cryopreservation and whether they had anti-cancer therapy before cryopreservation were explored.

Study design, size, duration: This study was a systematic review and individual participant level meta-analysis to synthesize the existing evidence on the use of fresh and cryopreserved ovarian tissue transplantation. The review protocol was registered with PROSPERO (CRD42018115233) in November 2018 and the review was concluded in December 2020, including 87 studies (768 women).

Participants/materials, setting, methods: Literature search was performed using MEDLINE, EMBASE, CINAHL and Cochrane Central Register of Controlled Trials from inception to October 2020. After screening 20,566 abstracts, 87 studies (768 women) were included in the review. Patient-level data was extracted for 388 women and study-level data for 380 women. Authors were also contacted for data if relevant outcomes were not reported in published manuscripts. Meta-analysis was performed using inverse-variance weighting to calculate summary estimates using a fixed-effects model.

Main results and the role of chance: Age at cryopreservation was provided for 319 out of 388 (82%) women at participant level data. Of these, 283 (88.7%) had ovarian tissue retrieved at ≤35 years of age. A subgroup of four studies that reported data on participants age at cryopreservation and transplantation were included in meta-analysis. Pregnancy rates were higher in participants at ≤35 years of age at cryopreservation, with results being statistically significant (OR, 0.35; 95% CI: 0.13 to 0.92; z = 2.13; P 0.03, I^2 = 0%). Return of hormonal function shown as a decrease in FSH (IU/L) was also lower in this group (MD, 4.38; 95% CI: -4.29 to 13.05; z = 0.99; P 0.32, I^2 = 0%. Whether a participant had received chemotherapy before cryopreservation was explicitly reported in 122 out of 388 (31%) participants and 56 of them (46%) had received anti-cancer treatment before OTC. Thirty-five pregnancies and twenty-four live births were reported in these women. A further meta-analysis from 5 studies showed that although the results were not statistically significant for return of endocrine function, a decrease in FSH, an increase in oestrogen and increased pregnancy rates were noted in participants who did not receive anti-cancer therapy before cryopreservation.

Limitations, reasons for caution: Although we gathered 768 cases of ovarian transplants published in the literature, most were case reports and therefore not included in the meta-analysis. Of the studies included in the meta-analysis, information such as age and anti-cancer therapy were not always provided for individual participants but as an aggregate.

Wider implications of the findings: There was no difference in reproductive and endocrine outcomes for anti-cancer therapy before OTC. Previous

chemotherapy alone should therefore not be a deterrent in offering young girls and women OTC. Furthermore, the ideal age to achieve higher pregnancy and live birth rates from OTC is less than 35 years.

[6]Société de Recherche pour l'Infertilité SRI, Société de Recherche pour l'Infertilité SRI, Brussels, Belgium ;
[7]Cliniques Universitaires Saint-Luc, Gynecology Department, Brussels, Belgium

Study question: Is cryopreserved ovarian tissue transplantation safe in patients with central nervous system (CNS) tumors?
Summary answer: Cancer cell contamination was not detected in any ovarian samples from patients with CNS tumors by histological analysis, immunohistochemistry, molecular biology or long-term xenotransplantation.
What is known already: Frequently encountered CNS cancers in childhood include astrocytoma, medulloblastoma, ependymoma, glioblastoma and germinoma. CNS tumors have the capacity for extraneural metastases in 0.5-18% of cases. There are two publications reporting metastases to patients' ovaries from medulloblastoma.
Study design, size, duration: Prospective experimental study conducted in an academic gynecology research laboratory using frozen-thawed ovarian tissue from 20 patients suffering from 6 types of CNS tumors, including the most common forms mentioned above and primitive neuroectodermal tumors (PNET). Five-month xenotransplantation was performed to severe combined immunodeficient (SCID) mice.
Participants/materials, setting, methods: Cryopreserved ovarian tissue from 20 patients with CNS cancers was thawed and analyzed for minimal disseminated disease and long-term xenografting to immunodeficient mice. The presence of malignant cells was assessed in both cryopreserved and xenografted ovarian tissue using histological analysis, immunohistochemistry for disease-specific markers (neuron-specific enolase [NSE] and glial fibrillary acidic protein [GFAP]) and reverse transcription droplet digital polymerase chain reaction (RT-ddPCR) for quantification of GFAP gene amplification.
Main results and the role of chance: No malignant cells were detected in frozen-thawed ovarian tissue from any of the patients by histology, immunolabeling for NSE and GFAP, RT-ddPCR for detection of GFAP gene amplification or xenotransplantation to SCID mice. One patient successfully underwent frozen-thawed ovarian tissue transplantation, resulting in the birth of 3 healthy children, but suffered a recurrence of her PNET 6 years after reimplantation and sadly died. Scrupulous analysis of her remaining frozen tissue showed no infiltration by malignant cells, neither after thawing nor long-term xenotransplantation. No relationship was ever established between the patient's relapsed cancer and reintroduction of her cryopreserved ovarian tissue. The risk of reseeding cancer cells when transplanting ovarian tissue in patients with CNS cancers can therefore be considered low.
Limitations, reasons for caution: The risk of ovarian metastases cannot be completely ruled out for any type of tumor because we cannot analyze the actual fragments that will be reimplanted.
Wider implications of the findings: Our results indicate that the risk of disseminated disease in ovarian tissue from CNS patients is minimal. This is useful information for doctors when counseling women looking to undergo ovarian tissue transplantation.

O-180 Oocyte vitrification for fertility preservation does not delay the initiation of neoadjuvant chemotherapy for breast cancer.

I. Sellami[1], M. Grynberg[1], A. Benoit[1], C. Sifer[2], A. Mayeur[1], C. Sonigo[1]

[1]Antoine Beclere Hospital, Reproductive Medicine and fertility preservation, Clamart, France ;
[2]Jean Verdier Hospital, Reproductive Medicine and fertility preservation, Bondy, France

Study question: Does oocyte vitrification for fertility preservation (FP) delay the initiation of neoadjuvant chemotherapy for breast cancer?
Summary answer: The indication of neoadjuvant chemotherapy for breast cancer should not be considered as an impediment to urgent oocyte vitrification for FP.
What is known already: FP is considered as one of the most important issues to address for young breast cancer patients. Cryopreservation of oocytes or embryos may be considered after controlled ovarian hyperstimulation (COH) or in vitro maturation (IVM). Pregnancies have been reported after reutilization of oocytes frozen following both procedures. Although oocyte competence is better after COH, this strategy requires on average 13 days to be achieved. In addition, the safety of ovarian stimulation before tumor removal is currently not formally established. In case of neoadjuvant chemotherapy, the risk-benefit balance of COH is not well known.
Study design, size, duration: Retrospective cohort study including all breast cancer patients eligible for oocyte vitrification following COH or IVM before initiation of neoadjuvant chemotherapy between January 2016 and December 2020.
Participants/materials, setting, methods: Inclusion criteria were: female patients with confirmed non metastatic breast cancer, 18 to 40 years of age, with indication of neoadjuvant chemotherapy, who have had oocyte retrieval for FP after COH or IVM +/- cryopreservation of ovarian tissue. Various time-points related to cancer diagnosis, FP or chemotherapy were obtained from medical record review.
Main results and the role of chance: A total of 198 patients with confirmed breast cancer who had oocyte retrieval following COH (n=57) or IVM +/- cryopreservation of ovarian tissue (n=141) for FP prior to neoadjuvant chemotherapy were included. Although women in IVM group were significantly younger as compared to patients who underwent COH (31.7 ± 4.2 *vs.* 33.3 ± 4.0 years, *p=0.019*), ovarian reserve parameters, BMI and cancer stage did not differ between the two groups. Overall, the average time from cancer diagnosis to chemotherapy start was similar between patients having undergone COH or IVM before oocyte vitrification (37.3 ± 13.8 *vs.* 36.9 ±13.5 days in COH and IVM groups respectively, *p=0.857*).
Limitations, reasons for caution: The time from referral to FP consultation may have influenced the type of FP. In addition, the retrospective nature of the present analysis may constitute a limitation. Moreover, the efficiency and security of the different FP strategies used has not been analysed.
Wider implications of the findings: Oocyte vitrification following COH or IVM was not associated with delayed breast cancer treatment in the neoadjuvant setting, so long as there was a prompt FP referral. Young patients undergoing neoadjuvant chemotherapy should be informed of these findings to avoid unnecessary anxiety due to concern for delays.

SESSION 63: EFFECTIVE EMBRYO TRANSFER, PREGNANCY RISKS AND MATERNAL IMPACT ON ART OUTCOME

30 June 2021 Stream 2 17:00 - 18:00

O-181 4D ultrasound guided embryo transfers statistically improve live birth rates - A randomised controlled trial

L. Nancarrow[1], N. Tempest[2], A. Drakeley[1], R. Hombury[3], K. Ford[1], D. Hapangama[4], R. Russell[1]

[1]Liverpool Women's Hospital, Hewitt Fertility Centre, Liverpool, United Kingdom ;
[2]University of Liverpool, Insitute of Translational Medicine, Liverpool, United Kingdom ;

[3]Homerton University Hospital, Homerton Fertility Centre, London, United Kingdom ; [4]University of Liverpool, Centre for Women's Health Research, Liverpool, United Kingdom

Study question: Does the use of 4D ultrasound to guide embryo transfers improve live birth rates in comparison to the clinical touch technique?
Summary answer: 4D ultrasound guided embryo transfers (4DUS) result in significantly higher live birth rates (LBR) in comparison to those performed using the clinical touch technique (CTT)(41%vs28%).
What is known already: A previous Cochrane review showed ultrasound guided embryo transfers (ET) improve pregnancy outcomes in comparison to CTT; however there was a large degree of heterogeneity between the studies and the largest study in the review showed no difference between ultrasound guidance and CTT. A further study demonstrated no difference in ongoing pregnancy rates between 2D vs 3D ultrasound guided embryo transfers, however this study did not use LBR as an endpoint and did not report on procedure duration/difficultly, both of which are known to impact ET success rates.
Study design, size, duration: This was a prospective, open labelled randomised controlled trial comparing superiority between two techniques for ET (4DUS vs CTT). A total of 320 (n=160/group) patients were recruited using computer generated randomisation that were centrally distributed in consecutive sealed opaque envelopes between July 2018 to December 2019. Main outcomes were clinical pregnancy rate (CPR) and LBR. Following the procedure, participants completed a survey based on their comfort and satisfaction.
Participants/materials, setting, methods: Inclusion criteria included single blastocyst transfer and a normal uterine cavity. Participants were recruited and randomized on the day of ET. Those allocated to the CTT group, had their embryo transferred without ultrasound, depositing the embryo 6cm from the external os. Those in the 4DUS group had their ET using transvaginal 4D ultrasonography and had their embryos deposited at the maximal implantation point (MIP).
Main results and the role of chance: Results were available from a total of 295 women (8% attrition rate, CTT n=153; 4DUS n=142)).

No demographic differences between the two groups (CTT and 4DUS) were noted including age (p=0.05), BMI (p=0.29), duration of infertility (p=0.94), type of infertility (p=0.68) or embryo quality (p=0.89). All the 4DUS and 95% of the CTT group were performed by the same practitioner.

The 4DUS resulted in significantly higher CPR (50% vs 36% p=0.015, OR 1.78 (1.12-2.84)) and LBR (41%vs 28%, p=0.021, OR 1.77 (1.09-2.87)).

There were no statistically significant differences between miscarriage (p= 0.494), pregnancy of unknown location (p= 0.141) or ectopic pregnancy rates (p=0.958) between the two groups. The 4DUS process took significantly longer time compared with the CTT procedure (15.7 vs 10.2 minutes respectively, p<0.01). The results of the survey showed no statistical difference between patient comfort (p=0.17) or satisfaction (p=0.08) between the groups however there were significantly more positive comments in the 4DUS (p<0.01). In the 4DUS group there was no difference in mean endometrial thickness (P=0.186) or endometrial volume (p=0.836) between pregnant and non-pregnant patients.
Limitations, reasons for caution: Due to the nature of this trial we were unable to blind the participants due to the obvious differences between the methods. Wallace catheters were used for the CTT and Kitazato catheters for the 4DUS, whilst a methodological weakness; previous meta-analysis has not shown any difference between different soft catheters.
Wider implications of the findings: LBRs, when utilizing 4DUS, are significantly higher than the current UK average (41%vs22-23%) and significantly higher than CTT. 4DUS allows for superior imaging of the uterine cavity, tailoring the embryo deposition point specifically to the patient. Further RCTs are required to confirm that 4DUS is the superior technique for ET.

Study question: Is there an increased risk of preeclampsia after Frozen-thawed Embryo Transfer(FET) compared to In Vitro Fertilization-fresh transfer(IVF-fresh-ET) according to endometrial type of preparation for FET?
Summary answer: The frequency of preeclampsia and hypertension were significantly higher in the group of artificial cycle (AC-FET) compared to ovulatory cycle (OC-FET) and fresh-ET (*P*<0.0001).
What is known already: Risks of maternal morbidity are known to be reduced in pregnancies resulting from FET compared to fresh-ET except for the risk of preeclampsia, that was reported to be significantly higher in pregnancies resulting from FET compared to fresh-ET or spontaneous conception. Most recent studies demonstrate an equal live birth rate with either OC-FET or AC-FET preparation. Few studies compared the maternal vascular morbidities with the two hormonal environments that preside over the early stages of embryonic development: OC (major role of the corpus luteum) and AC (prolonged hormone replacement with high doses of estrogen and progesterone).
Study design, size, duration: We conducted a 2013-2018 French nationwide cohort study comparing maternal vascular morbidities in 3 groups of single pregnancies> 22 weeks of gestation (WG): FET with AC or OC preparation, and IVF (conventional or ICSI)-fresh-ET.Data were extracted from the French National Health System database (>99% of national deliveries) in which all hospitalizations are registered, containing information on patient characteristics, diagnoses and treatments. Records were merged anonymously. Access to the database was legally approved.
Participants/materials, setting, methods: 68 025 deliveries were included: fresh-ET(n=48 152), OC-FET(n=9 500), AC-FET(n=10 373). In OC-FET, a luteal phase support with progesterone was administered for maximum 6 WG if pregnancy. In AC-FET, progesterone was co-administered with estrogen until 12 WG. Embryos were transferred at cleavage or blastocyst stage.

Vascular disorders were recorded if hospitalization for preeclampsia/eclampsia or hypertension (history of hypertension excluded). Maternal characteristics were included in multivariate analysis. Adjusted odds ratios(aOR) and 95% confidence intervals(CI) were estimated.
Main results and the role of chance: *Maternal characteristics:* In multivariate analysis, patients in the FET groups were older (33.4 years (std=4.3) *vs.* 33.2 years (std=4.4) for fresh-ET, respectively, *P*<0.0001), less often primiparous (aOR=0.68[0.66-0.71], *P*<0.0001) or smokers (aOR=0.84[0.75-0.95]) or with premature ovarian insufficiency (POI) (aOR=0.68 [0.58-0.79]), more frequently with polycystic ovaries (PCOS) (aOR=1.25[1.12-1.39]) and comparable for obesity or diabetes.

In FET groups, 52.2% were AC-FET. There was no difference for maternal age, parity, obesity, smoking, history of diabetes between AC and OC-FET. Endometriosis (aOR=1.26[1.16-1.38]), PCOS (aOR=1.79[1.50-2.15]) and POI (aOR=2.0[1.48-2.72]) were more frequent in AC-FET.

Risks of vascular disorders: The rate of preeclampsia (5.3% *vs.* 2.3% *vs.* 2.4%, respectively, *P*<0.0001) and hypertension (4.7% *vs.* 3.4% *vs.* 3.3%, respectively, *P*=0.0002) was significantly higher in AC-FET *versus* OC-FET and fresh-ET.

In multivariate analysis, the risk of preeclampsia increased with age, primiparity, obesity, diabetes and POI. The risk was higher in AC-FET *versus* OC-FET (aOR=2.42 [2.06-2.85]) and fresh-ET (aOR=2.43[2.2-2.7]), *P*<0.00001. No difference was found between OC-FET and fresh-ET (*P*=0.91). The risk of pregnancy-induced hypertension increased with age >40, primiparity, smoking, obesity and diabetes and was higher in AC-FET *versus* OC-FET (aOR=1.50[1.29-1.74],

P<0.0001) and fresh-ET (aOR=1.50[1.35-1.67], *P*<0.0001) and not different between OC-FET and fresh-ET (*P*=0.86).
Limitations, reasons for caution: While the strength of this study relies in the number and exhaustiveness of subjects analysed, its limitations are its retrospective and register-based nature that did not enable to refine the risk according to details of techniques and treatments in each group.
Wider implications of the findings: This large nationwide cohort study highlights 2 important information for physicians : i) the possible deleterious role of high supra-physiological and prolonged doses of estrogen-progesterone supplementation on vascular pathologies ii) the protective role of the corpus luteum present in stimulated or spontaneous OC for their prevention.
Trial registration number: Not applicable

O-183 Increased Risk Of Hypertensive Disorders Of Pregnancy In Hormone Replacement Therapy Cycle - A Multicenter Cohort Study In Frozen Blastocyst Transfer In Ovulatory Women

F. Gu[1], M. Tan[2], Y. Chen[3], X. Li[4], Y. Xu[1]

[1]The First Affiliated Hospital of Sun Yatsen university, Center for Reproductive Medicine, Guangzhou, China ;
[2]Jiangmen Central Hospital, Affiliated Hospital of Sun Yat-sen University-Guangdong., Center for reproductive medicine ;
[3]Shunde Women and Children's Hospital of Guangdong Medical University, center for reproductive medicine, Shunde, China ;
[4]Shenzhen Martinity&Child Healthcare Hospital, center for reproductive medicine, Shenzhen, China

Study question: Is hormone replacement therapy cycle (HRT) associated with a higher risk of adverse perinatal outcomes than natural cycle (NC) during frozen embryo transfer (FET)?
Summary answer: Higher rates of hypertensive disorders of pregnancy (HDPs) and macrosomia were detected in HRT-FET as compared to NC-FET in ovulatory women.
What is known already: Live-birth rates after HRT-FET and NC-FET are found to be comparable. Recent data showed that pregnancies following HRT-FET are associated with higher risks of HDPs. However, the results might be influenced by selection bias as patients with ovulation disorder were more prone to receive HRT than ovulatory women. As is known, patients with ovulation disorder might have more endocrine disturbances than ovulatory women, which could be associated with adverse obstetrical outcomes.
Study design, size, duration: Four large reproductive medical centers in Guangdong province, Southeast of China, took part in this multicenter retrospective cohort study. Patients with regular cycles (25-35 days), who underwent either HRT or NC blastocyst FET and delivered after 20 weeks of gestation between January 2017 and December 2019 were analyzed. Preimplantation genetic testing (PGT) cycles, multiple pregnancies and cases with type II diabetes or preconceptional hypertension were excluded. Each patient only contributed one cycle per cohort.
Participants/materials, setting, methods: Treatment cycles from each patient were linked to their obstetrical medication record and a comprehensive chart review was done to investigate their perinatal outcomes. Maternal and neonatal outcomes were compared between NC-FET and HRT-FET cycles. Multiple logistic regression analyses were performed to adjust the confounding factors including baseline demographics (maternal age, BMI, education level, parity, type of infertility and cause of infertility), as well as IVF characteristics (insemination method and embryo cryopreservation duration).
Main results and the role of chance: A total of 406 cases from NC-FET and 602 cases from HRT-FET were included. A multiple logistic regression analysis showed that pregnancies after HRT-FET had increased odds of HDPs [adjusted odds ratio (aOR) 2.44, 95% confidence interval (CI), 1.39–4.29] in comparison to pregnancies after NC-FET. Singletons born after HRT-FET were at increased risk of macrosomia compared to NC group (aOR 2.74, 95%CI 1.10–6.87). No significant difference could be seen regarding other obstetrical complications including gestational diabetes, placenta previa, placental abruption and postpartum hemorrhage between HRT-FET and NC-FET. No significant differences were noticed for preterm birth and low birthweight between the different endometrial protocols.
Limitations, reasons for caution: Our study was retrospective in nature, and some cases were excluded due to missing data.
Wider implications of the findings: Pregnancies following HRT-FET are associated with higher risks of HDPs and macrosomia in ovulatory women. Physicians should be cautious on the decision of the endometrium preparation for FET, especially for those who can ovulate normally.

Study question: Can mitochondrial DNA (mtDNA) variants explain the differences in birthweight between ART and spontaneously conceived (SC) individuals and how do they originate?
Summary answer: Children born after ART carry more frequently a different mtDNA variant composition, both maternally inherited and *de novo*, which are predictive of their birthweight percentile.
What is known already: Children born after ART show an increased risk of lower birthweight and of developing a mild abnormal cardio-metabolic profile later in life. Variation in the mtDNA associates with overall health in the general population, including cardio-metabolic fitness, and can result in changes in mitochondrial function. We hypothesized that mitochondrial DNA variants could explain the differences in birthweight between ART and SC individuals and that these differences may result from maternal transmission and/or from the ovarian stimulation (OS) used in ART.
Study design, size, duration: We deep-sequenced the mtDNA of 472 individuals of who 283 ART and 189 SC, 182 mother-child pairs and 113 single oocytes from both natural menstrual cycles and OS cycles. The mtDNA was compared between groups and Fisher linear discriminant analysis was used as predictive model for the birthweight percentile.
Participants/materials, setting, methods: Mitochondrial DNA was enriched by long-range PCR and subsequently sequenced on an Illumina platform. mtDNA server and MuTect were used for variant calling for variants with a load higher than 1.5%, versus the reference NC_012920.1. An orthogonally rotated factor analysis was used to reduce the dimensionality of the studied dependent variables in the complex data of the heteroplasmic variants.
Main results and the role of chance: ART individuals carried more frequently haplogroup U4 (p=0.004) and component analysis indicated that they carry a different mtDNA heteroplasmic variant composition than SC individuals (p=0.01), driven by non-synonymous protein-coding and rRNA-coding variants. These differences were also predictive of the risk of a lower birthweight percentile, especially for the SC children, together with the absence of haplogroup T, the presence of homoplasmic tRNA-variants, pregnancy-induced hypertension and the embryo culture medium used. The differences in heteroplasmic variation observed in the ART children resulted from both maternal transmission (p=0.03) and *de novo* mutagenesis (p=0.02). Mothers of ART children showed a similar mtDNA genotype as their children and differed in the same variant composition when compared to the mothers of SC children (p=0.03). Furthermore, the comparison of oocytes from the same donors retrieved in natural menstrual cycles and after one OS cycle showed that OS does not increase *de novo* mutagenesis. Additionally, clinical parameters such

as the total dosage of FSH units, the number of oocytes retrieved, and maternal age did not show any correlation with the differences observed in ART individuals.
Limitations, reasons for caution: This study is observational with no functional tests being performed.
Wider implications of the findings: We demonstrate an association between a lower birthweight percentile and a mtDNA variant composition which is more frequently carried by ART children. These non-disease associated mtDNA variants could cause a suboptimal mitochondrial function affecting the birthweight. Long-term health consequences of these differences remain to be further elucidated.

SESSION 64: HOW EFFECTIVE IS HIGH QUALITY INFORMATION IN SUPPORTING FERTILITY DECISION MAKING?

30 June 2021 Stream 3 17:00 - 18:00

O-185 Evaluation of the decision-making process of girls with Turner syndrome and their parents considering ovarian tissue cryopreservation

S. Van der Coelen[1], M. Schleedoorn[1], S. Nadesapillai[1], R. Peek[1], D. Braat[2], J. Van der Velden[3], K. Fleischer[4], A. Oerlemans[5]

[1]Radboud University Medical Centre, Reproductive medicine, Nijmegen, The Netherlands ;
[2]Radboud University Medical Centre, Gynaecology and obstetrics, Nijmegen, The Netherlands ;
[3]Radboud University Medical Centre- Amalia Children's Hospital, Pediatrics, Nijmegen, The Netherlands ;
[4]The Fertility Partnership-VivaNeo Center, Reproductive Medicine, Düsseldorf, Germany ;
[5]Radboud Institute for Health Sciences, IQ healthcare, Nijmegen, The Netherlands

Study question: What are the experiences with the decision-making process of girls with Turner syndrome (TS) considering ovarian tissue cryopreservation (OTC), their parents and healthcare providers?
Summary answer: Offering a new option to preserve fertility in TS caused unrealistic hope leading to challenges for healthcare providers to fulfil the ideal of informed consent.
What is known already: Due to premature ovarian insufficiency, girls with TS have only a small chance of genetic offspring. OTC might increase these odds. Healthcare providers and scientist are still cautious in offering OTC to girls with TS because of the many uncertainties regarding OTC in this patient group. Hence, OTC is now offered to girls with TS between 2 and 18 years old in a research setting: the TurnerFertility study.
Study design, size, duration: A retrospective qualitative study consisting of a survey and focus groups. Within a year after counselling, families (n=132) received a survey with 30 questions regarding their experiences with the decision-making process and also an invitation for a focus group. The focus groups were conducted between January and October 2019 and lasted 51-84 minutes. The topic lists were based on literature research and survey results. Results were analysed following a thematic analysis approach.
Participants/materials, setting, methods: This is a sub-study of the prospective intervention study within an academical medical centre. Focus groups were composed through purposive sampling. Focus group 1 (FG1) consisted of five gynaecologists involved in counselling, FG2 with seven paediatricians who referred girls for counselling, FG3 with nine parents of girls with TS between 2 and 12 years old and FG4 with three parents of girls with TS between 13 and 17 years old.
Main results and the role of chance: 90% of survey respondents appreciated counselling regarding fertility options and considered it an enrichment of existing healthcare. The individual consultation was rated as most contributing by 66% of the survey respondents, followed by the information meeting (37%) and decision aid (3%). The focus groups revealed that many had not discussed options for future parenthood with a healthcare provider before. Girls with TS and their parents indicated that the option of OTC raised hope for future genetic offspring, and at once made them feel like they had no choice but to take this chance. The small chance of success did not influence the decision for families who opted for OTC. Some parents who had to decide for their young daughter accepted OTC to give their daughter the option to decide herself whether to make use of the cryopreserved tissue later in life. Gynaecologists found it challenging to truly make families grasp a realistic perspective of OTC in TS and the associated mental and physical risks. Gynaecologists and paediatricians struggled with conflicting moral principles of non-maleficence against respect for autonomy: healthcare providers recognized the scientific relevance for the TS population, while it felt inconsistent with the disproportionate burden for some individual patients.
Limitations, reasons for caution: Because there was no validated survey for this topic in TS, we developed a survey based on literature research and experiences of a dedicated TS team. Among the survey responders and focus group participants a greater proportion decided for OTC compared to the overall counselled group (75% vs 60%).
Wider implications of the findings: This study gives insight in the issues to consider when implementing new technologies regarding fertility, in which parents have to decide for their child, where it is expected that anticipated decision regret plays a major role, or where healthcare providers experience conflicting duties as scientist and physician.
Trial registration number: not applicable

O-186 From knowing to helping-seeking: An examination of FertiSTAT and infertility-related treatment behaviours among Chinese female in Hong Kong

Y.K.G. So[1], C.H.Y. Chan[1]

[1]The University of Hong Kong, Department of Social Work and Social Administration, Hong Kong, Hong Kong

Study question: Do fertility health risks predict Hong Kong Chinese women's perceived susceptibility to infertility and engagement in treatment behaviours?
Summary answer: Presence of age-related, medical and lifestyle risk factors did not translate into actual infertility-related treatment behaviours among reproductive-aged women.
What is known already: The Health Belief Model posits that perceived susceptibility to a health condition determines whether one would engage in risk-reducing behaviour. There is yet to be large-scale studies that investigate the rate of fertility health risks among Hong Kong Chinese women. FertiSTAT is an empirically-derived tool that assesses risks to female fertility and provides personalised guidance on risk reduction. Using a Chinese version of the FertiSTAT, this study investigates the fertility risk profile of reproductive-aged women, for whom timely treatment-seeking would be especially pertinent. Additionally, we explore whether fertility health risks translate into awareness of personal susceptibility and actual treatment behaviours.
Study design, size, duration: This is a cross-sectional online survey conducted in Hong Kong between July and August 2020.
Participants/materials, setting, methods: Five-hundred twenty-nine childless women (mean age = 29±6.6) were recruited to the study through community network and social media. Respondents completed the fertility status awareness tool (FertiSTAT) and questions relating to reproductive intention and help-seeking behaviour. Logistic regression analyses were conducted to explore the impact of lifestyle-, medical- and age-related fertility health risks on perceived susceptibility and infertility-related treatment behaviours.
Main results and the role of chance: The fertility health risks most frequently reported by this sample of women were menstrual cycle irregularity (35%) and having stress one cannot cope with (26%). Among women who were trying to conceive (n=67), 40% had been trying for over 12 months, exceeding the critical threshold for risks of infertility. More than one third of women suspected that they had an underlying risk of infertility, however only a small minority had ever taken steps to investigate the issue further by seeking medical support. Binary logistic regression revealed that women who experienced severe menstrual pains (B=-2.70, P<.05) or who had excessive caffeine consumption

(B=-3.27, P<.05) were less likely to suspect that they had an underlying risk of infertility compared to when they had other risk factors. Prolonged time trying to conceive (B=1.52, P<.05) significantly predicted seeking gynaecological exam; whereas none of the fertility health risks had an impact on seeking medical consultation from a TCM practitioner.

Limitations, reasons for caution: Recruitment through social media may bias the sample towards women with greater access to online fertility-related information, posing questions on how generalizable the current findings are to less resourceful individuals. The relatively young age of the sample may also underestimate the rate of fertility health risks in the population.

Wider implications of the findings: Targeted public education initiatives are needed to raise awareness of the impact of not only age-related, but also medical and lifestyle risk factors on reproductive potential. Reproductive-aged women with fertility health risks should be alarmed of suspected infertility and be encouraged to seek proper medical examinations and treatments.

Trial registration number: not applicable

O-187 Smartphone application improves fertility treatment-related literacy: A large-scale surveillance and randomized controlled trial in Japan

R. Yokomizo[1,2,3], A. Nakamura[4], M. Sato[4], R. Nasu[4], M. Hine[4], K.Y. Urayama[5,6], H. Kishi[2], H. Sago[3], A. Okamoto[2], A. Umezawa[1]

[2]The Jikei University School of Medicine, Department of Obstetrics and Gynecology, Tokyo, Japan ;
[3]National Center for Child Health and Development, Center for Maternal-Fetal-Neonatal and Reproductive Medicine, Tokyo, Japan ;
[4]MTI Ltd., Department of Healthcare Business, Tokyo, Japan ;
[5]National Center for Child Health and Development, Department of Social Medicine, Tokyo, Japan ;
[6]St. Luke's International University, Graduate School of Public Health, Tokyo, Japan

Study question: Can providing quality-assured fertility-related information via a smartphone application improve fertility- and treatment-related literacy among smartphone application users?

Summary answer: Provision of quality-assured fertility-related information via a smartphone application contributed to enhancing fertility- and treatment-related literacy among the smartphone application users.

What is known already: For infertility patients, the interpretation of examination results may be overly complicated and complex, and patients may have difficulty in making sense of their own fertility problems. Accessing and learning about fertility-related information using the Internet via smartphone is reasonable; however, the information does not always reflect evidence-based recommendations and low-quality information may lead to adverse effects on users; thus, innovative methods to provide both accessible and high-quality information are desired.

Study design, size, duration: We performed a randomized control-group pretest posttest study and 4,137 smartphone application users were invited to participate between June 18 and 25, 2020. Participants' fertility treatment-related literacy were assessed with a pretest that comprised of 28 questions and participants were allocated with stratified randomization to either intervention or control group. The intervention comprised a one-week smartphone application-based provision of information on fertility- and treatment-related information and the control group received general information about women's healthcare.

Participants/materials, setting, methods: The 3,765 participants (91.0 %) who responded were randomly allocated into either the intervention group (N=1883) or the control group (N=1882). Characteristics of participants appeared similar between the groups reflecting that the randomization was successful in producing a balance in baseline characteristics. Effectiveness of intervention was assessed using pretest-posttest analysis. Ethical approval was obtained from the Institutional Review Board of the National Center for Child Health and Development of Japan (approval number: 2019-184).

Main results and the role of chance: The posttest was completed by 659 participants (17.5%), and finally 207 participants in the intervention group and 222 participants in the control group were available for pretest-posttest analysis. Demographic characteristics of these participants appeared similar between the groups. In comparing the demographic characteristics of participants who did and did not complete the posttest, there were significant differences between the two groups in age, overall test score, proportion living with a partner, and action for pregnancy. For the posttest, the overall mean test scores were significantly higher in the intervention group compared to the control group (P = 0.0082). Interestingly, we also observed that posttest scores were significantly improved compared to pretest scores in both the intervention group and control group (P<0.001). When examining by specific test question, the proportion answering correctly appeared to generally increase at posttest compared to pretest for intervention (P<0.001) and control (P<0.001) groups. There was over 10% improvement in 7 questions, and particularly, over 20% improvement for a question about clinical significance of anti-Müllerian hormone. Furthermore, directly comparing the difference in posttest versus pretest scores between the two groups showed, on average, greater improvements in the intervention group than the control group (P<0.001).

Limitations, reasons for caution: As the intervention was educational material, it was not possible to blind participants to intervention group assignment. We were not able to monitor the participants when completing the tests; thus, whether they accessed other resources could not be addressed.

Wider implications of the findings: Providing information through a smartphone application can be considered acceptable since retrieving information through a smartphone application is in line with the current modern day lifestyle. A smartphone application may offer alternatives such as chatbots and movie-based learning, and they have the potential to increase the effectiveness.

O-188 Participation in a video-based fertility awareness program advances the desire to have children sooner

J. Pedro[1,2], J. Fernandes[2,3], A. Barros[1,4], L. Schmidt[5], M.E. Costa[2,3], M.V. Martins[2,3]

[1]Centre for Reproductive Genetics A. Barros- Porto- Portugal, Porto, Portugal ;
[2]Centre for Psychology at University of Porto- University of Porto- Porto- Portugal, Porto, Portugal ;
[3]University of Porto- Porto- Portugal., Faculty of Psychology and Educational Sciences- Porto- Portugal., Porto, Portugal ;
[4]Faculty of Medicine- University of Porto. Institute of Health Research and Innovation I3S- Porto- Portugal., Department of Genetics-, porto, Portugal ;
[5]University of Copenhagen, Department of Public Health- University of Copenhagen-, Copenhagen, Denmark

Study question: Participating in a fertility awareness program accelerates the intention to have children 6 to 12 months after video- fertility awareness?

Summary answer: In combination with positive childbearing motivation, those in the video condition anticipated their intentions to have children at 6-12 months follow-up

What is known already: Fertility awareness education and initiatives have been focused on increasing fertility awareness and knowledge. However, the role of fertility awareness on reproductive decisions is less explored in literature. There are few studies showing that participating in fertility awareness education is related to higher intentions to have children or decreased time until trying to conceive regarding beforehand planned. Since intentions seem to be a good predictor of behaviour, we were interested in exploring the variables which might predict higher intentions to have children after participating in a fertility awareness education study based on a video intervention

Study design, size, duration: This study is part of a randomised controlled trial initiated in October 2016. Participants were randomly allocated into the intervention (IG) and control group (CG) at baseline (TO). The follow-up was evaluated 6 to 12 months later. IG participants were exposed to a 5-min video delivering information on age-related fertility decline, infertility risk factors, and pregnancy chances after having filled-in the T0 questionnaire: Participants in CG received no stimulus.

Participants/materials, setting, methods: Three hundred sixty-five individuals (65% women) were recruited through social media, gynaecology clinics, and religious pre-marital courses. From those, 128 responded to follow-up

(between 6 and 12 months). Childbearing Motivation Scale (positive and negative) and a question about childbearing timing intentions were used. Regression analysis was conducted to explore the role of video intervention and childbearing motivation on childbearing timing intention.

Main results and the role of chance: Participants were, on average, 29.5 years old (SD=5.13). From baseline to 6-12 months later, participants significantly anticipated their desire to have children ($p<.005$). Correlations showed that childbearing timing intention was positively and significantly associated with the following subscales of the positive motivations: personal fulfilment, continuity, and couple relationship; negative motivations were not associated with the childbearing timing intention. The regression analysis revealed that only the childbearing motivation regarding couple relationship (having a child would strengthening partnership ties, fulfilling partner's project, growing as a couple, fulfilling a shared project) and the visualization of the educational video significantly contributed to predicting at follow-up the increased desire to have children sooner at follow-up.

Limitations, reasons for caution: Other factors, not considered, might contribute to the prediction of childbearing motivation timing. Although we had randomly allocated people to CG and IG, the high attrition rate may limit the generalization of our results.

Wider implications of the findings: This study seems to indicate that watching an educational video about fertility awareness might contribute to a significant change in childbearing timing. In addition, the importance of the couple relationship is highlighted. These findings reinforce the importance to assist people with informed reproductive decisions in social and healthcare settings.

O-189 Male fertility restoration by direct transplantation of human infant testicular cells into infertile recipient mouse testis

D. Wang[1], S. Hildorf[2], L. Dong[1], S.E. Pors[1], L.S. Mamsen[1], E.R. Hoffmann[3], D. Cortes[4], J. Thorup[2], C.Y. Andersen[1]

[1]Copenhagen University Hospital Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark ;
[2]Copenhagen University Hospital Rigshospitalet, Department of Pediatric Surgery, Copenhagen, Denmark ;
[3]Institute of Molecular and Cellular Medicine, Center for Chromosome Stability, Copenhagen, Denmark ;
[4]Copenhagen University Hospital Hvidovre, Department of Pediatrics, Copenhagen, Denmark

Study question: Is colonization of human gonocytes and spermatogonial stem cells (SSCs) directly transplanted to seminiferous tubules of busulfan sterilised mice testis during an 8-week period feasible?

Summary answer: Gonocytes and SSCs from infant boys can settle on the basal membrane and form germline stem cell colonies in the seminiferous tubules of recipient mice.

What is known already: The neonatal or immature animal provides higher populations of gonocytes and/or SSCs than adults, and the number of transplanted donor SSCs directly affects the colonization rate of the recipient testes. Along with SSC transplantation restoring the recipient's spermatogenesis, donor gonocyte was also reported to be capable of establishing spermatogenesis in rodents.

Study design, size, duration: Transplantation of human testicular cells including gonocytes and SSCs into seminiferous tubules of infertile recipient mice. We included 10 infant testis biopsies from which single-cell suspension was transplanted individually into the seminiferous tubules of 10 immunodeficient mice. The immunodeficient mouse testes were injected with busulfan to deplete germ cells. Four weeks later, we did the xenotransplantation. Then after eight weeks, we collected all mouse testes to do further analysis.

Participants/materials, setting, methods: Testis biopsies were obtained from cryptorchid boys undergoing orchidopexy. After enzymatic digestion of the testis biopsies, dissociated single-cell suspensions were pre-labeled with a green fluorescent dye. Then the single-cell suspensions were transplanted into seminiferous tubules of the infertile recipient mice. Eight weeks later, the presence of gonocytes and SSCs was determined by immunohistochemistry and whole-mount immunofluorescence.

Main results and the role of chance: Without *in vitro* propagation, naturally enriched human germline stem cells settled on the basal membrane of seminiferous tubules and survived in the mouse testes at least for two months demonstrating that human gonocytes and SSCs were capable of colonizing the recipient mouse seminiferous tubules.

Limitations, reasons for caution: The study samples were from infant boys with undescended testes that were more likely to contain gonocytes. It was not possible to determine which germ-cell type at transplantation resulted in the detected gonocytes and SSC colonies after xenotransplantation. Transplantation of gonocytes may include the potential risk of stem cell-related malignancy.

Wider implications of the findings: Without *in vitro* propagation, male germline stem cell-based transplantation could provide a relatively safe therapeutic treatment for prepubertal boys with cryptorchidism and boys diagnosed with cancer. This method could also facilitate clinical translation.

Trial registration number: not applicable

O-190 Comparison between effects of exposure to platinum-based chemotherapeutics (cisplatin and carboplatin) on Sertoli cell number and functions in immature human testicular tissues

G. Matilionyte[1], M.D. Tharmalingam[1], I. Sanou[1], F. Lopes[1], R.A. Anderson[1], R.T. Mitchell[1]

[1]The University of Edinburgh, Centre for Reproductive Health, Edinburgh, United Kingdom

Study question: Does exposure to either cisplatin or carboplatin have a damaging effect on the Sertoli cell population in the immature human testicular tissues?

Summary answer: Exposure to cisplatin or carboplatin did not appear to have a major effect on Sertoli cell number or function in the immature human testicular tissues

What is known already: Long-term survival rates for children with cancer are more than 80%. However, childhood cancer treatment may result in subsequent infertility. Cisplatin is one of the most commonly used drugs for childhood cancers. Carboplatin, a second generation platinum drug, is administered at 10-times the dose of cisplatin and is believed to be less gonadotoxic. In our recent publication we have shown that exposure to both cisplatin and carboplatin acutely reduce the germ cell number in immature human testicular tissues. However, it is not known how cisplatin and carboplatin affect Sertoli cell number and function.

Study design, size, duration: In-vitro culture of human fetal and pre-pubertal testicular tissues was utilised. Tissue pieces were cultured for 1-3 days prior to exposure to clinically-relevant doses of chemotherapeutics or vehicle control for 24hrs in two sets of experiments: 1) 0.5 or 1 µg/ml cisplatin and culture ended at 24 and 96hrs post-exposure (fetal only); 2) 0.5 µg/ml cisplatin or 5 µg/ml carboplatin until 72 (both fetal and pre-pubertal) and 240hrs post-exposure (fetal only).

Participants/materials, setting, methods: Testicular tissue fragments from second trimester human fetal (14-22 gestational weeks; n=3-6) or pre-pubertal patients (1-8years old; n=5) were cultured in a 'hanging drop' system. Quantification of Sertoli cell number (cells per cord/tubular area (mm^2)) was performed on sections stained for expression of SOX9. Culture medium was collected to measure levels (ng/ml) of Anti-Mullerian hormone (AMH) and Inhibin B using ELISA. Statistical analysis was performed using two-way ANOVA to account for inter-individual variation between fetuses/patients.

Main results and the role of chance: Quantification of positively stained Sertoli cells showed that exposure to both doses of cisplatin had no effect on Sertoli cell number at 24 and 96hrs post-exposure. No changes in AMH and inhibin B levels were observed at these time-points. Comparison between cisplatin- or carboplatin-exposed human fetal testicular tissues showed no

difference in Sertoli cell numbers at either 72hrs or 240hrs post-exposure. No difference in Sertoli cell number was observed in pre-pubertal testicular tissues exposed to either cisplatin or carboplatin at 72hrs post-exposure.
Limitations, reasons for caution: Human fetal and pre-pubertal testis tissue is of limited availability, thus, sample sizes used in this study were relatively low. 'Hanging drop' culture might not recapitulate all in-vivo aspects of immature testis microenvironment.
Wider implications of the findings: Exposure to cisplatin or carboplatin did not affect Sertoli cell number in the immature human testicular tissues. Taken together with our recent publication, this suggests that these two platinum-based chemotherapeutic agents cause direct damage to germ cells. Functionality of Sertoli cells in chemotherapy-exposed tissues need to be further investigated.
Trial registration number: not applicable

O-191 Assessing the use of tumour-specific DARPin-toxin fusion proteins for ex vivo purging of cancer metastases from human ovarian cortex tissue fragments before autotransplantation

L. Eijkenboom[1], V. Palacio-Castañeda[2], F.A. Groenman[3], D.D.M. Braat[1], C.C.M. Beerendonk[1], R. Brock[2], W.P.R. Verdurmen[2], R. Peek[1]

[1]Radboudumc, Obstetrics and Gynaecology, Nijmegen, The Netherlands ;
[2]Radboud Institute for Molecular Life Sciences, Biochemistry, Nijmegen, The Netherlands ;
[3]Amsterdam university medical centre, Obstetrics and Gynaecology, Amsterdam, The Netherlands

Study question: Is it possible to eradicate cancer cells from ovarian cortex by using tumour-specific designed ankyrin repeat protein (DARPin)-toxin fusion proteins, without compromising the ovarian tissue?
Summary answer: Purging ovarian cortex *ex vivo* from experimentally induced breast cancer tumour foci is possible by tumour-targeted DARPin-toxin fusion proteins trough inhibition of protein synthesis.
What is known already: Ovarian tissue cryopreservation and autotransplantation is a successful technique for fertility restoration in cancer patients. The procedure is not without risk since malignant cells may still be present in the graft. Procedures to detect cancer cells render the tissue fragment useless for autotransplantation. Strategies to circumvent this problem such as *in vitro* maturation of follicles or the construction of artificial ovaries are pursued but are still experimental. Alternatively, we have shown *ex vivo* purging of ovarian cortex is possible by elimination of rhabdomyosarcoma after treatment with verteporfin. This allows treatment of cortex fragments before autotransplantation without compromising ovarian tissue integrity.
Study design, size, duration: Human ovarian cortex fragments harbouring breast cancer tumour foci were exposed for 24 h to DARPins fused to the translocation and catalytic domain of *Pseudomonas aeruginosa* exotoxin A (DARPin-toxin fusion proteins) targeting EpCAM or HER2. After treatment with the DARPin-toxin fusion proteins the tissue was cultured for an additional 6 days to allow any remaining tumour cells to form foci. In addition, the functional integrity of the ovarian tissue was analysed after purging.
Participants/materials, setting, methods: Breast cancer cell lines expressing different levels of EpCAM and HER2 were introduced in human ovarian tissue to form tumour foci. After purging with DARPin-toxin fusion proteins, the presence of any remaining cancer cells in the tissue was analysed with (immuno)histochemistry and RT-qPCR. Possible detrimental effects on the viability of ovarian cortex and follicles were determined by (immuno)histology, a follicular viability assay and an assay to determine the *in vitro* growth capacity of small follicles.
Main results and the role of chance: Ovarian cortex harbouring EpCAM-positive breast cancer cells showed a significant decrease in the number of tumour foci after treatment with the EpCAM-targeted DARPin-toxin fusion proteins. Although exposure to the EpCAM-specific DARPin had no effect on morphology or viability of follicles, a decrease in oocyte viability after *in vitro* growth experiments was observed, presumably due to low level expression of EpCAM on oocytes. In contrast to the EpCAM-specific DARPin-toxin fusion protein, the DARPin-toxin fusion protein targeting HER2 had no detrimental effects on morphology, viability or *in vitro* growth of follicles while foci of HER2-positive breast cancer cells were severely affected as indicated by the presence of apoptotic bodies, tumour cell remnants and the absence of viable tumour cells. The histological results after purging with the HER2-specific DARPin-toxin fusions proteins were confirmed by RT-qPCR, showing a decrease to basal levels of HER2 mRNA in the ovarian cortex tissue.
Limitations, reasons for caution: The effect of DARPin-toxin fusion proteins depends heavily on the expression of their target on the cancer cell. The target protein should not be expressed by ovarian cortex as this may lead to tissue damage. The functional integrity of ovarian cortex after the treatment requires further investigation *in vivo*.
Wider implications of the findings: Purging metastases from ovarian cortex without harming ovarian tissue is possible by targeting tumour specific surface expressed antigens with DARPin-toxin fusion proteins. Purging ovarian cortex tissue with DARPin-toxin fusion proteins provides a feasible therapeutic strategy to prevent reintroduction of cancer by autotransplantation in case of malignancies expressing tumour-specific surface markers.
Trial registration number: not applicable

O-192 Modulating hypoxia and oxidative stress in human ovarian tissue xenografts using adipose tissue-derived stem cells

L. Cacciottola[1], T.Y.T. Nguyen[1], C.A. Amorim[1], J. Donnez[2], M.M. Dolmans[3]

[1]Institut de Recherche Expérimentale et Clinique- Université Catholique de Louvain, Gynecology Research Unit, Brussels, Belgium ;
[2]Society for Research into Infertility, society for Research into Infertility, Brussels, Belgium ;
[3]Institut de Recherche Expérimentale et Clinique- Université Catholique de Louvain, Gynecology Research Unit- Department of Gynecology- Cliniques Universitaires Saint-Luc, Brussels, Belgium

Study question: To investigate whether adipose tissue-derived stem cells (ASCs) modulate hypoxia and oxidative stress in human ovarian tissue transplants to reduce early follicle loss.
Summary answer: ASCs protect the follicle pool by mitigating the hypoxia-related response through HIF1α signaling in human xenografts and enhancing revascularization by ensuring faster tissue reperfusion.
What is known already: ASCs are known for their angiogenic potential and capacity to boost angiogenesis by secreting growth factors and differentiating into vessels in numerous models of wound healing in regenerative medicine. In a 2-step ovarian tissue xenotransplantation involving grafting inside a fibrin scaffold two weeks prior to transplantation, ASCs reduced follicle loss after short- and long-term grafting, as well as abnormal follicle activation, by increasing reoxygenation and revascularization in human xenografts.
Study design, size, duration: Prospective experimental study. Cryopreserved ovarian cortex from five adult women was transplanted to 30 nude mice, with or without ASCs (ASC group; OT group). Ovarian grafts were retrieved on days 3 (n=5), 10 (n=5) and 21 (n=5). One piece of ovarian tissue per patient was fixed for analysis after thawing to serve as non-grafted controls.
Participants/materials, setting, methods: The 10 animals grafted for 21 days underwent in vivo microdialysis evaluation to investigate direct reactive oxygen species (ROS) kinetics. Analyses of ovarian grafts at all time points and non-grafted controls included immunolabeling for double CD34 (revascularization by host and graft components), immunofluorescence for HIF1 (hypoxia-related response), Nrf2 (oxidative stress-related response) and 8OHdG (oxidative stress-related DNA damage), and gene expression (RT-qPCR) for VEGF-A (neoangiogenesis), SOD2 (antioxidant activity) and Nrf1 (mitochondrial biogenesis).
Main results and the role of chance: ROS peaked sooner in the ASC group (day 2, $p<0.0001$) than the OT group (day 10, $p=0.01$) after grafting, indicating earlier tissue reperfusion. Total vascularization was stable in the ASC group at all time points, but lower in the OT group 3 days after grafting ($p=0.01$) due to a drop in both host and graft vascular components. HIF1 expression, detected mainly in follicles, was significantly lower in primordial follicles in the ASC group than the OT group on days 3 ($p=0.008$) and 10 ($p=0.01$). VEGF gene expression rose significantly (around 40x) in both groups on day 3 and persisted significantly longer in the ASC group (10 days) than the OT group (3 days) ($p=0.04$), emphasizing the role of ASCs as enhancers of proangiogenic factors. There was no upturn in the oxidative stress-related response (Nrf2 pathway) nor DNA damage (8OHdG) to follicles in any of the grafted groups over time, while a modest increase in both markers was observed only in the stroma after 21 days. Neither was there any major increase in SOD2 and Nrf1 gene

expression, suggesting no significant activation of the Nrf2 pathway for cytoprotection from oxidative stress.

Limitations, reasons for caution: Although Nrf2 signaling activation was detected in human granulosa cell cultures in increasing ROS concentrations, our findings did not confirm its role in tissue damage modulation after ovarian tissue transplantation. Further studies may evidence the involvement of other pathways that modulate oxidative stress after transplantation.

Wider implications of the findings: The role of ASCs in protecting the follicle pool appears to be related to a decrease in hypoxia and faster ovarian graft revascularization and reperfusion, sustained by an increase in VEGF for a longer period after grafting. There was no evidence of oxidative stress-related damage, irrespective of the transplantation strategy.

O-065 The naughty cells of the endometriumxx

C. Gargett[1]

[1]*Hudson Institute of Medical Research, The Ritchie Centre, Clayton, Australia*

Abstract text

Stem/progenitor cells are the naughty cells of the endometrium! The term "naughty" has a number of connotations, one being immaturity which I will apply to the rare stem/progenitor cell populations hiding in the endometrium, where they have eluded scientists for so long. Despite their rarity, these immature cells have the capability of growing up and differentiating into the functional cells of the endometrium, producing their progenies in the process. The self-willed human endometrial epithelial progenitor cells (eEPC) and mesenchymal stem cells (eMSC) first revealed themselves through their clonogenic activity, shunning their mates and setting up clones of cells on their own. Their risqué production of identical copies of themselves ensures their continuity, much to the chagrin of their mature counterparts. They are sneaky and can produce large numbers of mature progeny, but rarely proliferate themselves preferring to take life easy and do little. They also spit out viability dyes (Hoechst) at a greater rate than mature endometrial cells to become Side Population (SP) cells.

A number of approaches have been used to tame these naughty endometrial stem/progenitors. In order to determine the identity and location of these elusive cells, specific markers had to be found. The immature endometrial epithelial progenitor cells play tricks with the specific markers they express. For example, clonogenic eEPC are N-cadherin+, an epithelial mesenchymal transition marker, found by unbiassed gene profiling, revealed their hiding place in the bases of glands deep in the endometrial basalis. Similarly, SSEA-1+ basalis epithelial progenitors pirated their marker from mature neutrophils and differentiating human pluripotent stem cells. In mice the stem/progenitor cells like to play chase, with lineage tracing of individual genetically marked cells revealing their location in the intersection zone of the glands and luminal epithelium, and also in the gland bases (*Axin2*+ and *Lgr5*+).

The identity of eMSCs has also been determined by discovery of specific markers, but even here the eMSC play games in human endometrium where sometimes they are pericytes (CD140b and CD146 double positive cells), sometimes perivascular cells (SUSD2+) and sometimes CD34+ cells in the adventitia of blood vessels. They are also adventitial perivascular cells in ovine endometrium, but this time they are CD271+. Mature endometrial stromal cell progeny are also naughty, often pretending to be eMSC, particularly when shed into menstrual fluid, confusing many of their status. Adding further to their misbehaviour, they express the same official MSC surface markers. To get even immature endometrial MSC strike back, claiming immunomodulatory properties in attempt to upstage their mature stromal progeny, also endowed with these properties.

Finally, other endometrial cells such as macrophages may also be naughty as their mischievousness in evading detection can trick us to consider them as stem cells from the bone marrow, masquerading as endometrial epithelial or stromal cells.

Naughty implies behaving badly and I will show data suggesting that stem/progenitor cells may escape the endometrium to cause a nasty disease, endometriosis. They may also become wayward and unruly, invading the myometrium to form adenomyosis. Some naughty epithelial progenitors defiantly pick up mutations to become cancer stem cells and initiate endometrial cancer. They may also malfunction because they do not obey estrogen signalling instructions, failing to proliferate and causing thin unresponsive endometrium. In their naughtiness, they may run away or get totally lost, thereby resulting in Asherman's syndrome. Therefore, for numerous reasons, stem/progenitor cells are the naughty cells of the endometrium.

O-066 The naughty genes and 3D structure of the endometrium.

T. Enomoto[1], **M. Yamaguchi**[1], **K. Suda**[1], **K. Yoshihara**[1]

[1]*Niigata University Graduate School of Medical and Dental Sciences, Department of Obstetrics and Gynecology, Niigata, Japan*

Abstract text

The naughty genes and 3D structure of the endometrium

Takayuki Enomoto, Manako Ymaguchi, Kazuaki Suda, Kosuke Yoshihara

Department of Obstetrics and Gynecology, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan.

The human endometrium is a highly regenerative tissue and involved in menstruation and implantation of the fertilized egg, giving it a central role in women's reproductive health. However, the regenerative nature of the endometrial glands can lead to the development and progression of "endometrium-related diseases" such as adenomyosis, endometriosis, endometriosis-associated ovarian cancer, endometrial hyperplasia, and endometrial cancer. To clarify the pathogenesis of endometrium-related diseases and develop effective preventative measures and therapeutic strategies, comprehensive understanding of molecular biological linkage between endometrium and endometrium-related diseases was crucially important.

To this end, we focused on genomic alterations of endometrial epithelium which is considered the origin of endometriosis, and sequenced 107 ovarian endometriotic and 82 normal uterine endometrial epithelium samples isolated by laser-microdissection. Intriguingly, several genes recurrently mutated in endometriosis-associated ovarian cancers were frequently mutated in both endometriotic epithelium and normal uterine endometrial glands. In particular, *PIK3CA* mutation was detected in 41% of endometrial epithelium subjects but none of them had shared *PIK3CA* mutations across multiple regions collected from the same individuals. Mutation allele frequencies of somatic mutations in uterine endometrial epithelium samples were also significantly lower than those in ovarian endometriotic epithelium samples, suggesting the heterogeneous genomic compositions in uterine endometrium. To interpret this genomic heterogeneity in uterine endometrium, we focused on endometrial gland, the minimum functional unit of uterine endometrium, and conducted 109 single endometrial glands sequencing. As a result, we unveiled that each gland carried distinct somatic mutations in cancer-associated genes, such as *PIK3CA, KRAS*, and *PTEN,* with high mutant allele frequencies, suggesting the monoclonality of each gland. The presence of cancer-associated gene mutations in histologically normal endometrial glands provides important clues regarding the pathogenesis of endometrium-related diseases.

However, our previous study could not determine the spread of endometrial gland harboring cancer-associated gene mutation because there is a limitation

to two-dimensional assessment of the whole shapes of endometrial gland due to its complicatedly winding morphology. Therefore, we tackled with three-dimensional (3D) assessment of human endometrium. To construct a large picture of endometrial gland structure, we performed tissue-clearing-based 3D imaging of full-thickness human uterine endometrial tissue with the use of light-sheet fluorescence microscopy. Our 3D immunohistochemistry discovered some new and unique 3D morphologies of endometrial glands, including plexus network of glands or occluded glands. Notably, computational analysis of 3D layer clarified that the plexus structure of the glands was mainly located in the stratum basalis and expanded along muscular layer horizontally, similar to the so-called "rhizome of grass". Although previous studies have shown the 3D structure of murine endometrial glands, the bottom of these glands forms a crypt but not a rhizome. This can potentially be explained by the existence of menstruation, which is the crucial difference between the human and murine endometrium. The rhizome structure of endometrial gland in the human endometrium will have a functional advantage over the crypt in terms of the conservation of progenitor/stem cells and regeneration. In addition, some endometrial glands shared the plexus and rose toward the luminal epithelium, suggesting that these glands were the same origin. The rhizome of the endometrium may be a crucial element for understanding the expansion of endometrial glands harboring cancer-associated gene mutations.

Integrated analysis of the naughty gene alterations and the 3D structure in human endometrium will lead to a better understanding of the human endometrium in various fields, including histology, pathology, pathophysiology, reproduction, and oncology.

Abstract text

Training of clinicians: How to do it and how to best evaluate it?

Anis Feki, Tatjana Motrenko, Roy Farquharson

Many countries within Europe and EU do not have a specific national agency that provides the necessary structure or governance for appropriate training in Reproductive Medicine (RM). Therefore, The European Society of Human Reproduction and Embryology (ESHRE) has been the responsible agency for accreditation of RM training alongside its sister organization, the European Board and College of Obstetrics and Gynaecology (EBCOG). Both of these organizations are ultimately responsible to and approved by the Union of European Medical Specialties (UEMS), which represents the European Union (EU) governing body for medical practitioners' education.

The Reproductive Medicine subspecialist is a specialist in basic obstetrics and gynecology who has undergone theoretical and practical training in the medical and surgical management of infertility, including assisted reproductive techniques (ART). In general, the comprehensive management of these problems includes both diagnostic and therapeutic procedures allied to continuous audit of outcome.

The global aim is to improve the care of patients with disorders of reproductive function. To reach this target, both ESHRE and EBCOG put in place a program that starts with accreditation of training centers in obstetrics and gynecology and more specifically, specialist training centers in reproductive medicine. Fellows must have a structured program of a minimum of 2 years after completing their basic obstetrics and gynecology syllabus and/or obtaining EFOG European Fellow of Obstetrics and Gynecology) diploma for non-European basic training. When a training fellow in RM has completed their logbook, the fellow will finish by assessing an individual's knowledge and skills by passing an exit-training exam called the EFRM (ESHRE-EBCOG Fellow in Reproductive Medicine) diploma.

The success of and the need for such certification has led ESHRE to structure the training also for reproductive surgeons, embryologists, as well as nurses and midwives. In addition, several countries within the EU already have a national compulsory specialist accreditation system for RM training.

Recent proposals by the EU Commission to build European reference networks across all specialties, including RM may require the recognition of ESHRE/EBCOG–accreditation as an appropriate entry point for consideration of diagnostic and other interventions. Encouraging subspecialists and centers to apply for training accreditation may well prove to be an increasingly attractive option as educational needs across Europe become integrated and formalized through UEMS. ESHRE holds the view that accredited centers/subspecialists for training are beacons of excellence that often go hand in hand with high-quality research.

SESSION 68: MANAGING FERTILITY PATIENTS EXPECTATIONS IN A PANDEMIC CONTEXT

01 July 2021 Stream 3 08:30 - 09:30

O-193 A devastating double disruption: IVF patients' feelings and experiences regarding treatment delays due to Covid-19

Z. Gurtin[1]

[1]*University College London, Institute for Women's Health, London, United Kingdom*

Study question: How did patients experience the delays and disruptions to their fertility treatment that occurred as a result of the Covid-19 pandemic and resulting clinic closures?

Summary answer: Patients reported feeling 'powerless/helpless' (78.3%), 'frustrated' (59.3%), and 'anxious' (54.7%), and detailed why clinic closures were experienced as a devastating double disruption.

What is known already: Fertility patients found clinic closures and the disruption to their treatments stressful due to uncertainty and perceived threats to their goal of parenthood, and experienced an increase in anxiety and depression. However, paper goes far beyond the mostly quantitative data that has been published by analysing patients' detailed qualitative accounts of their feelings and experiences in their own words.

Study design, size, duration: A mixed-methods, anonymous, online questionnaire in English was live for 6 weeks between 19 May to 30 June 2020. All patients aged over 18, whose fertility treatment or investigations had been impacted by the coronavirus pandemic were eligible to take part. The questionnaire was widely distributed using mainstream media, social media, and the mailing lists of relevant organisations. In total 709 people began and 501 completed the questionnaire in the time available (70.7% completion rate).

Participants/materials, setting, methods: The questionnaire included ten parts with a mixture of quantitative and qualitative items. The responses of 457 female fertility patients who were resident in the UK were analysed. The average age was 34.6 (SD=4.9). The majority were in a heterosexual relationship (91.0%), white (90.6%), and had no children (87.1%). Descriptive and inferential statistics were used on quantitative data, and thematic analysis used for qualitative data.

Main results and the role of chance: Using insights from the sociology of reproduction, including how patients face and resolve "disruption" (Becker 1997), this paper presents qualitative accounts from fertility patients regarding their feelings, reactions and experiences regarding the Covid-19 pandemic and the resulting clinic closures. Respondents highlighted the intensity of their feelings,

noting that their lives seemed "paused", "stopped" or "thrown into a state of limbo", leaving them unable to move forward with crucial life plans. Moreover, many explained that clinics closures were not experienced simply as a disruption, but rather as an additional hurdle in what had already been a series of difficult disruptions to normalcy, including, in many cases, an unforeseen inability to conceive naturally, long waiting lists for fertility treatment, and treatment delays due to economic or other factors. The major themes to emerge from respondents' accounts were: lack of control; lack of support; and feelings of difference, isolation and being left out. In many ways, the Covid-19 related disruptions exacerbated and added to fertility patients' existing anxieties and frustrations. One respondent wrote, "IVF is one of the most stressful things you can go through. To then be in the middle of that during a global pandemic it makes it even more stressful."

Limitations, reasons for caution: Participants were self-selecting and reporting their feelings and reactions at one particular point in time. Only responses from 457 UK-residents were included in the analyses.

Wider implications of the findings: These findings show that patients attending fertility clinics need additional support and care during times of uncertainty and disruption, and that many regard their treatment as an essential medical service. We encourage governments and regulators to keep fertility clinics open whenever it is possible to safely do so.

Trial registration number: Not applicable

O-194 Insights from smartphone app based emotional tracking data on the impact of the Covid-19 pandemic on IVF patients.

Y. Cheong[1], I. Robertson[1], J. Boivin[2]

[1]University of Southampton, Human Development and Health, Southampton, United Kingdom ;
[2]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: Is the emotional experience of patients during IVF different since the start of the global Covid-19 pandemic?

Summary answer: Tracking data since re-opening demonstrated patients lower positive challenge emotions but no significant change in harm, threat, or stress.

What is known already: Covid-19 caused widespread shutdown of fertility centres, including in the UK, when the HFEA mandated closure from March until May 2020. Research shows clinic closure and an uncertain future were a significant psychological burden for patients anticipating treatment. However, emotional experiences before, during and after closure have not yet been compared, which is the aim of the study.

Study design, size, duration: Retrospective single-centre analysis of anonymised emotional tracking data entered by 707 patients using the MediEmo smartphone app alongside their IVF cycle, from May 2017-September 2020.

MediEmo includes medication timeline/ notifications, coping tools and emotional tracking. Patients rate 2 questions daily in each emotion domain (challenge, threat, harm, e.g. 'I am feeling tense') on a 0-3 scale and indicate coping ability ('I am unable to cope with the stress I am experiencing') on a binary scale.

Participants/materials, setting, methods: Egg donor, recipient and fertility preservation cycles were excluded. First, mood scores were analysed by 2020 month of entry to capture the emotional impact of closure. Second, "Pre-Covid" (May 2017-Feb 2020) and "After Re-opening" (May 2020–Sept 2020) emotional experiences were compared, using student t-tests. Mean and standard deviation of scores in each mood domain entered on each cycle day were calculated, centred on luteal day 0/ egg collection, from cycle day -14 to +14.

Main results and the role of chance: Graphical presentation of emotional data by month clearly demonstrates the significant increase in threat, harm and stress emotions and reduced positive emotions experienced immediately prior to and during mandatory clinic closure. Of patients entering emotional data during closure in March/April 2020, 40% (14/35) stated they felt unable to cope with the stress they were currently experiencing.

From May 2020 after the clinic reopened, analysis of in-cycle emotional tracking data showed there are no significant differences in harm or threat emotion levels or numbers reporting intolerable stress during IVF, compared to cycles pre-pandemic (May17-Feb 2020). Patients undertaking IVF cycles since closure are logging lower challenge scores (confident, encouraged, positive, hopeful), demonstrating less optimism, particularly in the 'two-week wait' phase of the cycle. The mean (s.d) of challenge scores pre-Covid was 1.50 (1.07), compared to 1.38 (1.04) after re-opening, p=0.00085.

The women who had treatment cycles post re-opening from May 2020 onwards were older (33.4(5.2) vs 32.6(4.4)), which may reflect clinical treatment prioritisation decisions. There was no significant differences in number of eggs collected (mean(s.d) Pre-Covid 12.08 (8.0) vs After re-opening 11.83 (9.4), p=0.84) or live birth/ ongoing pregnancy rates for undelivered pregnancies (p=0.69) between the groups.

Limitations, reasons for caution: Emotional data was only available for those who chose to use MediEmo, entered emotional tracking data and who gave consent for use of their clinical data in research. As such, this analysis may not fully reflect all patients' experiences. Most of the available data were entered prior to the pandemic.

Wider implications of the findings: For Covid-19 safety reasons, patients currently have less in-person staff contact when undertaking IVF. The findings reassuringly suggest emotional wellbeing was not markedly different in most domains. However, daily ratings did show the emotional fall-out of clinic closures which for most threatened attainability of parenthood goals (e.g., less hope).

Trial registration number: Not applicable

O-195 The impact of the COVID-19 outbreak on psychological distress due to the cancellation of ART. A systematic review and meta-analysis

Z. Donarelli[1], G. Lo Coco[2], S. Gullo[2], V. Oieni[1], A. Volpes[3], A. Allegra[3]

[1]ANDROS Day Surgery Clinic, Psychology Unit, Palermo, Italy ;
[2]University of Palermo, Department of Psychology. Educational Science and Human Movement, Palermo, Italy ;
[3]ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy

Study question: Is there evidence that infertile patients have been more likely to experience distress during the COVID-19 outbreak with the consequent interruption of treatment plans?

Summary answer: High levels of psychological distress among infertile patients have been found during the COVID-19 pandemic, greater than that reported in the general population.

What is known already: Preliminary research on the negative consequences of the COVID-19 outbreak on mental health evidenced heightened levels of anxiety, depression and post-traumatic stress in some clinical populations as well as in community samples. However, little is known about the impact of COVID-19 on psychological distress of infertile patients who have been forced to suspend infertility treatment and postpone parenthood goals during the pandemic. The aim of this meta-analytic review is to summarize extant literature on the prevalence of psychological distress symptoms in infertile patients during the COVID-19 pandemic.

Study design, size, duration: A systematic review and meta-analysis were conducted following the PRISMA guidelines on PsycInfo, PubMed, Embase, Web of Science, MedRxiv from March 2020 to mid-December 2020. Study inclusion criteria were specified according to the PICOS guideline. All naturalistic or RCT studies published in 2020 that examined infertility as the primary diagnosis and had a quantitative measurement of distress, were eligible. The primary outcomes were symptoms of psychological distress and secondary outcomes were indicators of psychological health.

Participants/materials, setting, methods: The database search identified 144 papers. Two reviewers independently screened potential studies by title and abstracts based on the inclusion criteria. The full texts were then screened for eligibility. The Newcastle-Ottawa Scale was used to judge the methodological quality of the studies. In order to estimate the pooled prevalence of distress, Odds Ratios with 95% Confidence Interval were calculated as the effect size by using a random-effects model. Heterogeneity was tested using I^2 statistics.

Main results and the role of chance: Fourteen studies met the inclusion criteria and were summarized for the systematic review (N=6473). Only six studies did not include males although, in the surveys, females made up 92% of the total sample. Ten studies adopted a cross-sectional study design. 100% gathered data through an online survey. Nine studies showed a high risk of bias, and five had a moderate risk. Review results showed that 56,4% of patients wished to resume treatment; participants were mostly worried about the delay in treatment because of their age (>35 years) or diminished ovarian reserve, or money

constraints and low education level. Only five studies examined the role of protective factors such as social support, coping, optimism trait and intolerance of uncertainty. Nine studies were included for meta-analysis. The prevalence of psychological distress was 0.58 (95% CI 0.32÷0.84). The pooled point estimates of prevalence for anxiety (N=6) were 0.56 (95% CI 0.24÷0.88), whereas the prevalence for depression (N=5) was 0.46 (95% CI 0.15÷0.77). There was significant heterogeneity among studies to estimate the prevalence (I^2 ranging from 99% to 100%).

Limitations, reasons for caution: Results are preliminary, given the small number of studies and their cross-sectional data.

The risk of bias was high or moderate across studies.

Wider implications of the findings: Infertile couples reported high levels of distress due to cancellation of their diagnostic procedures or treatment; they would benefit from information, appropriate support and advice from healthcare professionals, with an important role in maintaining the wishes of infertile couples to continue their parenthood goals.

Trial registration number: not applicable

O-196 The impact of providing couples with their IVF-prognosis on the expectations and anxiety of women and men.

J. Devroe[1,2], K. Peeraer[1,2], T. D'Hooghe[3,4,5], J. Boivin[6], J. Vriens[2], E. Dancet[2]

[1]Leuven University Hospital, Gynaecology, Leuven, Belgium ;
[2]Laboratory of Endometrium- Endometriosis & Reproductive Medicine- KU Leuven, Department of Development and Regeneration, Leuven, Belgium ;
[3]Global Medical Affairs Fertility- Merck Healthcare KGaA, Research and Development, Darmstadt, Germany ;
[4]Gynecology and Reproductive Sciences Yale School of Medicine, Department of Obstetrics-, New Haven- CT-, U.S.A. ;
[5]KU Leuven, Department of Development and Regeneration, Leuven, Belgium ;
[6]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: What is the impact of providing couples with their IVF-prognosis on expectations and anxiety in women and men on the day of embryo transfer?

Summary answer: Only couples with a less than average IVF-prognosis updated their high expectations and IVF-prognosis was negatively associated with anxiety, especially in women.

What is known already: Female IVF-patients are known to expect a pregnancy rate per IVF-cycle of no less than 49-55%. Qualitative interviews and a survey showed that well informed women expect unrealistically high pregnancy rates as they think that their (family's) fertility and their clinic is better than average. Several prognostic models have recently been published. The adapted van Loendersloot model including clinical and laboratory characteristics proved performant for our clinic (AUC=0.74) and was validated internally (Devroe et al, BMJ Open, 2020). The impact of providing couples with their IVF-prognosis on expectations and wellbeing of female and male patients has yet to be studied.

Study design, size, duration: A prospective survey, questioning a final sample of 148 partnered individuals, completing their 2nd-6th IVF-cycle (2019-2020) in a University clinic, on the days of oocyte aspiration (OA) and fresh embryo transfer (ET). Thirty other partnered individuals declined participation (participation rate=85%) and 26 were excluded due to ET-cancellation. The IVF-prognosis (live birth rate, LBR, per completed IVF-cycle including fresh and frozen ETs from the same ovarian stimulation) was calculated with the adapted van Loendersloot model.

Participants/materials, setting, methods: Each partner reported their perception of their expected IVF-LBR on a visual analogue scale on the day OA. After being informed on their IVF-prognosis by gynaecologists, they re-rated their expected IVF-LBR and filled out the reliable 'STAI-State-Anxiety Inventory' on the day of fresh ET. Linear mixed models, taking account of partnering and assessing the association with gender, explored whether individuals updated their expected IVF-LBR after receiving their IVF-prognosis and whether IVF-prognosis and anxiety were associated.

Main results and the role of chance: The mean IVF-prognosis was 30.9% (±16.8). The 148 partnered individuals had a mean expected IVF-LBR of 59.1% (±20.0) on the day of OA (no gender effect; p=0.079). After being informed on their IVF-prognosis (day of ET), women's and men's mean expected IVF-LBR was 50.9% (±24.5) and 58.1% (±22.1), respectively (gender effect; p=0.002). Linear mixed models, including couple and time as random factors, did not show an effect of time on expected IVF-LBRs (p=0.15). Although women were more likely than men to update their expected IVF-LBR (p=0.002), the updates were not significantly different from the IVF-LBR expected on the day of OA (p=0.10). Women were more anxious than men (41.5±10.6 and 21.9±7.2, respectively, p<0.001) after being given their IVF-prognosis. Linear mixed models, including couple as a random factor, showed an association between IVF-prognosis and anxiety (p=0.016), especially in women (gender effect; p=0.004). Subgroup analysis showed that partnered individuals with lower than average prognoses (n=78) did update their expected IVF-LBR (p=0.036) while others (n=70) did not update their expected IVF-LBR (p=0.761). Among the subgroup with lower prognoses women were more likely to update their expected IVF-LBR than men (p=0.013), while no gender effect was observed among the subgroup with higher IVF-prognoses (p=0.078).

Limitations, reasons for caution: This is an explorative study in preparation of an adequately powered randomized controlled trial, testing whether couples who are informed on their IVF-prognosis update their expected IVF-LBR and whether this causes anxiety, as compared to care as usual in which couples are not informed on their IVF-prognosis.

Wider implications of the findings: Men and especially women with a less than average prognosis update their IVF-expectations after having received this prognosis which may trigger anxious reactions. These findings should be re-examined in an RCT. Following up the effect of sharing IVF-prognoses on longer-term distress and IVF-discontinuation would be interesting.

Trial registration number: not applicable

SELECTED ORAL COMMUNICATIONS

SESSION 69: EARLY PREGNANCY - EVIDENCE AND IMPLEMENTATION INTO PRACTICE

01 July 2021 Stream 4 08:30 - 09:30

O-197 Maternal and neonatal characteristics and outcomes of COVID-19 from early pregnancy until labor: an overview of systematic reviews

H. Siristatidis[1], M. Papapanou[1], M. Papaioannou[1], A. Petta[1], E. Routsi[1], M. Farmaki[1], V. Nikolaos[1]

[1]National and Kapodistrian University of Athens, Second Department of Obstetrics and Gynecology- "Aretaieion Hospital", Athens, Greece

Study question: What is the current obstetric-perinatal and neonatal outcome of infected pregnant women and their newborns during the COVID-19 pandemic?

Summary answer: Miscarriage rates were <2.5%, even when only studies of moderate/high-quality were included. Increased rates of CS and preterm birth were found, with uncertain vertical transmission.

What is known already: A considerable number of systematic reviews, with substantial heterogeneity regarding their methods and included populations, on the impact of COVID-19 on infected pregnant women and their neonates, has emerged.

Study design, size, duration: Three bibliographical databases were searched (last search: September 10, 2020). Quality assessment was performed using the AMSTAR-2 tool. Primary outcomes included mode of delivery, preterm delivery/labor, premature rupture of membranes (PROM/pPROM) and abortions/miscarriages. Outcomes were mainly presented as ranges. A separate analysis, including only moderate and high-quality systematic reviews, was also conducted. The protocol was registered with PROSPERO (CRD42020214447);

Participants/materials, setting, methods: The search strategy followed the Preferred Reporting Items for Systematic Review and Meta-analysis (PRISMA) guideline. Keywords employed were (COVID-19 OR SARS-CoV-2 OR "Coronavirus disease 2019") AND ("Neonatal outcom*" OR "Neonatal

characteristic*" OR "Maternal outcom*" OR "maternal characteristic*" OR "pregnancy outcom*" OR "vertical transmission"). All retrieved studies were imported into the Rayyan QCRI and duplicated articles were removed. A snowball procedure was also implemented by hand-searching the reference lists of included systematic reviews for additional sources.

Main results and the role of chance: Thirty-nine reviews were analyzed. Twelve reviews (30.8%) were found to be of "very low quality", 11 of "low quality", 13 (33.3%) of "moderate", and three (7.7%) of "high quality".

Ten articles dealt with miscarriages. One review integrated them into pregnancy terminations (1.4% (4/295)), one into intrauterine fetal deaths (1(3%)), while another one described them as "spontaneous abortions" (0.8% (3/385)). Taking into account reviews, which calculated these rates for their entire included population, miscarriage rates were <2.5%. The reported rates by moderate and high-quality studies were ≤ 2%. Reported rates,regarding both preterm and term gestations, varied between 52.3%-95.8% for caesarean sections; 4.2%-44.7% for vaginal deliveries; 14.3%-63.8% specifically for preterm deliveries and 22.7%-32.2% for preterm labor; 5.3%-12.7% for PROM and 6.4%-16.1% for pPROM. Maternal anxiety for potential fetal infection contributed to abortion decisions, while SARS-CoV-2-related miscarriages could not be excluded. Maternal ICU admission and mechanical ventilation rates were 3%-28.5% and 1.4%-12%, respectively. Maternal mortality rate was <2%, while stillbirth, neonatal ICU admission and mortality rates were <2.5%, 3.1%-76.9% and <3%, respectively. Neonatal PCR positivity rates ranged between 1.6% and 10%. After accounting for quality of studies, ranges of our primary outcomes remained unchanged.

Limitations, reasons for caution: Results are presented in a narrative way using ranges as the primary mean of quantification. We also included studies with both RT-PCR positive women and women with suspected infection based on their clinical and imaging manifestations, whereas, if excluding them, we might have missed a considerable source of information.

Wider implications of the findings: In conclusion, a rapid increase of CS was observed, especially at the beginning of the pandemic, most likely due to lack of knowledge and robust recommendations. Preterm birth rates were elevated, with iatrogenic reasons potentially involved. Even though neonatal infections were rare, the probability of vertical transmission cannot be eliminated.

Trial registration number: not applicable'

O-198 Progesterone supplementation in women with threatened miscarriage: A randomised placebo-controlled clinical trial

L. McLindon[1], G. James[2], M.M. Beckmann[2], J. Bertolone[3], K. Mahomed[4], M. Vane[1], T. Baker[1], M. Gleed[1], S. Grey[1], L. Tettamanzi[1], B.W. Mol[5], W. Li[6]

[1]Mater Health, Natural Fertility Services, Brisbane, Australia ;
[2]Mater Health, Obstetrics and Gynaecology, Brisbane, Australia ;
[3]Mater Health, Pregnancy Assessment Centre, Brisbane, Australia ;
[4]Ipswich Hospital Queensland Health, Obstetrics and Gynaecology, Ipswich, Australia ;
[5]Monash Medical Centre, Obstetrics and Gynaecology, Melbourne, Australia ;
[6]Monash University, Obstetrics and Gynaecology, Melbourne, Australia

Study question: In women with threatened miscarriage, does progesterone supplementation increase the probability of live birth?

Summary answer: In women with threatened miscarriage, 400 mg progesterone nightly, from onset of bleeding until 12 weeks, did not increase live birth rates.

What is known already: Women with a history of miscarriage who present with bleeding in early pregnancy may benefit from the use of vaginal micronized progesterone 400 mg. A recently published large randomised clinical trial indicated no overall benefit for progesterone until 16 weeks, although subgroup analysis in women with bleeding and at least one previous miscarriage, progesterone might be of benefit (Coomarasamy et al; N Engl J Med 2019;380:1815-1824).

Study design, size, duration: We performed a single centre placebo-controlled randomised clinical trial. After informed consent, women with threatened miscarriage as apparent from vaginal bleeding under 10 weeks, were randomised to 400 mg vaginal micronized progesterone or placebo. The primary endpoint was livebirth. Secondary endpoints were perinatal outcomes, including preterm birth and birthweight. The planned sample size was 386 women. At a planned interim analysis randomisation was halted at 278 women due to lack of effectiveness and slow recruitment.

Participants/materials, setting, methods: Between February 2012 and April 2019 we randomised 139 women to 400 mg vaginal micronized progesterone and 139 women to placebo. Primary outcome data are available for 134 women in the progesterone arm and 130 women in the placebo arm. Mean age was 30.7 and 30.4 years. The number of women without a previous miscarriage was 68 (51%) and 55 (42%), while 66 (49%) and 75 (58%) women had at least one previous miscarriage.

Main results and the role of chance: The live birth rates were 113/134 (84.3%) and 112/130 (86.2%), respectively (RR 0.98, 95% CI 0.89-1.08). Among women with at least 1 miscarriage live birth rates were 55/66 (83.3%) and 65/75 (86.7%) (RR 0.96, 95% CI 0.84-1.11). The number of women with more than 1 miscarriage was limited (26 vs 33 in total), but no effect was seen from progesterone in these women. Preterm birth rates were 12.9% and 9.3% (RR 1.38; 95% CI 0.69 to 2.78). There were five pregnancy losses between 20 and 23 weeks, all in the progesterone arm. Mean birth weight was 3310 vs 3300 gram (p=.99). There were also no other differences in obstetric and perinatal outcomes. Anxiety, stress and depression scores did not differ between the groups.

Limitations, reasons for caution: Our study was single centre and did not reach the planned sample size. We stopped study medication at 12 weeks which might explain the difference between our study and studies that continued progesterone till 16 weeks.

Wider implications of the findings: In women with threatened miscarriage, 400 mg vaginal progesterone did not improve live birth rates.

Trial registration number: ACTRN12611000405910

O-199 Proof of concept: implantation window must be wider than proposed. Report of seven twins after asynchronous double embryo transfer

A. Gosálvez Vega[1], M. Rodriguez Mazaira[1], N. Martin Fernandez[1], M. Iglesias Nuñez[1], M. Brandt[1], L. Vidal Juan[1], P. Pastor Vargas[1], Z. Gonzalez Rodriguez[1], S. Corral Bermudez[1], R. García-Abadillo Seivane[1], R. Sainz de la Cuesta Abbad[2]

[1]Hospital Quironsalud Madrid, Unidad Reproducción Asistida, Madrid, Spain ;
[2]Hospital Quironsalud Madrid, Servicio Ginecología y Obstetricia, Madrid, Spain

Study question: Can simultaneous transfer of two embryos that were cryopreserved at different stages (D3 and Blastocyst) be appropriate to enhance success in women with more than three failed embryo transfers?

Summary answer: Double asynchronous embryo transfer offered excellent results in RIF. Unexpectedly high twin rate suggests that embryo-endometrium synchrony is overemphasized. Implantation window must be wider.

What is known already: Transcriptomic signature of the endometrium has been investigated in the last few years trying to understand the best moment for embryo implantation. Nevertheless, the optimal period has not been well established yet in humans. Simultaneous transfer of two human embryos at different developmental stages (D3 and Blastocyst) on Day 4 was proposed to help couples who have had RIF.

Study design, size, duration: Observational case-control study. From April 2016 to January 2021, we offered double asynchronous embryo transfer only after Recurrent Implantation Failure (RIF). Two requirements were necessary: 1) Double embryo transfer was acceptable by the couple due to poor reproductive outcome. 2) Availability of two embryos cryopreserved at different stage (D3 and Blastocyst). Results were compared with good prognosis patients (all patients under 35 years in that period who had elected to transfer two day 3 cryopreserved embryos).

Participants/materials, setting, methods: Forty-five patients accepted to participate in the study. Results were compared with all patients (237) under 35 years where two D3 thawed embryos were transferred. All cases received same protocol (oral estradiol 6mg/d or vaginal estradiol 4mg/d until ultrasound showed endometrial growth) LH, P4 and E2 were monitored in all patients to detect spontaneous LH surge. All cases received transvaginal micronized progesterone 800 mg/d. Embryo transfers were ultrasound guided and Wallace Embryosure catheter was employed.

Main results and the role of chance:

	Asynchronic	women < 35 years	Pearson's chi-squared test
Type of thawed embryos	D3 + Blastocyst in Prog. Day 4	two D3 in Prog. Day 3	
Transfers	51	237	
Embryos (n)	102	474	
Non pregnant (n) %	17 / 51 (33%)	61 / 237 (26%)	
Biochemical (n) %	3 / 51 (9%)	14 / 237 (8%)	
Clinical pregnancies (n) %	31 / 51 **(61%)**	162 / 237 **(68%)**	0,77 Probab. assoc. <90% (1)
Miscarriage/Ectopic (n) %	3 / 31 (10%)	16 / 162 (10%)	
Single ongoing preg. (n) %	21 / 28 **(75%)**	153 / 202 **(76%)**	
Twin ongoing preg. (n) %	7 / 28 (25%)	49 / 202 (24%)	0,03 Probab. assoc. <90% (2)

(1) Pregnancy rate was similar between groups, showing that double asynchronous transfer can be a good tool in some cases of RIF.
(2) Unexpectedly, simultaneous implantation of two embryos transferred with different progesterone timing wass possible. Even more, our results showed that multiple pregnancy rate was comparable to good prognosis patients prepared with optimal progesterone timing.

Limitations, reasons for caution: Multiple pregnancy rate was unacceptably high. Therefore, it should not be suggested for good prognosis couples where single embryo transfer is clearly advised. Our main limitation was the combination of D3 embryos with blastocysts. The retrospective design make the results to be considered as a proof of concept.
Wider implications of the findings: Double asynchronic embryo transfer can offer new insights in the understanding of human implantation. The concept of implantation window is clearly challenged. Aiming to the center of the window is fine, but we still don´t know how wide is that center.
Trial registration number: not applicable

O-200 Frozen embryo transfer: Miscarriage rates depending on the starting day of intramuscular progesterone.

N. Kalhorpour[1], B. Martin[1], O. Kulski[1], J.M. Mayenga[1], I. Grefenstette[1], J. Belaisch Allart[1]

[1]Gynecologie obstétrique et Médecine de la Reproduction, Haut de Seine, Saint Cloud, France

Study question: Objective was to assess whether adjusting starting day of intramuscular progesterone the day of vaginal supplementation versus day of embryo transfer or later, might affect the outcome of the cycle.
Summary answer: additional injection of intramuscular progesterone the day of progesterone initiation or later, is not likely to be more effective on live birth and miscarriage rates.
What is known already: There is no consensus on the most effective method of endometrium preparation prior to FET. However, many studies report that high serum progesterone concentration during the implantation period is associated with optimal live birth rates. Adjusting progesterone treatment the day of embryo transfer seems to be too late and ineffective for rescuing low progesterone levels and should be done before.
Study design, size, duration: In this single center prospective study from October 2019 to november 2020, 239 patients undergoing hormonal replacement therapy protocol for frozen embryo transfer were randomly divided into two groups: additional injection of intramuscular progesterone the day of progesterone initiation or intramuscular progesterone the day of embryo transfer. We compare these results to our previous protocol beginning intramuscular progesterone day 22 of the treatment.
Participants/materials, setting, methods: Our frozen embryo transfer protocol consists to initiate GnRH agonist the day 1 of the cycle. After 14 days of estrogens , we introduce vaginal progesterone , prior to embryo transfer. Patients in group A received an additional injection of intramuscular progesterone the day of progesterone initiation. The group B received intramuscular progesterone the day of embryo transfer. For both , intramuscular injection of progesterone was followed every 3 days.

Main results and the role of chance: 239 patients were enrolled in this study, 125 in the group A and 114 in the group B. The ongoing pregnancy rate in the group A was 26.4 % and miscarriage rate 7.2%, not statistically different from ongoing pregnancy rate and miscarriage rate of women in the group B (22.81 %, p= 0.66/ 6.14%, p= 0.8).

The ongoing pregnancy rate in the group D22 was 24.89 % et miscarriage rate 7.2%, not statistically different from ongoing pregnancy rate of women in the group A and B (p= 0.78 and p= 0.31).

	GROUP A	GROUP B	
Miscarriage (%)	7.2	6.14	NS
Ongoing pregnancies (%)	26.4	22.81	NS
Age (median age)	34.95	34.72	
Blastocyst (%)	91.49	90.90	

Limitations, reasons for caution: The main limitation of our study is the lack of randomization for the group with additional progesterone IM on day 22. The study is actually followed to enroll more patients in 3 different groups.
Wider implications of the findings: This study tries to determine optimal adaptive management of hormonal replacement treatment for embryo transfer in patients with potential low progesterone values.
Trial registration number: no applicable

Study question: To explore the effect of chromosomal mosaicism detected in preimplantation genetic testing (PGT-A) on prenatal and postnatal outcome of mosaic embryo pregnancies

Summary answer: No significant difference between euploid and mosaic embryos was observed in terms of weeks of gestation, average weight, and developmental defect of the babies born

What is known already: Mosaic embryos have the potential to implant and develop into healthy babies.Transfer of these embryos is now offered as an option for women who undergo IVF resulting in no euploid embryos. While, prenatal diagnosis has shown the depletion of chromosomal mosaicism in mosaic embryos, several concerns remain. For instance, the direct effects of different kind of mosaicism on prenatal/postnatal outcome and the possibility that intra-biopsy mosaicism in the TE is a poor predictor of the ploidy status of the ICM. Thus, there is certainly a need for comprehensive analyses of obstetrical and neonatal outcome data of transferred mosaic embryos.

Study design, size, duration: Compiled analysis from multicenter data on transfers of mosaic embryos (n=1,000) and their outcome, with comparison to a euploid control group (n=5,561). To explore the effect of embryonic mosaicism on newborns, we matched mosaic embryos resulting in a birth with a euploid embryo by a series of parameters (maternal age, embryo morphology, and indication for PGT-A). Prenatal tests and birth characteristics of >200 neonates from mosaic embryo transfers were compared to >200 euploid embryos.

Participants/materials, setting, methods: PGT-A was performed on blastocyst-stage embryos with 24-Chromosome whole genome amplification (WGA)-based Next Generation Sequencing (NGS). In accordance with established guidelines, embryos were categorized as mosaic when PGT-A results indicated 20-80% aneuploid content. Prenatal testing where performed in 30% of pregnancies with amniocentesis, 4% did an extra analysis for potential UPD for the suspected mosaic chromosome, and an additional 16% performed chorionic villus sampling (CVS) and 9.5% performed noninvasive prenatal testing (NIPT).

Main results and the role of chance: Of the 465 mosaic embryos that implanted, about 20% miscarried, and out of those, 75% were early spontaneous abortions. Of the pregnancies, 3 out of 368 were stillborn (2 out of them were twins that were extremely premature at 23 weeks, and the other died during pregnancy from a heart defect). The remaining 99% of those have been born or are late ongoing pregnancies at the time of analysis. Prenatal tests were performed in >200 pregnancies and the vast majority tested normal. All 5 abnormal cases were amniocentesis tests showing microdeletions or insertions of sizes smaller than the resolution used during PGT-A, so they were unrelated to the mosaicism detected with PGT-A. In fact, in none of the cases did the prenatal test reflect the mosaicism detected at the embryonic stage. Matching each of the 162 mosaic embryos resulting in a birth with a euploid embryo, we found that the length of gestation was similar on average, and so was the average weight of the babies at birth. We also gathered information on the routine physical examination performed on babies at birth, and of those 162 babies from mosaic embryo transfers, none had obvious developmental defects or gross abnormalities.

Limitations, reasons for caution: Even though newborns resulting from mosaic embryo transfers in this study invariably appeared healthy by routine examination, concerns for long-term health cannot yet be entirely dispelled. The question must therefore be carefully considered by each clinic and patient situation.

Wider implications of the findings: Prenatal testing of >200 pregnancies from mosaic embryo transfers showed no incidence of mosaicism that matched the PGT-A findings, indicating the involvement of self-corrective mechanisms. Pregnancy and obstetric data indicates that mosaic embryos prevailing through gestation and birth have similar chromosomal and physiological health compared to euploid embryos.

Trial registration number: none

O-202 Usage of laser during trophectoderm biopsy and its affect on PGT-A results and moscaism

H.K. Yelke[1], Y. Kumtepe Colakoglu[1], B. Yuksel[2], M. Cetinkaya[3], S. Kahraman[2]

[1]Memorial Sisli Hospital IVF Unit, Embryology, Istanbul, Turkey ;
[2]Memorial Sisli Hospital IVF Unit, ART Clinic, Istanbul, Turkey ;
[3]Memorial Sisli Hospital IVF Unit, Genetic, Istanbul, Turkey

Study question: Does laser use during trophectoderm biopsy affect biopsy results on prehatching embryos with regard to mosaicism ?

Summary answer: According to our findings laser usage during trophectoderm biopsy increases mosaic results on next generation sequencing (NGS) irrespective of embryo quality.

What is known already: Chromosomal mosaicism, which is a result of mitotic errors after fertilization, is defined as the presence of karyotypically distinct cell lines within an embryo. The introduction of NGS made it possible to detect chromosomal mosaicism at levels as low as 20%. The incidence of mosaicism is highly variable between clinics which reported the incidences between 4-32%. Apart from the biological reasons, there are also various technical factors that may impact the incidence of mosaicism. One of the most emphasized factors is the trophoectoderm biopsy technique. Laser usage and number of laser pulses may cause excessive heat during the procedure

Study design, size, duration: The mosaicism ratio in embryos in which trophectoderm biopsy was performed with or without laser, between January 2017 - December 2020 in Istanbul Memorial Hospital (IMH) were examined retrospectively. A total of 13002 embryos were analyzed. A subgroup analysis was also performed regarding mosaicism ratios in different embryo qualities. Blastocysts were classified according to Gardner's classification and classified as follows: top quality-TQ (4AA,5AA,6AA), good quality-GQ (3AA, 4,5,6AB,BA) and moderate quality-MQ (3,4,5 BB).

Participants/materials, setting, methods: The biopsy samples of the cases who had PGT-A in IMH between 2017-2020 were evaluated by NGS method. This method enables the identification of embryos with 20% to 80% mosaicism. The study assessed whether there was an increase in the embryos with mosaic results due to the use of laser during biopsy. The effects of laser use among the TQ (4AA,5AA,6AA), GQ (3AA, 4,5,6AB,BA) and MQ (3,4,5 BB) groups according to Garder classification were analyzed.

Main results and the role of chance: Trophectoderm biopsy was applied on 13002 embryos within the specified period. During biopsy in 5088 embryos laser was used and in 7843 embryos laser was not used, and biopsy was performed mechanically (flicking method). After observing the biopsy results, 945/5088 (18.5%) of the laser applied embryos; and 1087/7914 (13.7%) of laser not applied embryos were defined as mosaic($p < 0.0001$). When mosaicism rates were examined according to embryo qualities, the rate of mosaicism was 19.3%(469/2430), 18.2%(290/1591) and 13.2%(380/2875), 13.5 (426/3141) respectively in embryos with and without laser in TQ and GQ groups. A statistically high level of significance ($p < 0.0001$) was observed between the embryos evaluated as top quality and good quality before biopsy. Regarding the evaluation in the moderate group embryos, although the mosaicism rates tended to increase on the laser applied group side 40/248(16.1%), no statistical difference was observed when compared to non-laser group 103/670(15,4%). ($P > 0.05$)

Limitations, reasons for caution: The retrospective nature of the data is the main limitation of the study. On the other hand, the large number of NGS based PGT-A tested TQ and GQ embryos from a single center and resuts from single laboratory.However, further studies are required to corroborate our findings.

Wider implications of the findings: Laser dependent heat effect may increase mosaicism. To reduce the cell damage, teasing of cells should be avoided and a minimum number of laser pulses should be used in order to avoid excessive heat and contact points should be preferably confined to cell junctions

Trial registration number: None

O-203 Application of machine learning to predict aneuploidy and mosaicism in embryos from in vitro fertilization (IVF) cycles

J.A. Ortiz[1], R. Morales[1], B. Lledo[1], E. Garcia-Hernandez[1], A. Cascales[1], J.A. Vicente[2], J. González[3], J. Ten[4], A. Bernabeu[5], J. Llácer[5], R. Bernabeu[5]

[2]Universidad Nacional de Educacion a Distancia UNED, Economía Aplicada y Estadística, Madrid, Spain ;
[3]Universidad Nacional de Educacion a Distancia UNED, Economía de la Empresa y Contabilidad, Madrid, Spain ;
[4]Instituto Bernabeu, Embriología, Alicante, Spain ;
[5]Instituto Bernabeu, Medicina Reproductiva, Alicante, Spain

Study question: Is it possible to predict the likelihood of an IVF embryo being aneuploid and/or mosaic using a machine learning algorithm?
Summary answer: There are paternal, maternal, embryonic and IVF-cycle factors that are associated with embryonic chromosomal status that can be used as predictors in machine learning models.
What is known already: The factors associated with embryonic aneuploidy have been extensively studied. Mostly maternal age and to a lesser extent male factor and ovarian stimulation have been related to the occurrence of chromosomal alterations in the embryo.

On the other hand, the main factors that may increase the incidence of embryo mosaicism have not yet been established.

The models obtained using classical statistical methods to predict embryonic aneuploidy and mosaicism are not of high reliability. As an alternative to traditional methods, different machine and deep learning algorithms are being used to generate predictive models in different areas of medicine, including human reproduction.
Study design, size, duration: The study design is observational and retrospective. A total of 4654 embryos from 1558 PGT-A cycles were included (January-2017 to December-2020). The trophoectoderm biopsies on D5, D6 or D7 blastocysts were analysed by NGS. Embryos with ≤25% aneuploid cells were considered euploid, between 25-50% were classified as mosaic and aneuploid with >50%.

The variables of the PGT-A were recorded in a database from which predictive models of embryonic aneuploidy and mosaicism were developed.
Participants/materials, setting, methods: The main indications for PGT-A were advanced maternal age, abnormal sperm FISH and recurrent miscarriage or implantation failure. Embryo analysis were performed using Veriseq-NGS (Illumina).

The software used to carry out all the analysis was R (RStudio). The library used to implement the different algorithms was caret. In the machine learning models, 22 predictor variables were introduced, which can be classified into 4 categories: maternal, paternal, embryonic and those specific to the IVF cycle.
Main results and the role of chance: The different couple, embryo and stimulation cycle variables were recorded in a database (22 predictor variables). Two different predictive models were performed, one for aneuploidy and the other for mosaicism. The predictor variable was of multi-class type since it included the segmental and whole chromosome alteration categories.

The dataframe were first preprocessed and the different classes to be predicted were balanced. A 80% of the data were used for training the model and 20% were reserved for further testing. The classification algorithms applied include multinomial regression, neural networks, support vector machines, neighborhood-based methods, classification trees, gradient boosting, ensemble methods, Bayesian and discriminant analysis-based methods. The algorithms were optimized by minimizing the Log_Loss that measures accuracy but penalizing misclassifications.

The best predictive models were achieved with the XG-Boost and random forest algorithms. The AUC of the predictive model for aneuploidy was 80.8% (Log_Loss: 1.028) and for mosaicism 84.1% (Log_Loss: 0.929). The best predictor variables of the models were maternal age, embryo quality, day of biopsy and whether or not the couple had a history of pregnancies with chromosomopathies. The male factor only played a relevant role in the mosaicism model but not in the aneuploidy model.
Limitations, reasons for caution: Although the predictive models obtained can be very useful to know the probabilities of achieving euploid embryos in an IVF cycle, increasing the sample size and including additional variables could improve the models and thus increase their predictive capacity.
Wider implications of the findings: Machine learning can be a very useful tool in reproductive medicine since it can allow the determination of factors associated with embryonic aneuploidies and mosaicism in order to establish a predictive model for both. To identify couples at risk of embryo aneuploidy/mosaicism could benefit them of the use of PGT-A.
Trial registration number: Not Applicable

O-204 Is mosaicism affected by an embryologist's experience in biopsy?

W.Y. Yap[1], M.W. Lim[1], C.S.S. Lee[2]

[1]IVF Nexus, IVF Lab, Petaling Jaya, Malaysia ;
[2]Alpha IVF & Women's Specialists, Clinical, Petaling Jaya, Malaysia

Study question: Are there any correlations between blastocyst mosaicism rate and biopsy experience among embryologists?
Summary answer: Blastocysts biopsied by embryologists with ≥1 year of biopsy experience have significantly lower mosaicism rate compared to those with <1 year of biopsy experience.
What is known already: It has been reported that the incidence of blastocyst mosaicism is highly variable between centres (PGDIS, 2019). It is also suggested that the technical aptitude of the embryologist performing blastocyst biopsy may give rise to mosaicism. Thus, a retrospective study was conducted to investigate the relationship between blastocyst mosaicism rate and biopsy experience among embryologists in Alpha IVF.
Study design, size, duration: Thirteen competent embryologists who were trained in blastocyst biopsy were included in this study: 5 have ≥1 year of biopsy experience (Group A; Embryologist A-1, A-2, A-3, A-4, A-5); 8 have <1 year of biopsy experience (Group B; Embryologist B-1, B-2, B-3, B-4, B-5, B-6, B-7, B-8). Embryologists from Group A biopsied a total of 4795 blastocysts while those from Group B biopsied 4869 blastocysts from January 2018 to December 2019.
Participants/materials, setting, methods: TE biopsy was performed either on Day 5, 6 or 7 using the laser or flicking method. The biopsied cells had Preimplantation Genetic Testing for Aneuploidy (PGT-A) analysed using Next Generation Sequencing (Ion Torrent, USA) and chromosomal mosaicism analysis was done using ReproSeq Mosaic PGS w1.1 workflow. Mosaic blastocysts were reported when 20% - 80% of aneuploid cells are tested in the biopsied samples. Only successfully amplified biopsy samples were included in this study.
Main results and the role of chance: The mosaicism rate of blastocysts biopsied by embryologists from Group A and B were 17.8% and 19.8% respectively. Blastocysts from Group A showed significantly lower mosaicism rate compared to Group B ($p=0.01$). The mosaicism rates of blastocyst biopsied by Embryologist A-1, A-2, A-3, A-4 and A-5 were 17.3%, 19.1%, 16.8%, 15.2%, and 18.9% respectively. The mosaicism rates of blastocyst biopsied by Embryologist B-1, B-2, B-3, B-4, B-5, B-6, B-7, and B-8 were 17.5%, 18.6%, 22.5%, 20.4%, 27.8%, 20.6%, 20.1% and 20.3% respectively. There were no significant differences in blastocyst mosaicism rate between embryologists within Group A ($p>0.05$). Contrarily, in Group B, Embryologist B-5 had a significantly higher blastocyst mosaicism rate compared to the other embryologists within the same group ($p<0.05$).
Limitations, reasons for caution: Since this study is retrospective in nature, the biopsy technique (either the laser or flicking method) was not controlled. Hence, further studies to analyse the differences between these 2 biopsy techniques should be carried out to confirm its effect on the occurrence of blastocyst mosaicism.
Wider implications of the findings: Our study demonstrates that blastocysts biopsied by embryologists with ≥1 year of biopsy experience have significantly lower mosaicism rate compared to those with <1 year of biopsy experience. This indicates that the skill and experience of an embryologist in biopsy may have an impact on the mosaicism rate.
Trial registration number: Not applicable

O-205 Aneuploidy induces proteotoxic stress and autophagy-mediated apoptosis in human preimplantation embryos

M. Regin[1], E. Couvreu De Deckersberg[1], Y. Guns[2], P. Verdyck[3], G. Verheyen[2], H. Van de Velde[2], C. Spits[1], K. Sermon[1]

[1]Vrije Universiteit Brussel, Reproduction and Genetics, Brussels, Belgium ;

[2]UZ Brussel, Center for Reproductive Medicine, Brussels, Belgium ;
[3]UZ Brussel, Center for Medical Genetics, Brussels, Belgium

Study question: Are aneuploid cells in human preimplantation embryos eliminated by apoptosis due to proteotoxic stress and autophagy-mediated apoptosis?
Summary answer: Proteotoxic stress, autophagy and apoptosis are differentially activated in aneuploid embryos, showing that aneuploid cells are eliminated by these mechanisms during early human embryogenesis.
What is known already: Aneuploidies are a common feature of human preimplantation embryos which could explain low success rates after *in vitro* fertilization (IVF). While most aneuploidies of meiotic origin are detrimental, transfer of euploid-aneuploid mosaic embryos can lead to healthy live-births. Moreover, the proportion of aneuploid cells are lower in blastocysts when compared to cleavage stage embryos. In the mouse, aneuploid cells are eliminated from the epiblast by autophagy-mediated apoptosis in a p53-dependent manner. We propose that in human embryos, aneuploidy causes chronic protein misfolding which leads to autophagy-induced apoptosis.
Study design, size, duration: Eighty-one blastocysts that were diagnosed by PGT as euploid (n=49) or uniformly combined abnormal (CA, n=32), i.e. 2 or more chromosomes were abnormal in every cell, were warmed. Sixty-seven were suitable for trophectoderm (TE) biopsy, 54 biopsies were successfully tubed and sent for RNA-sequencing while the remainder of the embryos was fixed for immunostaining. Thirty-three day-3 embryos were overnight incubated in 0.5µM reversine allowed to develop into blastocysts and treated as the PGT embryos.
Participants/materials, setting, methods: After TE biopsy, we live-stained the embryos with either Caspase-3/7 or 8 and subsequently fixed them. The biopsies underwent RNA-sequencing using the SMART-seqv4 and the fixed embryos were immunostained for LC3B, p62 (autophagy) and HSP70 (proteotoxic stress). Confocal imaging was performed using a Zeiss LSM800 confocal microscope and the presence of signal was quantified using the Zen Blue 2.0 and Arivis software.
Main results and the role of chance: Forty-two percent of the embryos in which we induced aneuploidies using reversine developed into blastocysts, which is comparable to untreated embryos. After immunostaining, we observed that CA and reversine-treated (RT) embryos contained less cells than euploid embryos (median number of nuclei: 43.5, 47, 90, respectively). This correlates with a higher expression of apoptotic markers Caspase-3/7 in CA embryos (p=0.0199) and Caspase-8 in both aneuploid groups (CA: p=0.0085 and RT: p=0.0394). Aneuploid embryos showed significantly increased HSP70 levels (median intensity per cell: euploid=165, CA=313, RT=400), LC3B (median puncta per cell: euploid=3.07, CA=10.10, RT=19.62) and p62 (median puncta per cell: euploid=17.60, CA=30.53), suggesting increased proteotoxic stress and autophagy. Preliminary analysis of the RNA-sequencing data reveals enrichment for pathways such as the p53-pathway, protein secretion, TNFA signaling via NFkB and apoptosis, supporting the hypothesis of a link between aneuploidy and apoptosis.
Limitations, reasons for caution: No functional tests e.g. with inhibitors of autophagy were carried out. RNA-sequencing was carried out on a small sample; we will expand this sample in the near future.
Wider implications of the findings: This study shows for the first time the mechanism by which aneuploid cells are eliminated from the human preimplantation embryo, explaining how mosaic embryos can still lead to a healthy and genetically normal live birth.
Trial registration number: not applicable

O-206 Meiotic segregation analysis for reciprocal translocation carriers: Assessment of factors influencing meiotic segregation patterns

P. Xie[1], H. Liang[2], P. Yangqin[3], T. Yueqiu[2], L. Ge[4]

[1]1 Hunan Normal University School of Medicine- Changsha- 410013- China
[2]National Engineering and Research Center of Human Stem Cell-Changsha-410078- China, basic medicine, changsha, China ;
[2]2National Engineering and Research Center of Human Stem Cell-Changsha-410078- China 3Clinical Research Center for Reproduction and Genetics in Hunan Province- Reproductive and Genetic Hospital of CITIC-Xiangya-Changsha 410078- China 4 Laboratory of, , ;
[3]Clinical Research Center for Reproduction and Genetics in Hunan Province-Reproductive and Genetic Hospital of CITIC-Xiangya- Changsha 410078- China, genetic department, changsha, China ;
[4]2National Engineering and Research Center of Human Stem Cell-Changsha-410078- China 3Clinical Research Center for Reproduction and Genetics in Hunan Province- Reproductive and Genetic Hospital of CITIC-Xiangya-Changsha 410078- China 4 Laboratory of, ,

Study question: To analyze factors that could influence meiotic segregation patterns for reciprocal translocation carriers.
Summary answer: Involvement of an Acr-ch, female gender, and lower TAR1 (ratio of translocated segment 1 over the chromosome arm) were independent risk factors for alternate segregation.
What is known already: Reciprocal translocation is one of the more common structural rearrangements of chromosomes, which is associated with reproductive risks, such as infertility, spontaneous abortion and the delivery of babies with mental retardation or developmental delay. Extensive studies on meiotic segregation patterns of sperm, blastomere, and blastocysts have identified several factors that may influence the generation of unbalanced rearrangement of reciprocal translocations, including carrier's gender and age, location of breakpoints, chromosome type, and the quadrivalent structure. However, some results are controversial.
Study design, size, duration: A retrospective study from October 2013 to December 2019, a total of 10846 blastocysts originating from 2871 oocyte retrieval cycles from 2253 couples with one of the partners carrying reciprocal were investigated. The mean maternal age was 29.97±4 years (20 –47years).
Participants/materials, setting, methods: Trophectoderm biopsy of blastocysts was performed on the 5th or 6th day of development. Whole genome amplification (WGA) was performed on all samples, and the WGA was analyzed with SNP array or NGS. Segregation patterns of quadrivalent in 10846 blastocysts were analyzed. Risk factors for segregation patterns were explored through analyzing carriers' demographic and cytogenetic characteristics using multivariate generalized linear mixed models (GLMMs).
Main results and the role of chance: The percentage of normal/balanced blastocysts was 34.3%, and 2:2 segregation was observed in 90.0% of blastocysts. Increased TAR1 (the ratio of translocated segment 1 over the chromosome arm) was noted as an independent protective factor for the proportion of alternate segregation (P=0.004). The female gender and involvement of an Acr-ch were found independent risk factors for alternate segregation (P<0.001). A higher TAR1 reduced the risk of adjacent-1 segregation; longer translocated segment and female gender increased the risk of adjacent-2 segregation (P=0.009 and P<0.001, respectively). Female gender and involvement of an Acr-ch enhanced the risk of 3:1 segregation (P<0.001 and P=0.012, respectively).
Limitations, reasons for caution: About 1400 blastocysts were not diagnosed in the 2871 cycles, which might cause bias in the results. Secondly, the interchromosomal effect of reciprocal translocations was not analyzed in this study.
Wider implications of the findings: In conclusion, a carrier's gender, involvement of an Acr-ch, and location of breakpoints may influence the segregation patterns. Besides, involvement of an Acr-ch, female gender, and lower TAR1 are independent risk factors for alternate segregation. These results may provide more appropriate genetic counseling for couples with balanced translocation.
Trial registration number: no

SESSION 72: SPERM DNA FRAGMENTATION: ALIVE AND KICKING

01 July 2021 Stream 3 10:00 - 11:30

O-207 Which infertile patients mostly deserve to have a sperm DNA fragmentation index done? Findings from a cross-sectional study

E. Pozzi[1], L. Boeri[1], L. Candela[1], D. Cignoli[1], G. Colandrea[1], M. Raffo[1], W. Cazzaniga[1], N. Schifano[1], P. Capogrosso[2], E. Ventimiglia[1], C. Abbate[1], F. Montorsi[1], A. Salonia[1]

[1]Ospedale San Raffaele, Division of Experimental Oncology/Unit of Urology- URI-, Milano, Italy ;
[2]ASST Sette Laghi – Circolo e Fondazione Macchi Hospital, Urology, Varese, Italy

Study question: Current scientific guidelines do not clearly suggest which patients would benefit the most from a sperm DNA fragmentation (SDF) test.
Summary answer: We aimed to investigate potential predictive factors for altered SDF in a homogenous cohort of white-European men presenting for primary couple's infertility.
What is known already: High SDF has been associated with reduced fertilization rates, reduced chances of natural conception and an increased risk of early pregnancy loss.
Study design, size, duration: Data from 478 consecutive men with normal or altered SDF were analysed. Infertility was defined according to the WHO criteria. Semen analysis, SDF (according to SCSA) and serum hormones were measured in every patient. Health significant comorbidities were scored with the Charlson Comorbidity Index (CCI). Altered SDF was considered with a threshold of >30%.
Participants/materials, setting, methods: Descriptive statistics compared the overall characteristics of patients with normal SDF and altered SDF. Logistic regression analysis tested potential predictors of altered SDF. ROC curve was used to test the accuracy of the model in predicting SDF alteration
Main results and the role of chance: Of 478 patients, 253 (57.7%) had altered SDF. Median (IQR) age and BMI of the whole cohort were 38 (35-42) years and 25.1 (23.3-27.1) kg/m^2 respectively. Patients with altered SDF were older (median (IQR) age: 39 (36-43) vs. 37 (34-38) years, p<0.0001), had lower sperm concentration (5 (1.1–18) vs. 17 x10^6/mL (6–38.8), p<0.0001), testicular volume (15.1 (12 –20) vs. 16.8 (12 – 25) Prader, p=0.0005), and total motile sperm count (TMSC) (1.8 (0.21–10.71) vs. 11.8x10^6 (2–37.26), p<0.0001). Conversely, men with altered SDF had higher FSH (6.1 (3.85–9.7) vs. 4.8 (3.85 – 7.9) mIU/mL, p<0.0001) and prolactin levels (9.8 (7.43–14.04) vs. 8.3 (6.6–11.3) pg/mL, p=0.0004) than those with normal SDF. At multivariable logistic regression analysis, patients' age >35 years (OR: 2.45, p=0.0009), FSH > 8.0 mIU/mL (OR: 2.23, p<0.0001) and lower TMSC (OR: 2.04, p=0.002) were identified as indipendent predictors of altered SDF, after adjusting for testicular volume and CCI≥1. ROC curve (Figure 1) revealed that the model has a good predictive ability to identify patients with SDF alteration (AUC: 0.72, 95%CI: 0.67 - 0.77).
Limitations, reasons for caution: It is a retrospective analysis at a single, tertiary-referral academic centre, thus raising the possibility of selection biases. In spite of this, all patients have been consistently analysed over time with a rigorous follow-up, thus limiting potential heterogeneity in terms of data reporting
Wider implications of the findings: Primary infertile men older than 35 years, with high serum FSH and low TMSC at baseline are the ones who mostly deserve a SDF test over their diagnostic work-up and that would potentially benefit the most of certain treatments to improve SDF value, thus increasing chances of conceiving.
Trial registration number: Not applicable

O-208 High sperm DNA fragmentation index negatively impacts embryo morphokinetics, but not embryo morphology and development rates: the importance of time-lapse imaging system

E. Borges Junior[1,2], A. Setti[2,3], D. Braga[2,3], R. Provenza[4], P. Guilherme[4], A. Iaconelli Junior[1]

[1]Fertility Medical Group, Clinical Department, São Paulo, Brazil ;
[2]Sapientiae Institute, Scientific research, São Paulo, Brazil ;
[3]Fertility Medical Group, Scientific research, São Paulo, Brazil ;
[4]Fertility Medical Group, IVF lab, São Paulo, Brazil

Study question: Can time-lapse imaging (TLI) identify morphokinetic events impacted by high sperm DNA fragmentation index (DFI), irrespective of conventional morphological embryo assessment and development rate?
Summary answer: Embryo morphokinetic parameters are negatively impacted by high DFI, whereas conventional morphological embryo assessment and blastocyst development rate are not related to DNA integrity.
What is known already: Paternal genome activation occurs late in the embryo, and therefore, the negative impact of sperm factors on embryo development is more often observed in the outcomes of pregnancy, such as embryonic implantation and pregnancy loss, than in the potential for embryonic development itself, such as successful development to the blastocyst stage. With the development of TLI technology, and the possibility of assessing complete embryonic development, we hypothesized that sperm factors related to DNA fragmentation may interfere with the speed and pattern of cell divisions, leading to slower embryos; something that would not be detected by conventional morphological embryo assessment.
Study design, size, duration: The study included 978 zygotes cultured until day five in a TLS incubator between March/2019 and August/2020, derived from 118 patients undergoing ICSI in a private university-affiliated IVF center. Kinetic markers from the point of insemination were recorded. Generalized linear models adjusted for potential confounders, followed by Bonferroni post hoc were used to compare timing of specific events in patients with low (<30%) of high (≥30%) DFI. The post hoc achieved power was > 90%.
Participants/materials, setting, methods: Recorded kinetic markers were: timing to pronuclei appearance and fading (tPNa and tPNf), timing to two (t2), three (t3), four (t4), five (t5), six (t6), seven (t7), and eight cells (t8), and timing to morulae (tM), start of blastulation (tSB) and blastulation (tB). Durations of second and third cell cycles (cc2 and cc3) and timing to complete synchronous divisions s1, s2, and s3 were calculated. The KIDScore ranking was also recorded.
Main results and the role of chance: Blastocyst development (53.1% ± 1.3 vs. 55.1% ± 1.5, p=0.380) and high-quality rates (87.9% ± 2.9 vs. 86.2% ± 3.6, p=0.749) were similar between embryos derived from sperm samples with <30% DFI (n=592) and ≥30% DFI (n=386), respectively. Embryos derived from sperm samples with ≥30% DFI showed significantly slower divisions compared to those from <30% DFI: tPNa (6.1h ± 0.2 vs. 6.8h ± 0.2, p=0.030), tPNf (23.0h ± 0.3 vs. 24.2h ± 0.3, p=0.009), t2 (25.4h ± 0.3 vs. 26.9h ± 0.3, p=0.002), t3 (34.8h ± 0.3 vs. 37.3h ± 0.4, p>0.001), t4 (37.5h ± 0.4 vs. 39.3h ± 0.4, p=0.003), t5 (46.2h ± 0.5 vs. 49.5h ± 0.6, p<0.001) , t6 (49.7h ± 0.5 vs. 52.8h ± 0.6, p=0.001), t7 (52.4h ± 0.6 vs. 55.6h ± 0.7, p=0.001), t8 (56.2h ± 0.7 vs. 58.9h ± 0.8, p=0.017), tSB (97.5h ± 1.5 vs. 105.9h ± 1.7, p=0.002), tB (108.6h ± 0.8 vs. 112.4h ± 1.2, p=0.016). The KIDScore ranked significantly different between embryos derived from samples with <30% or ≥30% DFI (4.5 ± 0.1 vs. 3.9 ± 0.2, p=0.033, respectively). A significant difference was observed in implantation rate (<30% DFI: 51.5% ± 2.2 vs. ≥30% DFI: 30.5% ± 1.3, p<0.001).
Limitations, reasons for caution: Retrospective nature of this study and the small sample size may be a reason for caution, despite adequate power has been achieved.
Wider implications of the findings: Increasing DFI correlates with delayed cell cleavage and blastulation, leading to reduced implantation rates, without compromising blastulation rate and quality. This finding highlights the importance of TLI for the identification and de-selection of slow-growing embryos for transfer, in cycles with high DFI.
Trial registration number: Not applicable

O-209 The impact of sperm DNA fragmentation on pregnancy outcomes depends on oocyte dimorphisms

D. Braga[1,2], A. Setti[1,2], R. Provenza[3], P. Guilherme[3], A. Iaconelli Jr.[4], E. Borges Jr.[2,4]

[1]Fertility Medical Group, Scientific research, Sao Paulo, Brazil ;
[2]Sapientiae Institute, Scientific research, São Paulo, Brazil ;
[3]Fertility Medical Group, IVF lab, São Paulo, Brazil ;
[4]Fertility Medical Group, Clinical department, São Paulo, Brazil

Study question: Does the impact of sperm DNA fragmentation (SDF) on Intracytoplasmic sperm injection (ICSI) outcomes depend on the presence of oocyte dimorphisms?
Summary answer: There is a significant influence of oocyte quality on the impact of SDF on pregnancy outcomes.
What is known already: Sperm DNA fragmentation has been associated with ICSI outcomes. DNA damage is commonly encountered in human spermatozoa and it has been widely accepted that the oocyte assumes responsibility for the repair and remodelling of both the maternal and paternal genomes during the oocyte-embryo transition. Indeed, spermatozoa with DNA damage can fertilise oocytes and still lead to embryo development due to the oocyte DNA repair capacity. Considering the vital role played by the oocyte in the developmental process, it could be hypostatised that the oocyte quality, translated as oocyte morphology, would influence the machinery responsible for sperm DNA repair after fertilization.
Study design, size, duration: This cohort study included 3,035 oocytes from 525 patients undergoing ICSI cycles in a university-affiliated IVF-center, between June/2016 and July/2019. Oocytes were split into groups according to the SDF

index of the sample used for ICSI: low-fragmentation (<30% SDF, n= 2,277) and high-fragmentation (≥30% SDF, n=758). Oocytes were evaluated before sperm injection and the dimorphisms were recorded. The influence of SDF index on ICSI outcomes, depending on the presence of oocytes dimorphisms was evaluated.

Participants/materials, setting, methods: Data was evaluated using generalized linear models (GZLM) followed by Bonferroni post hoc. The results are expressed as mean ± standard error for continuous variables or percentages for dichotomous variables, and p-values. The sample size calculation suggested that a sample of at least 504 subjects had 95% power to detect a 20% effect with a significance level of 5% ( ). The study was performed in a private university–affiliated in vitro fertilization (IVF) center.

Main results and the role of chance: The association of both factors: the presence of oocyte dimorphisms (dark cytoplasm, vacuoles in the ooplasm, and resistant membrane) and high SDF index resulted in the lowest fertilization rate among groups, while oocytes free of these dimorphisms injected with samples with <30% SDF had the highest fertilization rate (p=0.05, p<0.01 and p <0.01 for dark cytoplasm, vacuoles in the ooplasm and resistant membrane respectively). The impact of SDF index on high quality embryos rate on cleavage stage was also influence by the presence smooth endoplasmic reticulum clusters and resistant membrane oocytes (p=0.013 and p= 0.018). As for the clinical outcomes, the impact of SDF index on the implantation rate was influenced by the presence of vacuoles in the ooplasm (p<0.01), smooth endoplasmic reticulum clusters (p<0.01), large perivitelline space (p<0.01), resistant membrane (p<0.01), and non-resistant membrane (p<0.01), while the influence of SDF index on the pregnancy rate was influenced by the presence large perivitelline space (p<0.01), resistant membrane (p=0.018) and non-resistant membrane (p<0.01). The effect of SDF on the miscarriage rate was also increased in the presence of large perivitelline space (p=0.045), non-resistant membrane (0.037) and centrally located cytoplasmic granular area (p=0.025).

Limitations, reasons for caution: The retrospective nature is a limitation. It could be argued that using samples with high SDF index does not necessarily mean that a sperm cell with a fragmented DNA was injected, however, the higher the SDF index, the higher the chance of selecting one with fragmented DNA.

Wider implications of the findings: The findings presented here highlight the crucial role of male and female factors when facing assisted reproduction. The association of low oocyte quality and high SDF index may lead to impaired results. As the oocyte defect cannot be modified, in vivo upgrading of spermatozoa before the treatment should be encouraged.

Trial registration number: Not applicable

O-210 Sperm DNA fragmentation (SDF) is not associated with adverse maternal and neonatal outcomes in IVF-ICSI cycles with autologous oocytes

R. Rivera Egea[1], I. Hervas[2], A. Pacheco[3], M. Gil Julia[2], A. Navarro-Gomezlechon[2], N. Garrido[2]

[1]IVIRMA Valencia- Plaza de la Policia Local 3- 46015- Valencia- Spain., Andrology Laboratory and Sperm Bank, Valencia, Spain ;
[2]IVI Foundation- Health Research Institute La Fe- Av. Fernando Abril Martorell-nº106- Torre A- Planta 1ª- 46026- Valencia- Spain, Andrology and Male infertility research group, Valencia, Spain ;
[3]IVIRMA Madrid- Av. del Talgo 68-70- 28023- Madrid- Spain., Andrology Laboratory and Sperm Bank, Madrid, Spain

Study question: Does an elevated SDF (>15%) increase the odds of adverse maternal and neonatal outcomes in autologous oocyte IVF-ICSI cycles from unselected couples?

Summary answer: No adverse effects of high SDF on obstetric and neonatal outcomes have been found in couples with sperm fragmentation undergoing IVF-ICSI cycles with own eggs.

What is known already: Sperm chromatin integrity assessment has been implemented as an additional tool in the clinical evaluation of sperm quality in infertile patients undergoing an assisted reproduction treatment. All of the published reports to date appraise its effect on clinical outcomes, and how it impacts embryo quality and the pregnancy chances after IVF and ICSI cycles. Sperm DNA integrity has also been hypothesized to affect offspring health but not many studies have reported in humans if an elevated SDF raises the risks of obstetric, delivery and neonatal outcomes.

Study design, size, duration: Multicentric retrospective cohort study of all IVF-ICSI cycles using autologous oocytes between January 2000-March 2019 at Spain IVIRMA clinics of couples with a SDF test on their ejaculated semen. The sperm fragmentation index was measured in all men with TUNEL assay. The database included 228 couples which had a delivery with at least a newborn. Subjects were divided into two study groups according to their level of SDF: ≤15% (low SDF) or >15% (high SDF).

Participants/materials, setting, methods: Patients with missed information on maternal and neonatal outcomes were not counted for the analysis. The obstetric outcomes were gestational age, gestational diabetes, preeclampsia (hypertension with proteinuria after 20 weeks of gestation) and type of delivery. Neonatal outcomes were sex, birth weight, length, head circumference, Apgar score at 1, 5, 10 minutes, and neonatal intensive care unit (NICU) admission. Student's t-test and Fisher's test were used for statistical analysis. A *p-value*<0.05 was considered statistically significant.

Main results and the role of chance: Maternal age mean was 37.4 years (95%CI 36.9-38.0) in ≤15%SDF group and 37.2 years (95%CI 36.1-38.4) in >15%SDF group (p=0.8). Similar gestational age was found, 41.8 weeks (95%CI 41.3-42.2) in ≤15%SDF and 41.3 weeks (95%CI 40.4-42.3) in >15%SDF. Gestational diabetes incidence was higher in >15%SDF compared to ≤15%SDF group (3.5% versus 1.7% (OR=2.0 (95%CI 0.03-39.8), p=0.5). Equally, the incidence of preeclampsia was 3.6% in patients with high SDF versus 1.7% in couples with low SDF, OR=2.1 (95%CI 0.03-41.3), p=0.5. Type of delivery frequency was in the ≤15%SDF group 61.9% vaginal and 38.1% cesarean, while in the >15%SDF group 62.1% vaginal and 37.9% cesarean (OR=1.0 (95%CI 0.4-2.6), p=1.0). The overall proportion of singleton pregnancies was 87.2% (95%CI 82.4-91.2) and twins 12.8% (95%CI 8.8-17.6). There were no statistically differences between groups in the rate of delivery of twins and in the sex ratio of the newborns. When comparing the newborns of ≤15%SDF with >15%SDF group, the average of weight was 3011.7g (95%CI 2912.2-3111.2) versus 2986.4g (95%CI 2753.1-3219.7), of length was 49.2cm (95%CI 48.3-50.0) versus 49.5cm (95%CI 49.2-49.9), of head circumference was 34.9cm (95%CI 34.6-35.2) versus 34.3cm (95%CI 33.4-35.2). No statistically differences were observed for Apgar punctuation and for NICU admission.

Limitations, reasons for caution: Due to the retrospective nature of the study we have missing data from the lack of follow-up of many patients after the confirmation of the ongoing pregnancy. Although pregnancies of couples with elevated SDF have a higher incidence of gestational diabetes and preeclampsia, the sample size evaluated is a limitation.

Wider implications of the findings: This is one of the first reports to evaluate the relationship between paternal DNA damage and obstetric risks and neonatal health in couples with high SDF who underwent IVF-ICSI in our centers. Despite SDF did not jeopardize the maternal and neonatal outcomes, more studies are needed to confirm this conclusion.

Trial registration number: NA

O-211 The DNA double-strand break repair genes expression exhibits significant changes in the postnatal mouse testes from early to aged terms

G. Talibova[1], Y. Bilmez[1], S. Ozturk[1]

[1]Akdeniz University, Department of Histology and Embryology- Akdeniz University School of Medicine- Antalya- Turkey, Antalya, Turkey

Study question: How does the DNA double-strand break (DSB) repair genes, *Rad51*, *Rpa70*, *Ku80*, and *Xrcc4*, expression change in the postnatal mouse testes from early to aged terms.

Summary answer: The *Rad51*, *Rpa70*, and *Ku80* genes expression decreased in the postnatal mouse testes from early to aged terms.

What is known already: The DSB levels occurring in the spermatogenic cells during spermatogenesis increase during biological aging in men. DSBs can be repaired by specific repair mechanisms including homologous recombination (HR) or non-homologous end joining (NHEJ) pathways. While RAD51 and RPA70 are the main components of HR process, KU80 and XRCC4 play important roles in NHEJ pathway. As is known, gH2AX is a commonly used biomarker for determining the DSBs.

Study design, size, duration: The potential reasons of DSB levels in the spermatogenic cells during aging is not fully addressed yet. In this study, we aimed to analyze the expression of the *Rad51*, *Rpa70*, *Ku80* and *Xrcc4* genes

at mRNA and protein levels in the postnatal mouse testes from early to aged terms.

Participants/materials, setting, methods: We comprised five groups based on the testicular histology, consisting of early (1- and 2-week-old), young (3- and 4-week-old), adult (5- and 6-week-old), late-adult (16-, 18- and 20-week-old), and aged (48-, 50- and 52-week-old). DSB repair genes expression at mRNA and protein levels were determined using qRT-PCR and immunohistochemistry techniques, respectively. The data were evaluated by using one-way ANOVA and Tukey post hoc test. $P<0.05$ was considered statistically significant.

Main results and the role of chance: The *Rad51*, *Rpa70, Ku80,* and *Xrcc4* mRNA levels significantly decreased in the aged group when compared to the young, adult and late-adult groups ($P<0.05$). gH2AX was intensively localized in the nucleus of primary spermatocytes of postnatal testes, and its levels either in the total or seminiferous tubules or germinal epithelial cells involving primary spermatocytes, round spermatids, elongating spermatids, elongated spermatids, and Sertoli Cells were higher in the aged group than the remained groups ($P<0.05$). The DSB repair proteins were detected in the spermatogenic cells, in which pachytene spermatocytes showed stronger intensity. The levels of RAD51 and RP70 proteins implicating in HR pathway were lower in the seminiferous tubules of the aged group when compared to the adult and late-adult groups ($P<0.05$). Moreover, the total and seminiferous tubules analysis revealed that KU80 levels decreased in the aged group in comparison to the remaining groups except for early group, as observed for the spermatogonia, primary spermatocytes and round spermatids of the aged group ($P<0.05$). Although there were no significant differences found in the total and seminiferous tubule analysis for XRCC4 protein, its levels decreased in the round spermatids and elongating spermatids of the aged group compared to the adult and late-adult groups.

Limitations, reasons for caution: The limitation of this study is that we did not isolate spermatogenic cell types from aged mice to compare adult ones.

Wider implications of the findings: The increase of DSB in the spermatogenic cells of aged mice may derive from reduced levels of RAD51, RPA70 and KU80 proteins playing roles in DSB repair. Further researches are required to determine the molecular mechanisms resulting in decrease of these protein levels.

Trial registration number: not applicable

O-212 MACS vs TESA for raised sperm DNA fragmentation index – a RCT

K.C. Mantravadi[1], D.R. Gedela[2]

[1]Oasis Fertility, EMBRYOLOGY, Hyderabad, India ;
[2]Oasis Fertility, Fertility, Hyderabad, India

Study question: In Individuals with raised Sperm DNA Fragmentation Index (SDF), will sperm selection by magnetic activated cell sorting (MACS) or surgical retrieval of testicular sperms (TESA) optimize the reproductive outcomes?

Summary answer: Couples with failed implantation raised SDF, TESA /MACS offer similar results. This RCT doesn't prove superiority or added benefit with any of the above interventions.

What is known already: It is evident that raised SDF negatively affects the reproductive outcomes. Management for raised SDF to optimize reproductive outcomes is still elusive.

Study design, size, duration: This was a Randomized Control Trial (RCT) with prior approval from institutional Ethical Committee and trial registration. Couples undergoing stimulation with raised SDF were randomized to MACS (n=75) and TESA (n=75) for sperm selection between April2019 & February2020.

Participants/materials, setting, methods: Couples with history of one failed IVF had SDF testing and SDF>30% were recruited. SDF test done with SCSA method and randomized using software. ICSI was the method of insemination. Extended embryo culture till blastocyst was done and freeze all policy was opted. Two Blastocysts that showed 100% survival were transferred in a Frozen Embryo transfer (FET) cycle. Embryonic and Reproductive outcomes were compared between both groups. Live birth and Miscarriage were the primary outcomes.

Main results and the role of chance: Reproductive Outcomes of MACS Vs TESA were:

Average Blastocyst conversion - 32% Vs 39% (RR 1.22, CI1.00 to 1.50)

Implantation rate (IR) - 50% Vs 35% (RR - 0.71, CI 0.51 to 0.98)

Miscarriage rate (MR) - 5.3% Vs 11% (RR1.6333, CI 0.5227 to 5.1039)

Multiple Pregnancy rate (MPR) - 8% Vs 4%

Live birth Rate (LBR) per Intention to treat (ITT) - 41.3% Vs 44% (RR 0.95, 95% CI 0.72 to 1.26)

LBR per ET cycle - 63% Vs 56% (RR 1.23, 95% CI 0.77 to 1.94)

Our preliminary results suggest that despite greater availability of blastocysts for transfer in the TESA group, no difference in ART outcomes was observed between the groups.

Though the IR was statistically low with TESA, our primary outcomes LBR and MR were comparable.

TESA or MACS seem to offer similar outcomes. Considering the invasiveness with TESA, MACS can be offered for better sperm selection for couples with raised sperm DFI & failed implantation.

Limitations, reasons for caution: Small sample size. TESA is a surgical intervention

Wider implications of the findings: Optimal intervention for management of SDF still needs further research.

Trial registration number: CTRI/2019/07/020140

SESSION 73: EMBRYO CULTURE AND DEVELOPMENT

01 July 2021 Stream 4 10:00 - 11:30

O-213 Slow day 5 development affects implantation potential of fresh transferred embryos but not birthweight once pregnancy occurs: A multi-center retrospective cohort study

K. Watson[1], K. Ong[2], I. Korman[2], R. Turner[3], B. Vollenhoven[4], D. Zander-Fox[5], Y. Liu[6]

[1]Monash IVF Group, Embryology, Southport, Australia ;
[2]Monash IVF Gold Coast, Clinical, Southport, Australia ;
[3]Monash IVF Auchenflower, Clinical, Brisbane, Australia ;
[4]Monash University, Department of Obstetrics and Gynecology, Melbourne, Australia ;
[5]Monash University, Department of Obstetrics & Gynaecology, Melbourne, Australia ;
[6]Monash IVF Gold Coast, Embryology, Southport, Australia

Study question: Does slow development of fresh transferred day 5 embryos lead to decreased implantation potential and birthweight?

Summary answer: Slow day 5 development was associated with reduced implantation potential when transferred fresh but the subsequent birthweight of the resulting baby was not impacted.

What is known already: Slow development of *in vitro* cultured cleavage stage embryos is associated with reduced blastocyst development and implantation rates. There is no current consensus regarding whether to transfer fresh slow developing day 5 embryos or to extend culture for a subsequent day with potential for cryopreservation. It is therefore important to understand the true prognosis of fresh transferred day 5 embryos at less advanced developmental stages. This would provide evidence based guidelines for the decision making process in regard to embryo transfer.

Study design, size, duration: This is a retrospective multi-center cohort study, including 1213 consecutive patients undergoing autologous oocyte *in vitro* fertilization (IVF) treatment during 2016-2019,with fresh transfer of a single day 5 embryo (selection based on developmental stage and inner cell mass and trophectoderm morphology if blastocyst was at the ≥expanding stage). Cycle data were collected from 4 associated private clinics, with repeat cycles of same patients excluded to avoid clustering effect at statistical analysis.

Participants/materials, setting, methods: Live birth and birthweight were followed up in all 1213 fresh day 5 SETs. Multiple regression (logistic or linear) was performed to investigate association between slow day 5 development (defined as ≤ early blastocyst) and (a)live birth, (b) birthweight, and (c) gestation-adjusted birthweight (Z score) to account for gestational age, gender and

compared to embryos at ≥ expanded stage. Results were expressed as adjusted odds ratio (aOR) with 95% confidence interval (CI)or coefficients (β).
Main results and the role of chance: No implantation was achieved following single fresh transfer of day 5 embryos that failed to reach early blastocyst stage (n=76) and were transferred as ≤ morula stage. Live birth rate was significantly lower following single day 5 fresh transfer of an early blastocyst (n=237, 16%), in comparison to expanding (n=329, 27%, P=0.001), expanded(n=392, 41%, P=0.000), and hatching/hatched blastocysts (n=169, 44%, P=0.000). After adjusting for potential confounding factors including; maternal age, hours post insemination at day 5 assessment, number of oocytes collected, number of 2PN embryos, and number of embryos frozen; multiple logistic regression showed significantly reduced likelihood of live birth resulting from early blastocysts in reference to those at the expanding (aOR=0.584, 0.371-0.917, P=0.020), expanded (aOR=0.322, 0.208-0.501, P=0.000), or hatching/hatched stages (aOR=0.255, 0.147-0.443, P=0.000). However, multivariate linear regression indicated that early blastocysts resulting in a live birth (n=39) did not lead to altered birthweight (β=-9.091, P=0.904; β=-34.960, P=0.343; β=-26.074, P=0.414; respectively) or Z score (β=0.045, P=0.706; β=-0.051, P=0.426; β=-0.028, P=0.506; respectively) in reference to the expanding (n=90), expanded (n=160), or hatching/hatched stages (n=75).
Limitations, reasons for caution: The retrospective nature of this study does not allow controlling of unknown confounders. The 4 participating clinics are associated within the same network with shared protocols, therefore, results may not be generalized to other clinics with different settings.
Wider implications of the findings: The findings suggest no clinical value of fresh day 5 transfer of embryos ≤morula stage. Although early blastocysts implant at reduced rate, assuring birthweight outcomes suggest clinical value. Future studies intend to investigate slow growing day 5 fresh transfers versus embryos that were slow growing but transferred after day 6.
Trial registration number: NA

O-214 Undisturbed embryo culture under High Humidity atmosphere in a time-lapse system increases pregnancy rates

M.D.L.Á. Valera Cerdá[1], C. Albert[2], L. Bori[1], J. Marcos[3], Z. Larreategui[4], A. Pellicer[5], M. Meseguer[2]

[1]IVIRMA, Research Laboratory, Valencia, Spain ;
[2]IVIRMA, IVF Laboratory, Valencia, Spain ;
[3]IVIRMA, IVF Laboratory, Murcia, Spain ;
[4]IVIRMA, IVF Laboratory, Bilbao, Spain ;
[5]IVIRMA, Reproductive Endocrinology and Infertility, Rome, Spain

Study question: Does culture in high relative humidity conditions (HC) improve pregnancy rates when using a time-lapse system (TLS) and single-step (SS) culture medium?
Summary answer: Using an integrated-TLS and SS medium, culture under HC increases the likelihood of embryos to achieve a pregnancy with respect to those cultured in DC.
What is known already: Many variables affect embryo development, and need to be precisely tuned in every IVF laboratory, especially inside the incubators. TLS provide stability during embryo culture, which is a well-known key factor for a proper embryo development. The humidity content of culture atmosphere is especially relevant in order to avoid oscillations in culture media osmolality. It has been previously reported that culture under HC has a significant effect on embryo quality and morphokinetics. However, studies assessing the effect of HC in clinical outcome are rare and inconclusive, mostly due to the variability in the incubator device used and insufficient sample size.
Study design, size, duration: The present is a retrospective study performed over 1624 ICSI treatments from 3 fertility clinics from December 2017 to October 2020. Zygote cohorts were randomly assigned to dry (N=794) or humid conditions (N=830). It includes autologous treatments with (N=555) and without (N=368) pre-implantation genetic testing (PGT) and egg donation treatments (N=701). Following selection by combining morphological and morphokinetic criteria, 1611 mostly single embryo transfers (92%) were performed, 779 from DC and 832 from HC.
Participants/materials, setting, methods: Stimulation, oocyte pickup and fertilization were performed according to the standard procedures of the clinic. We used a GERI incubator (Genea Biomedx), with 6 separated chambers for individual patients, 3 of them configured to work in DC, and 3 in HC. Embryos were cultured in specific 16-well GERI trays with single-step Gems® culture medium (Genea Biomedx). The effect of HC in pregnancy rate was assessed by multivariate logistic regression and Pearson Chi Square Test.
Main results and the role of chance: Types of treatment and patient demographics were homogeneously distributed in the two study groups. Mean patient age was 39.88±4.47 years, BMI: 23.54±4.21 Kg/m2 and number of correctly fertilized oocytes: 7.86±3.87. A logistic regression was performed, including other possible affecting factors: ovum age and origin, transfer day, fresh or frozen-warmed embryo transfer, number of transferred embryos and the use of PGT. Said analysis revealed that embryos cultured in HC are more likely to achieve a pregnancy than those cultured in DC (OR=1.30, 95% CI (1.05-1.59), p=0.014). Pregnancy rate was significantly higher in HC (66.7%) than in DC (60.9%) in the total embryo transfers (p=0.017). Pregnancy rate was also higher in HC in fresh embryo transfers (68.6% in HC vs 63.2% in DC; p=0.133) and frozen-thawed transfers (65.2% in HC vs 59.1% in DC; p=0.062), although differences were not statistically significant due to the reduced sample size. Stratifying the results, the significant difference remained in transfers belonging to autologous cycles (68.4% HC vs 56.5% in DC; p=0.030) and in treatments in which PGT was performed (67.1% HC vs 56.0% in DC; p=0.023), but the difference in egg donation procedures was not statistically significant (66.4% in HC vs 64.7% in DC, p=0.577).
Limitations, reasons for caution: This is a retrospective analysis performed over the clinics' treatments, so it might be compromised by some bias, although multivariable analysis may overcome them. For further assessing the effect of HC in clinical results a prospective controlled study, with a larger sample size could be performed, also comparing life-birth rates.
Wider implications of the findings: These results, alongside our previous findings (Valera *et al*. 2020, Albert *et al*. 2020), support that HC contributes to optimize embryo development and clinical results in undisturbed culture in TLS with single-step medium. To our knowledge, this is the largest study on the matter and the first performing multivariable analysis.
Trial registration number: Not applicable

O-215 How common is add-on use and how do patients decide whether to use them? A national survey of IVF patients

S. Lensen[1], K. Hammarberg[2], A. Polyakov[3], J. Wilkinson[4], S. Whyte[5], M. Peate[1], M. Hickey[1]

[1]University of Melbourne, Obstetrics and Gynaecology, Parkville, Australia ;
[2]Victorian Assisted Reproductive Treatment Authority, Research, Melbourne, Australia ;
[3]Melbourne IVF, Melbourne IVF, Melbourne, Australia ;
[4]University of Manchester, Centre for Biostatistics- Manchester Academic Health Science Centre, Manchester, United Kingdom ;
[5]Queensland University of Technology, School of Economics and Finance, Brisbane, Australia

Study question: How common is IVF add-on use in Australia, and what drives the use?
Summary answer: Most women (82%) had used one or more IVF add-ons and more than half (54%) first learned about the add-ons from their fertility specialist.
What is known already: IVF add-ons are procedures, techniques or medicines which may be considered nonessential to IVF, usually used in attempts to improve the probability of conception and live birth. Despite widespread concern about unproven IVF add-ons, information about the prevalence of their use is limited because these data are not available in national registries or datasets.
Study design, size, duration: Women who had undergone IVF in Australia since 2017 were recruited via social media. Women were excluded if they were gestational surrogates, had used a surrogate, or underwent IVF for oocyte donation or elective oocyte cryopreservation only. Eligible women completed an online survey which was open from 21st June to 14th July 2020.
Participants/materials, setting, methods: Survey questions included demographics, IVF and medical history, and questions specifically about IVF add-ons such as: the type of add-ons used, information sources consulted, and where participants first heard about add-ons. Women also responded to questions about the importance of scientific evidence regarding safety and

effectiveness, factors considered in decision-making around add-on use and the presence of any decision regret.

Main results and the role of chance: A total of 1,590 responses were analyzed after excluding 287 ineligible responses. Participants were generally representative of women who undergo IVF in Australia in terms of age, indication for IVF, and use of ICSI for fertilisation. Most women had used at least one add-on (82%), and these were usually associated with an additional fee (72%). It was most common to first learn about IVF add-ons from the fertility specialist (54%), and most women reported that they and their specialist contributed equally to the decision to use add-ons.

Women viewed scientific evidence for safety and effectiveness as very important: on a scale from 0-100, an importance score over 90 was selected by more than half of the participants. Additionally, many (49%) assumed that add-ons were risk-free. Most women experienced regret at the decision to use IVF add-ons (66%), and this regret was greatest among women who experienced IVF failure when using add-ons (83%) and those who believed that the specialist drove the decision to use the add-ons (75%).

Limitations, reasons for caution: This was a retrospective survey of IVF patients, therefore it may suffer from bias due to patient recall. It does not consider the perspective of the IVF clinic or fertility specialist. Certain questions may be more prone to biased responses, such as those regarding who contributed to decision making.

Wider implications of the findings: The high prevalence of add-on use is likely generalizable to other settings where IVF treatment is largely private. Although women viewed scientific evidence as very important, most had used unproven IVF add-ons. This might suggest that women were not aware of the lack of robust evidence to support their use.

Trial registration number: Not applicable

O-216 Culture medium used in IVF-treatment impacts post-implantation embryonic growth and developmental trajectories in a sex-specific manner

L. Van Duijn[1], R. Steegers-Theunissen[1], E. Baart[2], S. Willemsen[3], J. Laven[4], M. Rousian[1]

[1]Erasmus MC- University Medical Centre, Obstetrics and Gynaecology, Rotterdam, The Netherlands ;
[2]Erasmus MC- University Medical Centre, Obstetrics and Gynaecology- Division of Reproductive Endocrinology and Infertility, Rotterdam, The Netherlands ;
[3]Erasmus MC- University Medical Centre, Obstetrics and Gynaecology and Department of Biostatistics, Rotterdam, The Netherlands ;
[4]Erasmus MC- University Medical Centre, Obstetrics and Gynaecology - Division of Reproductive Endocrinology and Infertility, Rotterdam, The Netherlands

Study question: What is the (sex-specific) impact of two different culture media used in *in vitro* fertilization (IVF) treatment on post-implantation growth and development?

Summary answer: Embryos, especially males, cultured in SAGE 1-Step grow and morphologically develop faster in the first trimester, when compared to those cultured in Vitrolife G-1 PLUS.

What is known already: Increasing success rates after IVF can be attributed to several advancements, such as improved culture conditions. Culture media are of special interest, as they supply the embryo with essential nutrients and have previously been shown to impact birthweight. Moreover, IVF pregnancies are associated with an increased male:female ratio. However, it is unknown if culture media also have an impact prenatally. Therefore, our aim is to study the (sex-specific) impact of two different culture media (SAGE 1-Step and Vitrolife G-1 PLUS) used in IVF treatment on first-trimester embryonic growth and development, and fetal outcomes.

Study design, size, duration: Women with a viable singleton pregnancy were included before 10 weeks of gestation in the Rotterdam Periconception Cohort, an ongoing prospective tertiary hospital-based study, conducted since November 2009.

Participants/materials, setting, methods: A total of 879 pregnancies were included; 153 after culture in Vitrolife G-1 PLUS, 251 after culture in SAGE 1-Step and 475 naturally conceived. First-trimester growth and development, defined by serial crown-rump length (CRL), embryonic volume (EV) and Carnegie stages measurements were performed using state-of-the-art imaging techniques. Secondary outcomes included second trimester estimated fetal weight (EFW) and birth outcomes, and were retrieved from medical records.

Main results and the role of chance: Linear mixed model analyses, adjusted for gestational age and maternal characteristics, showed that embryos cultured in SAGE 1-Step grow faster than those cultured in Vitrolife G-1 PLUS (β_{EV} 0.030 $\sqrt[3]{cm^3}$ (95%CI 0.008-0.052), p=0.007). CRL and Carnegie stages were not statistically different between culture media. After stratification for fetal sex, similar results were observed for male embryos (β_{EV} 0.048 $\sqrt[3]{cm^3}$ (95%CI 0.015-0.081), p=0.005), but not for female embryos. EFW and birth outcomes were comparable between culture media in the total population and after stratification for fetal sex. Embryos cultured in SAGE 1-Step also grow faster than those conceived naturally (β_{EV} 0.033 $\sqrt[3]{cm^3}$ (95%CI 0.006-0.060), p=0.018). This association was also most pronounced in male embryos (β_{EV} 0.066 $\sqrt[3]{cm^3}$ (95%CI 0.024-0.108), p=0.002).

Limitations, reasons for caution: Although this study has a prospective design, its observational character does not exclude residual confounding. Furthermore, the external validity of this explorative study is limited, since participants were recruited from a tertiary university hospital.

Wider implications of the findings: Culture in SAGE 1-Step culture medium is associated with faster first-trimester growth and development, especially in male embryos. This may be the result of altered susceptibility to preimplantation environmental stressors. Further research should focus on the (sex-specific) impact of culture media on postnatal development and the susceptibility to non-communicable diseases.

Trial registration number: N/A

O-217 Bitter Taste Receptors expression in human follicular cells: new perspectives in female fertility

A. Luddi[1], B. Semplici[1], F.P. Luongo[1], L. Governini[1], R. Ponchia[1], G. Morgante[1], V. De Leo[1], P. Piomboni[1]

[1]University of Siena, Molecular and Developmental Medicine, Siena, Italy

Study question: Bitter TasteReceptors (TAS2Rs)role in female reproductive system cells: potential implications in mechanisms underlying oocyte maturation and sperm-oocytes interaction.

Summary answer: TAS2Rs and genes involved in their transduction cascade are differentially expressed in granulosa (GCs)and cumulus cells(CCs).

What is known already: TASRs expression can be found also in extraoral location wherein their function appears less obvious. TASRs are reported to be involved in signal transduction cascade induced by chemotactic activation in spermatozoa and the expression of TAS2Rs in ejaculated human sperm has been demonstrated. The presence of these receptors in male reproductive system and in sperm gives cues to investigate their possible role in sperm-oocyte interaction.Functional implications have been collected indicating that taste receptors are also important to increase the number of highly fertilization-competent sperm cells within the female genital tract hypothesizing a role in the field of female reproduction.

Study design, size, duration: We enrolled for this study 30patients undergoing IVF cycles because of couple infertilityfrom June 2019 to October 2020at the UOSA of Assisted Reproductive techniques, Siena University Hospital(Italy).

Participants/materials, setting, methods: Female patients referring to UOSA of Assisted Reproductive techniques(median age 35 years) underwent a personalised controlled ovarian hyperstimulation protocol. After oocyte pickup, GCs were isolated from the follicular fluid through differential gradient. CCs were collected after oocytes denuding. TAS2Rs and genes involved in the transduction cascade elicited expression/localization in both GCs and CCs were confirmed by Droplet Digital PCR, western blot andimmunofluorescence.

Main results and the role of chance: For the first time, the expression and cellular localization of the TAS2Rs (TAS2R3, TAS2R4, TAS2R14, TAS2R19 and TAS2R43), their G-coupled proteins (GNAT1 oro-transducinandGNAT3 or α-gustducin) and enzymes involved in the transduction signal (PDE4A, TRPM5 and PLCB2)were demonstrated in the female reproductive system.Overall expression of TAS2Rs emerged higher in GCs than in CCs, confirming the specific molecular fingerprinting during differentiation of ovarian somatic cells. TAS2R14 is the most expressed gene in both GCs and CCs, this could account for its potential involvement in follicular cells physiology and/or for a key role of this receptor in fertilization, as supported by data showing TAS2R14 to be

correlated with sperm progressive motility. We demonstrated a positive correlation in GCs between the expression of the TAS2Rs and GNAT3; interestingly, when each subset of TAS2Rs genes was correlated with the signaling gene, TAS2R14 emerged as the one with the higher correlation with GNAT3. Immunofluorescence showed different localization of TAS2Rs and their G-coupled proteins between GCs and CCs. Interestingly some of them presented some fluorescent granules, suggesting a possible involvement of proteins in membrane trafficking. Finally, results of G-coupled proteins western blot, revealed the higher expression of -gustducin then -transducin, confirming the gene expression.
Limitations, reasons for caution: All findings have to be validated in a larger cohort. Moreover, our data pave the way to the understanding of biological functions exerted by these receptors in the female reproductive tract.
Wider implications of the findings: Further studies might contribute to better understanding the physiologic role of taste receptorsfemale reproductive system. This should becrucial to clarify the role of these receptors in maturation or competence acquiring of oocytes, or also in sperm-oocytes attraction and recognition, crucial point in fertilization process
Trial registration number: Not applicable

O-218 The effect of mTOR activation on human primordial follicle activation during in-situ culture

Z. Ghezelayagh[1,2], N. Abtahi[1], M. Rezazadeh Valojerdi[1,3], B. Ebrahimi[1]

[1]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology, Tehran, Iran ;
[2]University of Science and Culture, Department of Developmental Biology, Tehran, Iran ;
[3]Faculty of Medical Sciences- Tarbiat Modares University, Department of Anatomy, Tehran, Iran

Study question: What is the effect of mTOR pathway activation on human primordial follicles in-situ activation and subsequent development following tissue cryopreservation?
Summary answer: Temporary treatment of cryopreserved human ovarian tissue with mTOR activators cause the initiation of primordial follicle development and influence steroidogenesis.
What is known already: In-vitro activation of primordial follicles to produce mature oocytes provides an alternative technique for fertility preservation. The employment of different stimulators of PI3K pathway has been successfully used to activate resting follicles during culture or prior to grafting in patients with premature ovarian insufficiency. The addition of phosphatidic acid (PA) and propranolol (PP), as mTOR stimulators, in the culture medium has promoted primordial follicle activation morphologically in mouse and human ovaries. Molecular and functional evaluations of primordial follicle activation after treatment with the mentioned stimulators has not been conducted.
Study design, size, duration: Ovarian tissues which were donated from 6 transsexual patients (23-35 years old), were dissected and cryopreserved with slow-freezing technique. After thawing, they were cut into 1×1×1 mm fragments and incubated with different stimulators in three groups: 1) Control (without stimulators), 2) PA (200μM), and 3) PA+PP (200μM & 50μM respectively). In groups two and three, ovarian fragments were cultured for 24 hours in presence of stimulators and then cultured for additional 6 days without stimulators.
Participants/materials, setting, methods: The cultured ovarian fragments were directly processed for Hematoxylin and Eosin staining and Western blot analysis. The proportion of morphologically normal and degenerated primordial and growing follicles and 17β-estradiol (E2) level in the culture medium were compared after 1 and 7 days of culture to assess follicular development and function. Western blot analysis for phosphorylated and non-phosphorylated status of FOXO3a and RSP6 proteins expression were compared after 24 hours of incubation.
Main results and the role of chance: The proportion of primordial and growing follicles were not significantly different in the experimental groups after 24 hours of incubation with either of the stimulators. Western blot analyses indicated a significant reduction of FOXO3a in the PA+PP group compared to the control group. The phosphorylation level of RPS6 protein did not significantly change in either of the groups. The proportion of transitional follicles were significantly higher in the PA group compared to other groups after 7 days of culture. The E2 secretion level was significantly higher at the last day of culture compared to day 1 for all groups. At the end of the culture period, E2 levels was significantly higher in both PA and PA+PP groups compared to the control group.
Limitations, reasons for caution: Due to ovarian fragmentation before culture, the HIPPO pathway downstream molecules should have also been evaluated by western blot, which was not contributed in this study.
Wider implications of the findings: The results demonstrate the beneficial effect of mTOR signaling to accelerate early primordial follicle recruitment in cryopreserved-thawed human ovarian fragments.
Trial registration number: not applicable

POSTER DISCUSSION
SESSION 74: ETHICS AND LAW POSTER DISCUSSIONS
1 July 2021 Stream 1 11:45 - 12:30

P-351 Ethical challenges posed by an increase of surplus frozen embryos in Argentinean fertility centers

N.S. Lima[1], A.G. Martínez[2]

[1]National Scientific and Technical Research Council - CONICET, Ethics Department, Buenos Aires, Argentina ;
[2]Fertilis Medicina Reproductiva, Laboratorio de Biología de la Reproducción, Buenos Aires, Argentina

Study question: Can an increase in the quantity of frozen embryos lead to more difficulties in embryo disposition decisions (EDD)?
Summary answer: EDD posed clinical and ethical challenges and might be influenced by having more available embryos, due to changes in the laboratory procedures.
What is known already: Previous research suggests that many people find EDD difficult and emotionally distressing. Patients face ambivalence during the decision-making process which could lead to embryo abandonment. Regulation of embryo dispositions varies among countries, but in the Latin American context, the regulatory gap generates insecurities in healthcare professionals. Cultural values towards the embryo can be associated with discomfort, guilt, or psychological burden. Studies suggest that patients often feel that they are unable to make a satisfactory decision when presented with the current embryo disposition options. Thus, other 'solutions', such as the request for nonreproductive transfer, appear and raises ethical questions and concerns.
Study design, size, duration: This is an observational study which follows a thematic literature review, that identifies the main reasons for difficulties with embryo disposition decisions, in different countries. It focuses on the regulatory background of the principal ART providers worldwide to discuss the best course of action for Argentina, that faces the problem of EDD at a regulatory level. To inform the discussion, a comparative survey from an Argentinean context, was carried out.
Participants/materials, setting, methods: Most fertility clinics in Argentina are private entities, as there are very few public providers. Access to ART treatments has been regulated since 2013, but the law fails to define a number of important issues, including EDD and national registries. An online survey was sent to all reproductive facilities to collect data on storage content and the results were complemented with data from the Latin American Register (RedLara) and the Argentine Registry of Assisted Fertilization.
Main results and the role of chance: The survey results showed that in 2017, there were approximately 54.432 frozen embryos stored in 46 Argentinean fertility centers and the total amount in 2020 reached 91.724 stored in 54 centers. Despite the number of treatment cycles (IVF + OD) being constant between 2017 and 2020 (with a slight increase of 8%), the number of frozen embryos has increased exponentially (by 68.5%). This is a consequence of the improvements in cryopreservation techniques (vitrification) and the development of more efficient ovarian stimulation protocols, that have facilitated a rise in elective single embryo transfer. These advances, coupled with an inefficient regulatory

framework, generate uncertainties in physicians who might already be conflicted and therefore provide little or inadequate guidance for patients facing EDD. Three strategies could be implemented to facilitate EDD under this particular setting. First, counseling sessions at different treatment stages should be encouraged and are conducted by trained mental health professionals, who are aware of their patient's changing attitudes towards surplus embryos. Second, both aneuploid embryos and embryos which were cryopreserved more than 10 years ago could form part of a national bank for research purposes, using classified storage content. Third, promote effective regulation that includes EDD and explicit storage limits.

Limitations, reasons for caution: The influence of the Catholic Church on policy makers regarding embryo dispositions is the main drawback. There is a need to foster a regulatory framework that considers the changes in IVF procedures and practices. On a practical level, psychosocial care is missing as part of healthcare teams' practices.

Wider implications of the findings: The survey results revealed that IVF centers in Argentina will face an increase in euploid, aneuploid and untested frozen embryos, due to the changes registered in laboratory procedures. This tendency shows the need to discuss EDD with patients from the beginning of fertility treatment, through to its conclusion.

Trial registration number: not applicable

P-352 Beyond individualisation: towards a more contextualised understanding of women's social egg freezing experiences

M. De Proost[1], G. Coene[1], J. Nekkebroeck[2], V. Provoost[3]

[1]Vrije Universiteit Brussel, RHEA Research Centre on Gender- Diversity and Intersectionality, Brussels, Belgium ;
[2]UZ Brussel, Centre for Reproductive Medicine, Brussels, Belgium ;
[3]Ghent University, Bioethics Institute Ghent, Ghent, Belgium

Study question: What are the moral perceptions and views of women considering social egg freezing?

Summary answer: Participants did not perceive egg freezing as a morally problematic solution to societal problems but addressed concerns about relationship formation and wanted more social efforts.

What is known already: Central to the social egg freezing debate is the individualisation argument which underlines the idea that it is morally problematic to use individual medical-technological solutions, such as egg freezing, to solve the societal challenges women face, for instance in the current labour market. It has been said that, instead of quick medical-technical solutions that target individual women's bodies, we should focus on substantive changes that target the androcentric work culture. This theme relates to feminist concerns about unnecessary medicalisation geared towards women. Furthermore, there is a call for more empirical studies to back up this central normative claim.

Study design, size, duration: Seventeen participants were recruited by psychologists working in two Belgian centres for reproductive medicine which offer egg freezing for social reasons. In addition, four participants were recruited through via social networks. Interviews took place between February 2019 and November 2020 at a location of the participants' preference or through online video connections.

Participants/materials, setting, methods: At the beginning of the interview, open questions were asked to invite the participants to speak about social egg freezing in their own words. In the second part of the interview, we used four cards with controversial statements based on a study of the bioethics literature, to encourage the participants to reflect about ethical concerns. In this part, we engaged in Socratic dialogue. For the analysis, thematic analysis was used combined with interdisciplinary collaborative auditing.

Main results and the role of chance: This is the first study providing empirical evidence about (potential) egg freezers' moral reasoning about individualisation arguments. Most participants in our study could make sense of the individualisation argument but emphasised another societal challenge rather than the current labour market. They highlighted 'the lack of a partner relationship' as driving their motivation for this procedure. The shortage of eligible partners has been well defined in social science scholarship about social egg freezing but this element has rarely been articulated in the premises of individualisation arguments. This topic of relationships is challenging to analyse from a normative perspective because it was experienced as much more personal and intimate by the women in our study than for instance measures to realise more fair labour conditions, such as improved access to childcare. Some participants believed egg freezing resulted from individual problems and found the individualisation argument not applicable to their own situation. Furthermore, no participant found the individualisation argument legitimate to depict social freezing as morally problematic. Nonetheless, the participants showed a sense of sympathy with women who lack access to egg freezing and were in favour of societal solutions in several public domains.

Limitations, reasons for caution: Given that we report on a small-scale qualitative study of possible social egg freezers at two Belgian fertility clinics, and that our study foregrounds the voices of mostly white higher educated women who were able to afford this technology, our results cannot be generalised to all social egg freezers.

Wider implications of the findings: Our findings can contribute to a better understanding of previously identified normative arguments (e.g., individualisation and unnecessary medicalisation). There is a definite need to further analyse the complex interplay between respecting autonomous choices and evaluating contextual factors in this debate and other practices where similar individualisation arguments are used.

Trial registration number: Not applicable

P-353 When Parents and Minor Children Disagree about Fertility Preservation: A Scoping Review and Ethical Analysis

M. Bayefsky[1], V. Dorice[2], A. Caplan[3], G. Quinn[4]

[1]NYU Langone Health, Obstetrics and Gynecology, New York, U.S.A. ;
[2]NYU Grossman School of Medicine, Medical Library, New York, U.S.A. ;
[3]NYU Langone Health, Division of Medical Ethics, New York, U.S.A. ;
[4]NYU Langone Health- NYU School of Medicine, Obstetrics and Gynecology-Department of Population Health, New York, U.S.A.

Study question: Periodically, parents and children disagree about whether to pursue fertility preservation (FP). How should medical teams navigate these ethically complex situations?

Summary answer: Several considerations must be weighed, including the minor's age, the burden of the proposed procedure, and whether the minor or parent seeks to decline FP.

What is known already: As reproductive technology advances, FP prior to gonadotoxic therapy has become the standard of care. Periodically, parents and children disagree about whether to pursue FP. To date, there is no clear guidance on how to navigate these difficult situations. Prior studies have demonstrated that adolescents undergoing gonadotoxic therapy want their views regarding FP to be taken into account, and also that most children and adolescents are comfortable with parental involvement in decision-making. However, transgender adolescents pursue FP at lower rates than adolescents with cancer, and more research is required to elucidate the unique needs and barriers of transgender youth.

Study design, size, duration: This study involves a scoping review and ethical analysis about parent-child disagreement regarding FP in minors. The review analyzes papers that either demonstrate that parent-child disagreement occurs, describe the preferences of parents or children regarding decision-making around FP, or provide recommendations that can be used to resolve parent-child conflicts. The ethical analysis weighs relevant rights and interests, including the child's best interest, the right to an open future, the child's autonomy, and parental autonomy.

Participants/materials, setting, methods: A search string was developed to identify all relevant published manuscripts on the topic of FP in minors, including studies on decision-making, family relations and ethical challenges. The search was run through several databases, abstracts were screened using Covidence, and data were extracted from full texts. Data abstracted from the review and existing literature on general medical decision-making for minors were used to construct an ethical framework for parent-child disagreements regarding FP in minors.

Main results and the role of chance: Published work directly on the topic of parent-child disputes regarding FP is limited, however a number of studies tangentially discuss parent-child disagreements and provide insight into the desires of parents and children regarding decision-making around FP. Studies suggest that adolescents desire to have their views taken into account, and a minority of adolescents believe their wishes alone should be followed. The age of the minor is a crucial factor, and some propose that as adolescents approach

adulthood, their autonomy should increase. At the same time, in practice, legal and financial constraints often render parents the ultimate decision-makers. Our ethical analysis weighs competing considerations, including the child's best interest, the right to an open future, the child's autonomy, and parental autonomy. It concludes that who prevails should depend on contextual factors, including the minor's age, the burden of the proposed procedure, and whether the minor or parent seeks to decline FP. There may also be special considerations for transgender adolescents, some of whom might have deeply personal reasons for pursuing or forgoing FP that are not well-understood by cisgender parents.
Limitations, reasons for caution: The scoping review captured a variety of results, including survey and interview studies, society guidelines, and ethical analyses. As such, we were unable to define a uniform quality metric. However, we aimed to be more rather than less inclusive because of the limited results directly pertaining to parent-child disagreements.
Wider implications of the findings: This study provides a robust review of decision-making for FP in minors and offers an ethical framework for weighing countervailing considerations when parents and children disagree about whether to pursue FP. The conclusions can be used to inform guidance for clinicians presented with this challenging ethical dilemma.
Trial registration number: N/A

POSTER DISCUSSION

SESSION 75: REPRODUCTIVE SURGERY POSTER DISCUSSIONS

1 July 2021 Stream 2 11:45 - 12:45

P-745 The efficacy of Buscopan® in reducing pain during ultrasound-guided manual vacuum aspiration (USG-MVA): A double-blind randomised placebo-controlled trial

J.P.W. Chung[1], T. Law[1], D. Sahota[1], J. Mak[1], T.C. Li[1]

[1]The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Does Buscopan® reduce abdominal pain experienced by women undergoing ultrasound-guided manual vacuum aspiration (USG-MVA)?
Summary answer: The addition of 20mg Buscopan® intravenous injection was not associated with a statistical reduction in pain score but leads to a higher patient satisfaction score.
What is known already: Ultrasound-guided Manual Vacuum aspiration is a feasible and effective out-patient treatment option for treating early pregnancy loss. However, it is associated with a moderate amount of pain due to uterine contraction.
Study design, size, duration: This randomised, double-blinded, placebo-controlled trial was conducted in a university-affiliated tertiary hospital. The study assessed whether 1 ml of 20mg Buscopan® intravenous injection 5 minutes before the USG-MVA will reduce the abdominal pain experienced by the women immediately and 2 hours after the procedure. Participants were randomised between June 2018 to January 2020 using a computer-generated number series in a 1:1 ratio.
Participants/materials, setting, methods: Women aged 18 years or older with first-trimester miscarriage undergoing the USG-MVA procedure were eligible. In total, 122 participants out of 128 eligible were included. Of whom, 111 underwent the USG-MVA procedure, 60 randomised to the Buscopan® group, and 62 to the placebo group.
Main results and the role of chance: The median abdominal pain scores in the Buscopan® group were 16.0% and 21.2% lower than the placebo group immediately post-procedure and 2 hours after the procedure in the Buscopan® group. Repeated measures ANOVA indicated that the both vaginal and abdominal pain scores improved significantly with the time (Vaginal $F(1,108)= 180.1, p<0.0001$;
Abdominal: $F(1,108)=83.41, p<0.001$) but not with group. No difference was noted in the complications and side effects profile. The physiological stress measured by Log10 sAA levels reduced significantly with time ($F(2.8,286.1)= 6.3$, $p<0.001$) but not with group ($F=0.1$, $p=0.96$). Women randomised to Buscopan® had a significantly higher ($p=0.032$) mean VAS satisfaction scores compared to those receiving placebo (79.0±17.3 vs 73.4±24.1).
Limitations, reasons for caution: This study was a single-centre study, thus one should be cautious in the overall generalisability of the results.
Wider implications of the findings: Few studies have evaluated the use of anti-spasmodic agents to minimise uterine contraction pain in women undergoing outpatient uterine evacuation. We consider Buscopan® a useful adjunct in the pain control of USG-MVA to specifically reduce uterine cramps. Further larger studies are required to evaluate its efficacy

P-746 Obstetric outcomes of singleton birth after hysteroscopic division of septate uterus

O. Abuzeid[1], C. Heiselman[2], A. Fuchs[2], J. La Chance[3], K. Herrera[2], D. Garry[2], M. Abuzeid[4]

[1]Renaissance School of Medicine at Stony Brook University, Maternal Fetal Medicine, Nesconset, U.S.A. ;
[2]Renaissance School of Medicine at Stony Brook University, Maternal Fetal Medicine, Stony Brook, U.S.A. ;
[3]Hurley Medical Center/Michigan State University- College of Human Medicine, Department of Research, Flint, U.S.A. ;
[4]- Department of Obstetrics and Gynecology- Hurley Medical Center/Michigan State University- College of Human Medicine, Division of Reproductive Endocrinology and Infertility, Flint, U.S.A.

Study question: The aim of this study is to determine the obstetric outcomes in patients with a singleton birth after hysteroscopic division of septate uterus.
Summary answer: The data suggest excellent obstetric outcomes for singleton gestation after hysteroscopic division of a septate uterus reaching either the internal or the external cervical os.
What is known already: Septate uterus is a rare Müllerian anomaly with major impact on reproductive outcomes, particularly with a septum over 10mm. Controversy still exists over the need for surgical correction of the septum due to conflicting data on outcomes, particularly in women with histories of good obstetric outcomes and incidental septum findings. Placental location in relation to the septum may account for such conflicting reports. Most data on reproductive outcomes after hysteroscopic surgical correction combine both septate and subseptate uteri. There is limited published data on obstetric outcomes after hysteroscopic surgical correction of septate uteri, especially septate uteri reaching the external os.
Study design, size, duration: This retrospective cohort study included 107 patients with infertility and/or recurrent pregnancy loss (RPL) who received treatment between 2002 -2019. The study group included 24 patients with a singleton birth after hysteroscopic correction of septate uterus (Class Va; ASRM classification) that was diagnosed on trans-vaginal 3D ultrasound. The control group included 83 patients with a singleton birth who had normal endometrial cavity on hysteroscopy during the same period of time, before starting treatment.
Participants/materials, setting, methods: This study was conducted at an infertility clinic affiliated with a teaching hospital. In the study group the septum reached the internal or the external cervical os in 14 and 10 patients respectively. After hysteroscopic correction, all patients were offered various infertility treatments depending on the underlying etiology. The inclusion criterion in this study was to have a singleton birth after hysteroscopy. Demographic and clinical data and obstetric outcomes were compared between the two groups.
Main results and the role of chance: There was no significant difference in mean age, infertility duration, infertility type and incidence of male infertility or ovulatory disorders between the two groups. There was a significantly higher BMI (0.048), and a higher incidence of history of miscarriage ($P=0.002$) and history of RPL ($P=0.017$) in the study group. There was significant lower incidence of tubal factors infertility ($P=0.005$) and endometriosis ($P=0.03$) in the study group, therefore there was higher incidence of spontaneous conception (70.8% vs 19.3%; $P=0.000$) and lower incidence of conception with IVF-ET (20.8% vs 66.3%; $P=0.000$) in the study group compared to the control group respectively. There was significantly higher incidence of prophylactic cervical cerclage (17.4% vs 0%; $P=0.000$), and delivery by CS (69.6% vs 41.2%; $P=0.019$) and lower incidence of vaginal delivery (30.4% vs 58.8%; $P=0.019$), in the study group compared to the control group. There was no significant difference in

gestational age in weeks (38.3+1.8 vs 38.6+2.0), newborn birth weight in grams (3173.9+630.0 vs 3202.1+555.6), incidence of premature birth (12.5% vs 12.2%), or other obstetric complications (25% vs 17.6%) between the study and the control groups respectively. For premature births, mean gestational age was 34.3+0.47 and 34.6+1.2 weeks in the study and control groups respectively.

Limitations, reasons for caution: A retrospective study has its own inherent bias. Furthermore, the small sample size is explained by the fact that a septate uterus is a rare anomaly leading to difficulties finding cases and organizing a prospective study to achieve a larger sample size. A multicenter prospective study is needed.

Wider implications of the findings: Regardless of whether the septum reached the internal or external os, there were excellent obstetric outcomes in singleton gestations after hysteroscopic correction of septate uteri. There was no increased risk with septate uteri involving the cervix. Hysteroscopic surgical correction should be the treatment of choice for patients with septate uteri.

Trial registration number: Not Applicable

P-748 Diode laser hysteroscopic metroplasty for dysmorphic uterus: a pilot study

A. Bilgory[1], E. Shalom - Paz[1], Y. Atzmon[1], N. Aslih[1], D. Estrada[1], Y. Shibli[1], S. Haimovich[2]

[1]Hillel Yaffe Medical Center- IVF unit- Hadera- Israel., Department of Obstetrics and Gynecology- Hillel Yaffe Medical Center- Hadera- Israel- and The Ruth and Bruce Rappaport School of Medicine- Technion- Haifa- Israel., Hadera, Israel ; [2]Gynecology Ambulatory Surgery Unit- Hillel Yaffe Medical Center- Hadera- Israel., Department of Obstetrics and Gynecology- Hillel Yaffe Medical Center- Hadera- Israel- and The Ruth and Bruce Rappaport School of Medicine- Technion- Haifa- Israel., Hader

Study question: Whether diode laser hysteroscopic metroplasty for dysmorphic uterus is a safe and efficacious procedure and its effect on reproductive outcomes.

Summary answer: Diode laser hysteroscopic metroplasty is a safe and effective procedure for infertile women with dysmorphic uterus with comparable results to those reported in the literature.

What is known already: A T-shaped uterine anomaly is categorized by the ESHRE/ESGE consensus as dysmorphic uterus class U1a, characterized by an abnormal hypoplastic uterine cavity. A Y-shaped uterus is a dysmorphic uterus with a fundal subseptum. Dysmorphic uteri are associated with infertility, recurrent implantation failure (RIF), recurrent pregnancy loss (RPL), and adverse pregnancy outcomes. According to several studies, it seems that hysteroscopic metroplasty may improve the chances of conception and live birth. Previous studies described the procedure using bipolar systems, monopolar needle or scissors. The purpose is to achieve a uterine cavity of normal shape and volume by cutting the thickened lateral walls.

Study design, size, duration: This was a retrospective pilot study with a prospective follow-up. We retrospectively evaluated all cases operated between February 2018 to February 2020, at Hillel Yaffe Medical Center, Hadera, Israel. Reproductive outcomes for women who underwent the procedure were followed until September 2020. Pregnancies that were ongoing on September 2020 were followed until January 31st 2021.

Participants/materials, setting, methods: Nulliparous women with a diagnosis of infertility or RPL, who were diagnosed with dysmorphic uterus by three-dimensional ultrasound (3D-US) and underwent diode laser hysteroscopic metroplasty were included. All the metroplasties were done in one tertiary center by the same specialist. Reproductive outcomes were evaluated retrospectively and prospectively for a total follow-up time of 32 months. Reproductive performances before and after metroplasty were compared where possible.

Main results and the role of chance: Twenty-five women underwent diode laser hysteroscopic metroplasty for dysmorphic uterus in our institute. No perforations, excessive bleeding, or other complications were encountered during the procedures. Follow-up hysteroscopy and 3D-US were satisfactory in all cases 2 months after the metroplasty. A total of 15 nulliparous women returned to fertility treatments afterwards, among whom 9 conceived (60% pregnancy rate). Their infertility period before the procedure was 56.6 ± 36.1 months. The duration between the metroplasty to pregnancy was 5.2 ± 3.5 months. The rate of deliveries and ongoing pregnancies (pregnancies beyond 20 weeks of gestation) was 78% (7/9), with five successful liveborn deliveries and two ongoing pregnancies. All deliveries were between 36-37 weeks. The 10 women who were not treated by our infertility unit were contacted, among whom 6 discontinued their attempt to conceive. The other 4 conceived; three of them spontaneously. Among those 4 women,the rate of deliveries and ongoing pregnancies was 75%, with one term delivery and two ongoing pregnancies.

Limitations, reasons for caution: First, we included both T-shaped and Y-shaped uteri as both represent close versions of dysmorphic uteri, but in fact they differ. The subseptum might interfere with reproduction in a different mechanism. Second, the small and heterogeneous sample as well as the short duration of follow-up limit the conclusions.

Wider implications of the findings: We present the first application of diode laser in hysteroscopic metroplasty for dysmorphic uteri. This technique seems promising and our results are comparable with other series using different cutting devices. Only larger controlled trials with a longer follow-up can confirm the safety, efficacy, and impact on reproductive outcomes.

Trial registration number: Not Applicable

P-750 Clinical efficacy of virtual reality for acute pain and anxiety management during outpatient hysteroscopy and endometrial biopsy in subfertile patients

V. Schutyser[1], R. Buyl[2], M. De Vos[1], H. Tournaye[1], C. Blockeel[1]

[1]Universitair Ziekenhuis, Centre for Reproductive Medicine- CRG, Brussels, Belgium ; [2]Vrije Universiteit Brussel, Biomedical Statistics And Informatics, Brussels, Belgium

Study question: Does the use of virtual reality (VR) headsets in diagnostic office hysteroscopy (HSC) with endometrial biopsy (EB) reduce anxiety and pain scores in the patient?

Summary answer: Virtual reality during office HSC do not seem to improve relaxation, anxiety, or pain scores. Physicians have a good perception of patients' pain.

What is known already: Women undergoing outpatient HSC experience high levels of preoperative anxiety, which increase pain and discomfort during the procedure. The experience of pain is a complex phenomenon, which simultaneously occurs on cognitive, emotional, and behavioural levels, and is influenced by many factors. A Cochrane review failed to show a significant difference between different types of pain relief (analgesics, local anaesthetic and verbal support techniques …). VR is a multisensory immersion providing an interactive high level distraction, occupying a large portion of humans' finite attentional resources (vision and audio), and leaving less cognitive capacity available to process pain.

Study design, size, duration: The sample size for this prospective randomized controlled trial was calculated at 196 patients (98 per group), considering a power of at least 80% to detect superiority of adding a VR headset versus standard care, standard deviation (SD=2.0), using a two-sided, t-test, at significance level alpha of 0.05.

The preliminary results after 1 month include a sample of 48 patients: 25 in the VR group and 23 controls.

Participants/materials, setting, methods: All 48 patients suffer subfertility and underwent HSC with EB at our tertiary-care fertility center. We used Oncomfort®, a commercially available VR autohypnosis relaxation program designed for perioperative settings. The headmounted smartphone display with headphones provides image sound distraction with suggestive hypnosis techniques incorporated. Before and immediately after the exam, both patients and surgeons fill out a questionnaire using the 10.0cm visual analog scale (VAS).

Main results and the role of chance: The mean duration of HSC was 3min43sec in the VR group, (range 2-6min), compared to 4min50 in the control group (range 1-12minutes), which was not significantly different (p=0.09). Subjective variables of stress, anxiety and pain were evaluated at four different time points, i.e. before, during, immediately after HSC and one week later.

According to VAS, stress levels did not differ significantly (p>0.05) between the VR group and the control group, or within time: 5.08 to 5.36 to 3.08 vs 4.48 to 4.83 to 2.48 before, during and after HSC respectively. Fear levels prior to HSC at 4.28 for VR patients and 3.52 for controls did not increase significantly during HSC in both groups: 4.44 vs 4.17. During HSC, pain levels increased from 1.40 to 4.720 in the VR group vs 0.65 to 4.109 (NS) in the controls, to decrease again afterwards to 2.60 vs 2.17 (NS) respectively.

Physicians rated the average pain levels of VR patients as 3.32 compared to 3.0 for controls, which was significantly correlated to patients' perception (p<0,005). Patients gave a positive rating to the VR experience (satisfaction score 7.17).

Limitations, reasons for caution: These are preliminary results, evaluating only a fourth of the required sample. A population selection bias could exist, as recruited patients were willing to accept VR. The very short induction period of 2 minutes could influence the effect of (immersiveness into) VR.
Wider implications of the findings: Pain management in ambulatory procedures should be multimodal and should include both pharmacological and non-pharmacological interventions. Introducing VR might increase patient tolerance for longer or more painful procedures. Offering a range of options will increase the spectrum of successful procedures *in the outpatient setting* and improve patient experience.

POSTER DISCUSSION

SESSION 76: STEM CELLS POSTER DISCUSSIONS

1 July 2021 Stream 3 11:45 - 12:45

P-796 Trial of Autologous Marrow derived Stem Cell Ovarian Transplantation (TAMSCOT) in young infertile women with diminished ovarian reserve for ovarian rejuvenation – HOPE still persists

N. Singh, M.B.B.S.- M.D.[1], Y. Dogra[1], S. Mohanty[2], T. Seth[3]

[1]All India Institute Of Medical Sciences AIIMS, Department of Obstetrics & Gynaecology, New Delhi, India ;
[2]All India Institute Of Medical Sciences AIIMS, Stem cell facility, New Delhi, India ;
[3]All India Institute Of Medical Sciences AIIMS, Department of Haematology, New Delhi, India

Study question: Does autologous bone marrow derived stem cell (BMDSC) ovarian transplantation optimize ovarian reserve parameters in young infertile women with diminished ovarian reserve (DOR) ?
Summary answer: The autologous stem cell ovarian transplantation (ASCOT) improves AFC and AMH by facilitating the recruitment of existing dormant follicles in young women with DOR.
What is known already: Oocyte donation is the practical therapeutic option when patients with premature ovarian ageing desire pregnancy. It involves significant psychological burden in terms of not able to have their own biological child. ASCOT has opened new doors in poor responders and premature ovarian insufficiency through its beneficial effects on ovarian reserve and IVF outcomes. However recent studies have shown contradictory results in terms of its efficacy. No prior study has been contemplated in DOR group
Study design, size, duration: An open label non randomized controlled trial was conducted at Division of Reproductive Medicine in collaboration with stem cell facility at tertiary care institute. Forty two infertile women less than 35 years age with DOR (AFC<5, AMH<1.2ng/ml and /or high FSH>8IU/l) were enrolled in the study during a period from January 2020 to December 2020. 20 women who did not opt for the intervention were treated as control group whereas 22 women received the intervention.
Participants/materials, setting, methods: Baseline hormonal profile (Day 2 FSH, estradiol, AMH and AFC) was done in all patients. Women with abnormal uterine cavity, endometriosis, prior ovarian surgery, abnormal karyotype were excluded. Bone marrow aspiration followed by mesenchymal stem cells isolation was performed. The stem cells were transplanted in both the ovaries through transvaginal route on the same day. Follow up visits were planned at one and six months to assess ovarian reserve parameters.
Main results and the role of chance: The mean age, BMI and duration of infertility were comparable between the control and study group (29.5±3.34vs 29.36±2.95years, 21.51±1.40vs21.87±1.93kg/m2, 6.9±1.94vs7.04±3.67 years). The positive response in terms of improved AMH and AFC was seen in 68% (15/22) patients. The mean number of stem cells injected in these women were 77.71±25.33 million. At first follow up, there was no significant difference between mean FSH, estradiol levels and mean right and left ovarian volume (9.23±3.95 vs 9.02±3.92mIU/l, 61.46±29.25 vs 68.12±62.52 pg/ml, 2.82±2.18 vs 2.44±1.25 cc, 2.02±1.54 vs 2.72±1.06 cc, p<0.05). There was significant increase in AMH and AFC values as compared to baseline (0.79±0.43 vs 1.26±0.82ng/ml, p=0.03; 3.47±1.30 vs 6.40±2.23, p<0.001). At second follow up visit, the significant increase in ovarian reserve persisted for AMH and AFC (0.79±0.43 vs 1.22±0.76 ng/ml, p=0.02; 3.47±1.30 vs 6.93±1.71,p<0.001). There was no significant difference between serum FSH , Estradiol and ovarian volume. None of the patients developed any complication and the improvement in AFC and AMH persisted during 10 month follow up period.
Limitations, reasons for caution: The limitation of present study is small sample size and non randomization. However, time period for which positive effect lasts has not been documented in earlier studies. This study is currently being endeavored, and women with improved ovarian reserve are followed up for any spontaneous conception or following assisted reproduction.
Wider implications of the findings: The present study demonstrates beneficial role of stem cells in improving ovarian reserve parameters in women with DOR with no acquired cause. If supported by future randomized clinical studies, it could represent a paradigm shift for fertility treatment in these women providing an opportunity to have their own biological child
Trial registration number: CTRI/2020/01/022726

P-797 A novel method for establishing human embryonic stem cells independent of feeder cells

B. Cai[1]

[1]First Affiliated Hospital of SunYat-sen University, reproductive medicine center, Guangzhou-Guangdong, China

Study question: Is there a efficient establishing method of human embryonic stem cells directly from the human blastocysts independent of feeder cells?
Summary answer: We established a novel method of generating human embryonic stem cells directly from human blastocysts independent of feeder layer cells.
What is known already: Establishing embryonic stem cells lines mainly needed to coculture ICM clumps with feeder cells (like mouse or human fibroblasts) ,this brought in potential heterogeneous pollution.Although there had be some reports about generating human ESCs independent of feeder cells,but the efficiency was low and conditioned medium were unstable and also had the biological contamination.
Study design, size, duration: We used ten day5/6 donated human blastocysts from our reproductive center ,most of them were genetically diseased embryos with abnormal PGT diagnosis.After establishing ESCs procedure , all the cell lines were identified with pluripotency and differentiation potential tests. The success rate of system was calculated and compared with the conventional methods.
Participants/materials, setting, methods: In brief, ICM clumps were separated mechanically by using a micromanipulation system,and then transferred to a 30ul mTESR plus culture media drop pretreated with the geltrex (1:100 dilution) matrix and oxygen concentration was 5%. When cells attached and migrated,we also used laser to destroy the remaining trophoblast cells.About 10 days,the typical ES clone can be mechanically passaged and cells can be cultured in normal oxygen concentrations after passage 2..
Main results and the role of chance: Using this method we had successfully established nine embryonic stem cell lines from donated human blastocysts ,the success rate was 90% (9/10). Each cell lines had passed the evaluation test of embryonic stem cell. When compared with the conventional feeder cells dependent method,our novol methods not only eliminated the pollution from heterogeneous cells,but also had higher success rate (90% vs 25%).
Limitations, reasons for caution: Due to the scarcity of donated human blastocysts, this experiment was a single-center experiment with small samples.
Wider implications of the findings: We speculated that the batch differences of culture dishes, matrix and culture medium might affect the establish efficiency , and how to carry out a high level of quality control work might be the key factor to keep the system stable.
Trial registration number: basic research

P-798 Fertility preservation in pre-pubertal boys with cancer: A three-dimensional prepubertal testicular organoid for in vitro spermatogonial stem cell propagation and spermatogenesis

S. Tang[1], C. Jones[1], K. Coward[1]

[1]University of Oxford, Department of Women's and Reproductive Health, OXford, United Kingdom

Study question: Can a three-dimensional (3D) prepubertal testicular organoid be formed and provide an *in vitro* microenvironment for spermatogonial stem cells (SSCs) maintenance and future spermatogenesis?
Summary answer: Primary cells extracted from immature testicular tissue (ITT) or SSCs can be grown long-term as 3D organoids, providing the potential for *in vitro* study.
What is known already: Aggressive cancer treatments, such as chemo- or radiotherapy, can leave young prepubertal boys infertile. Such patients are recommended to undergo the cryopreservation of testicular material to protect future fertility. Within the testes, the specialized 3D structure and direct cell-to-cell interactions play a critical role in the proliferation and development of SSCs. Over recent decades, 3D culture systems and organoids have been used to culture cells *in vitro*, however, a system that allows investigations into testicular organogenesis *in vitro*, and its impact on the SSC niche, has yet to be developed.
Study design, size, duration: This study aims to develop a 3D organoid culture system to support the proliferation of SSCs and spermatogenesis. Primary bovine ITT cells and enriched SSCs were isolated and 3D organoids were generated by *in vitro* culture for up to 40 days. Organoid formation was observed after using different foundation cells seeded at different densities and cultured in medium containing gonadotropic supplements.
Participants/materials, setting, methods: Post-thaw bovine ITTs (2 weeks-of-age) were dissociated using two-step enzymatic digestion. Enriched SSCs were selected by Percoll gradients and differential plating. Viability and apoptosis were evaluated by trypan blue staining and TUNEL assays, respectively. SSCs were evaluated immunocytochemically for germ-cell markers (PGP-9.5, PLZF) and Sertoli cell markers (Vimentin, Sox9). Expression levels of SSCs and spermatogenesis-related genes (*Plzf, Gfrα-1, Nanog, Oct4, Stra8, Thy1*) were determined by real-time quantitative polymerase chain reaction (RT-qPCR).
Main results and the role of chance: The viability of digested cells from thawed ITTs was 78.667% ± 2.03. Total testicular cells (<10% SSCs) and enriched SSCs(>50% SSCs) were observed to self-assemble into structurally complex organoids recapitulating the cell type compartmentalization of the testis, in a 3D Matrigel-based culture system with 10% knockout serum replacement (KSR) culture medium, but not with 10% fetal bovine serum(FBS) medium. Testicular organoids were found to exhibit either a grape-like structure and a round-shape structure. Cytoplasmic extensions of spermatogonia/Sertoli cells were in contact with each other within a forming colony. Organoids were formed faster and larger when seeded at a final concentration of 1.5 × 106 cells/ml, compared to 5 × 105 cells/ml and 1.5 × 105 cells/ml. Organoids grew to a diameter of 400 µm within 10 - 15 days and were passaged by mechanical disruption at a ratio of 1:3 every 7 - 10 days. Immunocytochemistry results showed that clusters of PGP9.5 and PLZF-positive cells were present within the organoids. The expression of selected germ cell and spermatogenesis markers in the testicular organoids closely resembled that of primary testicular cells for up to 20 days of culture.
Limitations, reasons for caution: We used calves (2 weeks-of-age) as an animal model to study testicular organoids. This tissue may act differently than human tissues and may not fully represent prepuberty. Furthermore, we only evaluated gene expression levels for selected markers that may not represent the full functional capability of germ cells.
Wider implications of the findings: Testicular organoids, as an *in vitro* bioengineering testicular model, could potentially be used to study testicular tissue development, cellular interactions, endocrinology, and spermatogenesis, in the laboratory but may also be applied for clinical purposes in the future.
Trial registration number: University of Oxford

P-805 Artificial oocytes: from somatic cells to fertile pups

O. Kocur[1], A. Trout[1], P. Xie[1], A. Petrini[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: We analyzed the efficacy of generating artificial oocytes using somatic cells (SCs) from two mouse strains (B6D2F1 and FVB) and followed their full pre-/post-implantation development.
Summary answer: While artificial oocytes generated from the new strain (FVB) had higher fertilization rates, those from the standard strain (B6D2F1) provided expanded blastocysts and fertile pups.
What is known already: B6D2F1 is a popular hybrid mouse strain for cloning and transgenic creation due to its geno-/pheno-typic uniformity and high oocyte yield and quality. Indeed, B6D2F1 oocytes have a distinct metaphase II (MII) spindle complex, making them an ideal candidate to generate ooplasts used in SC nuclear transfer (SCNT). However, because they lack genetic variance, they are less suitable for reciprocal SCNT studies. In contrast, FVB mice have single nucleotide polymorphisms and indels on each chromosome that can aid in tracing the pedigree of progeny.
Study design, size, duration: A total of 10 experiments were performed over the course of 3 months, using 30 stimulated mice. SCs were retrieved from cumulus oophorus harvested from FVB and B6D2F1 mice. SCs from both strains were injected into enucleated MII B6D2F1 oocytes. Unmanipulated B6D2F1 oocytes were piezo-ICSI inseminated, serving as controls. The occurrence of haploidization, fertilization, and full preimplantation development was compared. Some blastocysts were transferred into pseudo-pregnant CD-1 mice to obtain offspring.
Participants/materials, setting, methods: Oocyte enucleation was performed under Oosight™ visualization and cytochalasin B exposure. An FVB or B6D2F1 SC was transferred into the perivitelline space of the ooplast with Sendai virus to promote fusion. Haploidization was monitored by pseudo-meiotic spindle formation followed by extrusion of a pseudo-polar body after insemination. Conceptuses were cultured in a time-lapse imaging system, with piezo-ICSI controls. Expanded blastocysts were transferred into uterine horns of pseudo-pregnant mice. Offspring were mated to test their fertility.
Main results and the role of chance: FVB (n=278) and B6D2F1 (n=905) SCs at G0 phase, with a diameter <10 mm, were chosen for SCNT and transferred into enucleated B6D2F1 ooplasts. Enucleation of 1,212 oocytes yielded a survival rate of 97.6%. Both FVB and B6D2F1 SCNT resulted in similar survival rates of 100% and 98.5%, respectively. Successful haploidization, determined by the presence of a pseudo-meiotic spindle 2 hours after SCNT, was also comparable, with 59.9% of FVB and 63.7% of B6D2F1. Survival after piezo-ICSI was also comparable between FVB- and B6D2F1-reconstituted oocytes, with rates of 64.3% and 60.3%, respectively, albeit lower than the control (75.2%, $P<0.00001$). FVB embryos fertilized at a rate of 88.7%, comparable to the control zygotes at 85.8%, while B6D2F1 conceptuses demonstrated a lower fertilization rate (70.8%, $P<0.00001$). Blastulation of FVB- and B6D2F1-derived embryos was 15.1% and 24.0%, respectively, while the control was 80.7% ($P<0.00001$). Whole-genome karyotyping of 9 B6D2F1-derived blastocysts confirmed 5 of the samples to be euploid. FVB blastocysts (N=8) and B6D2F1 blastocysts (N=81) were transferred into pseudo-pregnant mice, resulting in 3 fertile offspring only from the B6D2F1 conceptuses.
Limitations, reasons for caution: This is still a limited number of observations, and pups were delivered only from the B6D2F1 strain. The utilization of a strain with higher genetic variance may help facilitate offspring fingerprinting.
Wider implications of the findings: This study demonstrates the ability to generate artificial genotyped conceptuses, yielding live offspring. The identification of a feasible donor cell, together with optimization of cell cycle stage and standardization of post-implantation development, will help promote this technique for human reproduction in couples with age-related infertility or poor ovarian reserve.

INVITED SESSION

SESSION 77: DEMOGRAPHIC IMPACT OF ART

01 July 2021 Stream 4 11:45 - 12:45

O-069 A demographic revolution? Social representations confronted with statistics

E. De La Rochebrochard[1]

[1]National Institute for Demographic Studies, Sexual and reproductive Health and Rights Research Unit, Aubervilliers, France

Abstract text

Assisted reproductive technologies (ART) regularly hit the media. Most people have an idea of ART that is based only on this prism. This restrictive view may

lead to major discrepancy between what the general population thinks of these treatments and the everyday reality of ART. The most striking example of this discrepancy is probably the use of third party donors (sperm, oocyte, embryo or gestational donation). In France, the media focus almost exclusively on ART with a third party donor. The personalities who relate their experience in the media or in autobiographies are all children (now adults or adolescents) who were conceived with a third-party donor. Nevertheless, 95% of children conceived by ART in France have not been conceived through a third party. The media also highlight exceptional individual stories that give rise to strong societal controversies, such as Natalie Suleman (USA) who was called "Octomom" after she gave birth to octoplets, or Maria del Carmen Bousada de Lara (Spain) and Adriana Iliescu (Romania) who gave birth at age 66, or more recently Lulu and Nana (China) who were genetically modified twin sisters. Such reports can arouse wonder or fear, but both lead to a social representation of ART as an "omnipotent" technique. Infertile couples whose knowledge of ART is based on the media coverage may venture into these treatments thinking that as their case is an "ordinary" one, there should be no problem for them in having a baby through these technologies.

Clinical statistics on ART show that even if the success rate is high, there is a gap between social expectations and reality. These statistics can be misleading, as they often assume that the couple has undergone several ART cycles. The objective of clinical statistics is usually to measure the efficacy of ART from a medical viewpoint, not from the standpoint of the couples' care pathways. The gap between the two is considerable. The pathways of couples who undertake ART are marked by pitfalls that strongly affect success rates because of the risk of treatment dropout. In some countries, economic factors are a major reason for dropout because of the high cost of ART. France is a very interesting textbook case to explore this issue, as all infertility treatments are fully reimbursed for up to six artificial inseminations and four in vitro fertilizations for each birth. Economic barriers to ART access are minimal in such a favorable national context. Nevertheless, only about half of couples treated by ART finally become parents and success rates drop dramatically in older women. This epidemiological statistical reality is difficult to reconcile with the media presentation of ART as "omnipotent". However, "natural miracles" can also occur as spontaneous births have been observed among couples unsuccessfully treated by ART. There are also other pathways to parenthood, such as adoption of a child.

Thanks to ART, every year numerous couples become parents. But for infertile couples, the everyday reality is far from the "omnipotence" acclaimed by media headlines. The social representation of ART must move toward a more balanced perception of these technologies, bearing in mind its successes and also its limitations, especially with the current demographic trend towards childbearing at a later age that may lead to an increase in demand for ART. Change in the social representation of ART will probably need to go far beyond classic public health campaigns. ART will need to be approached differently in cultural spaces such as the media but also in movies, series or novels that have a major influence on collective social imaginaries and representations.

O-070 Demographic impact of increased ART use in European countries

SESSION 78: RECENT DEVELOPMENTS IN EMBRYO SELECTION

01 July 2021 Stream 1 14:00 - 15:15

O-219 Detailed morpho-kinetic analysis of the first cleavage can help in evaluating the viability of direct-cleaved human zygotes

T. Shimura[1], **K. Yumoto**[1], **M. Sugishima**[1], **Y. Mio**[1]

[1]*Mio Fertility Clinic, Reproductive Centre, Yonago, Japan*

Study question: Why do some direct-cleaved human zygotes still lead to a live birth?

Summary answer: Direct-cleaved zygotes which have undergone the 2-cell stage can lead to a live birth, while zygotes cleaved from 1-cell to ≥3-cell do not.

What is known already: In recent years, zygotes that develop from 2-cell to 3-cell within 5 hours after the first cleavage have been evaluated as "direct-cleaved" zygotes, because normal cleavage takes approximately 12 hours to complete. It was reported that their implantation rate was significantly lower than zygotes with normal cleavage pattern, and eliminating direct-cleaved zygotes from transfer could improve the implantation rate. However, some direct-cleaved zygotes at the first cleavage could still lead to a live birth. Few reports have examined the difference between a cleavage from 1-cell to ≥3-cell and 2-cell to ≥3-cell within 5 hours after the first cleavage.

Study design, size, duration: A retrospective study involving 2,077 cycles of IVF/ICSI between July 2012 and July 2019. A total of 5,991 normally fertilized zygotes (2PN/2PB) were included. Of those, 3,508 were evaluated as usable good/fair quality embryos on Day2/3, and the rest (n=2,483) were evaluated as poor quality and rejected from transfer or cryopreservation after 7 days of culture. Of 3,508 usable embryos, 884 were selected based on the availability of results of live birth for this study.

Participants/materials, setting, methods: Time-lapse imaging (5 slices along Z-axis every 10 minutes) was performed in EmbryoScopeTM. Zygotes were morphokinetically analyzed in detail and classified into four groups by their cleavage patterns: Group1 (1-cell→2-cell); Group 2 (1-cell→3-cell); Group 3 (1-cell→2-cell→≥3-cell within 5 hours after the first cleavage); and Group 4 (1-cell→2-cell→≥5-cell). The proportion, mean maternal age and live birth rate of each group were examined.

Main results and the role of chance: The proportion of Groups 1-4 was 83.6% (n=739), 3.8% (n=34), 5.9% (n=52), and 6.7% (n=59), respectively. 0f 884 zygotes examined in this study, the mean maternal age was significantly higher in Group 2 and 4 than in Group 1 ($P < 0.05$; 37.4±4.9 in Group1, 39.1±5.2 in Group 2, 38.6±6.0 in Group 3, and 38.7±5.1 in Group 4). The rate of confirmed gestational sac was significantly lower in Group 2 and 4 than in Group 1 [$P < 0.01$; 36.3% (n=268/739), 0% (n=0/34), 25.0% (n=13/52), and 18.6% (n=11/59) in Groups 1-4, respectively]. Furthermore, the live birth rate was significantly higher in Group 1 than in Groups 2, 3 and 4 [$P < 0.01$; 28.4% (n=210/739), 0% (n=0/34), 13.5% (n=7/52), and 15.3% (n=9/59) in Groups 1-4, respectively]. Above all, while zygotes in Group 2 showed no pregnancy and live birth at all, zygotes in Group 3 showed a live birth rate of 13.5%. However, they had a significantly higher miscarriage rate (42.9%, n=6) compared to zygotes in Group 1 (19.5%, n=55).

Limitations, reasons for caution: It is very difficult to capture cleavage patterns by routine observations because the timings of developmental events are different between embryos. A time-lapse imaging and culturing system is essential to solve this problem, however, it cannot visualize the distribution of chromosomes, and no chromosomal analysis was conducted in this study.

Wider implications of the findings: This study revealed that zygotes previously classified as "direct-cleaved" and eliminated from transfer included viable zygotes which could lead to a live birth. Therefore, it is crucial to optimize the use of time-lapse imaging of human zygotes in order to precisely evaluate the first cleavage.

Trial registration number: not applicable

O-220 An annotation-free embryo scoring system (iDAScore®) based on deep learning shows high performance for pregnancy prediction after single-vitrified blastocyst transfer

S. Ueno[1], **M. Ito**[1], **K. Uchiyama**[1], **T. Okimura**[1], **A. Yabuuchi**[2], **K. Kato**[3]

[1]*Kato Ladies Clinic, IVF Laboratrory, Tokyo, Japan ;*
[2]*Kato Ladies Clinic, R&D division, Tokyo, Japan ;*
[3]*Kato Ladies Clinic, Gynecology, Tokyo, Japan*

Study question: How is the performance of an automated embryo scoring system for pregnancy prediction after single-vitrified blastocyst transfer (SVBT) compared to other, annotation-dependent blastocyst grading systems?

Summary answer: Automatic embryo ranking by iDAScore shows a higher or equal performance, with regards to pregnancy prediction after SVBT, compared to manual, annotation-dependent grading systems.

What is known already: Blastocyst viability can be assessed by blastocyst morphology grades and/or morphokinetic parameters. However, morphological and morphokinetic embryo assessment is prone to both inter- and intra-observer variation. Recently, embryo ranking models have been developed based on artificial intelligence (AI) and deep learning. Such models rank embryos according to their potential for pregnancy only based on images and do not require any user-dependent annotation. So far, no study has independently assessed the performance of AI models compared to other embryo scoring models, including traditional morphological grading.
Study design, size, duration: A total of 3,014 SVBT cycles were retrospectively analysed. Embryos were stratified according to SART age groups. The quality and scoring of embryos were assessed by iDAScore v1.0 (iDAS, Vitrolife, Sweden), KIDScore™ D5 v3 (KS; Vitrolife), and Gardner criteria. The performance of the pregnancy prediction for each embryo scoring model was compared using the area under curve (AUC) of the receiver operating characteristic curve for each maternal age group.
Participants/materials, setting, methods: Embryos were cultured in the EmbryoScope+ and EmbryoScopeFlex (Vitrolife). iDAS was automatically calculated using the iDAScore model running on the EmbryoViewer (Vitrolife). KS was calculated in EmbryoViewer after annotation of the required parameters. ICM and TE were annotated according to the Gardner criteria. The degree of expansion in all blastocysts was Grade 4 due to our freezing policy. Furthermore, Gardner's scores were stratified into four grades (Excellent: AA, Good: AB BA, Fair: BB, Poor: others).
Main results and the role of chance: The AUCs of the < 35 years age group (n = 389) for pregnancy prediction were 0.72 for iDAS, 0.66 for KS and 0.64 for Gardner criteria. The AUC of iDAS was significantly higher (P< 0.05) compared to the other two models. For the 35–37 years age group (n = 514) the AUCs were 0.68, 0.68, and 0.65 for iDAS, KS and Gardner, respectively, and were not significantly different. The AUCs of the 38–40 years age group (n = 796) were 0.67 for iDAS, 0.65 for KS and 0.64 for Gardner criteria and where was not significantly different. The AUCs of the 41–42 years age group (n = 636) were 0.66, 0.66, and 0.63 for iDAS, KS and Gardner, respectively, and there was no significant difference among the pregnancy prediction models. For the > 42 years age group (n = 389) AUCs were 0.76 for iDAS, 0.75 for KS and 0.75 for Gardner criteria and not significantly different. Thus, for all age groups, iDAS was either highest or equal to the highest AUC, although a significant difference was only observed for the youngest age group.
Limitations, reasons for caution: In this study, SVBT was performed after minimal stimulation and natural cycle in vitro fertilisation (IVF). Therefore, we had only few cycles with elective blastocyst transfer. However, there was also no bias in selecting the embryos for SVBT.
Wider implications of the findings: Our results showed that objective embryo assessment by a completely automatic and annotation-free model, iDAScore, does perform as good or even better than more traditional embryo assessment or an annotation-dependent ranking tool. iDAS could be an optimal pregnancy prediction model after SVBT, especially in young and advanced age patients.
Trial registration number: not applicable

O-221 Stage and morphology of the competent blastocyst are associated with pregnancy and birth outcomes; a multicenter cohort study

M.L. Groendahl[1], M. Buhl Borgstrøm[2], U. Schiøler Kesmodel[3]

[1]Copenhagen University Hospital, Fertility Clinic, Herlev, Denmark ;
[2]Copenhagen University Hospital and Aalborg University, Fertility Clinic, Herlev, Denmark ;
[3]Aalborg University Hospital and Aalborg University, Fertility Clinic, Aalborg, Denmark

Study question: Do stage and morphology of the competent blastocyst associate with initial hCG rise, gestational age, preterm birth, child birth weight, length, and child sex?
Summary answer: Higher stage, TE- and ICM-scores associated with higher hCG-rise; ICM- and TE-scores associated with length at birth, and higher stage and TE-score associated with boys.
What is known already: Many studies have focused on the developmental stage and morphology of the blastocysts in order to find biomarkers of competence to improve the efficacy of assisted reproduction technology treatment. In contrast, the associations between blastocyst assessment score parameters (individually or by combined score) and perinatal outcome have only been reported in few and smaller single center studies, and conflicting results have been presented. In the present study, we focused on the in vitro cultured blastocyst leading to a live birth and how the stage and morphology of these competent blastocysts relate to implantation and birth outcomes.
Study design, size, duration: Multicenter historical cohort study based on exposure (blastocyst stage (1-6) and morphology (trophectoderm (TE) and inner cell mass (ICM): A,B,C)) and outcome data (serum human chorionic gonadotrophin (hCG), gestational age, preterm birth, child weight, length, and sex) from women undergoing single blastocyst transfer resulting in singleton pregnancy and birth. Data from 16 private and university-based facilities for clinical services and research from 2014 to 2018 was included.
Participants/materials, setting, methods: 7246 women, who underwent ovarian stimulation or Frozen-thawed-Embryo-Transfer with single blastocyst transfer resulting in singleton pregnancy were identified. Linking to the Danish Medical Birth Registry resulted in a total of 4842 women with live birth being included. Initial serum hCG value (IU/L) (11 days after transfer), gestational age (days), preterm birth (%) child weight (grams), length (cm) and sex. The analyses were adjusted for female age, BMI, smoking, center, diagnosis, parity, gestational age and sex.
Main results and the role of chance: Higher mean initial hCG was consistently positively associated with higher developmental stage (p<0.001), TE (p<0.001) and ICM score (p=0.02); for stage 6, TE (A) and ICM (A): 508.4, 436.5 and 428.5 IU/L, respectively. No differences between blastocyst morphology (stage, TE, ICM), gestational age (mean 276.6 days), preterm birth (8.3%) and birth weight (mean 3461.7 gram) were statistically significant. While stage showed no association with length at birth (mean 51.6 cm), length at birth between blastocysts with a TE score C and a TE score A were statistically significant (mean difference 0.5 cm (0.07;0.83)) as was the length at birth between blastocysts with an ICM score B and C compared to score A, mean differences respectively 0.2 cm (0.02;0.31) and 0.5 cm (0.03;0.87). Stage and TE, but not ICM were associated with the sex of the child. Blastocysts transferred with stage score 5 compared to blastocysts transferred with score 3 had a 33% increased probability of being a boy (OR 1.33 (1.08;1.64)). Further, TE score B blastocysts compared to TE score A blastocysts had a 28% reduced probability of being a boy (OR 0.72 (0.62;0.82)).
Limitations, reasons for caution: The assessment scores of the blastocysts´ stage and morphology were based on subjective evaluation, and information bias may have influenced the results. By adjusting for center, we took the potential variation in scoring between clinics into considerations.
Wider implications of the findings: Stage and morphology of the competent blastocyst was associated with initial hCG rise suggesting an effect on implantation, which may be used in routine, everyday information to women and couples on the day of blastocyst transfer.
Trial registration number: j.nr.: VD-2018-282

O-222 An artificial intelligence model that was trained on pregnancy outcomes for embryo viability assessment is highly correlated with Gardner Score

S. Diakiw[1], M. VerMilyea[2,3], J.M.M. Hall[1,4], K. Sorby[5], T. Nguyen[1], M.A. Dakka[1], D. Perugini[1], M. Perugini[1]

[1]Presagen, Life Whisperer, Adelaide, Australia ;
[2]Ovation Fertility, IVF Laboratory, Austin, U.S.A. ;
[3]Texas Fertility Center, IVF Laboratory, Austin, U.S.A. ;
[4]Australian Research Council Centre of Excellence for Nanoscale BioPhotonics, The University of Adelaide, Adelaide, Australia ;
[5]Number 1 Fertility, IVF Laboratory, Melbourne, Australia

Study question: Do artificial intelligence (AI) models used to assess embryo viability (based on pregnancy outcomes) also correlate with known embryo quality measures such as Gardner score?
Summary answer: An AI for embryo viability assessment also correlated with Gardner score, further substantiating the use of AI for assessment and selection of good quality embryos.
What is known already: The Gardner score consists of three separate components of embryo morphology that are graded individually, then combined to give a final score describing Day 5 embryo (blastocyst) quality. Evidence suggests

the Gardner score has some correlation with clinical pregnancy. We hypothesized that an AI model trained to evaluate likelihood of clinical pregnancy based on fetal heartbeat (in clinical use globally) would also correlate with components of the Gardner score itself. We also compared the ability of the AI and Gardner score to predict pregnancy outcomes.

Study design, size, duration: This study involved analysis of a prospectively collected dataset of single static Day 5 embryo images with associated Gardner scores and AI viability scores. The dataset comprised time-lapse images of 1,485 embryos (EmbryoScope) from 638 patients treated at a single in vitro fertilization (IVF) clinic between November 2019 and December 2020. The AI model was not trained on data from this clinic.

Participants/materials, setting, methods: Average patient age was 35.4 years. Embryologists manually graded each embryo using the Gardner method, then subsequently used the AI to obtain a score between 0 (predicted non-viable, unlikely to lead to a pregnancy) and 10 (predicted viable, likely to lead to a pregnancy). Correlation between the AI viability score and Gardner score was then assessed.

Main results and the role of chance: The average AI score was significantly correlated with the three components of the Gardner score: expansion grade, inner cell mass (ICM) grade, and trophectoderm grade. Average AI score generally increased with advancing blastocyst developmental stage.

Blastocysts with expansion grades of ≥3 are generally considered suitable for transfer. This study showed that embryos with expansion grade 3 had lower AI scores than those with grades 4-6, consistent with a reduced pregnancy rate. AI correlation with trophectoderm grade was more significant than with ICM grade, consistent with studies demonstrating that trophectoderm grade is more important than ICM in determining clinical pregnancy likelihood.

The AI predicted Gardner scores of ≥2BB with an accuracy of 71.7% (sensitivity 75.1%, specificity 45.9%), and an AUC of 0.68. However, when used to predict pregnancy outcome, the AI performed 27.9% better than the Gardner score (accuracies of 49.8% and 39.0% respectively).

Even though the AI was highly correlated with the Gardner score, the improved efficacy for predicting pregnancy suggests that a) the AI provides an advantage in standardization of scoring over the manual and subjective Gardner method, and b) the AI is likely identifying and evaluating morphological features of embryo quality that are not captured by the Gardner method.

Limitations, reasons for caution: The Gardner score is not a linear score, creating challenges with setting a suitable threshold relating to the prediction of pregnancy. The 2BB treshold was chosen based on literature (Munné et al 2019) and verified by experienced embryologists. This correlative study may also require additional confirmatory studies on independent datasets.

Wider implications of the findings: The correlation between AI scores and known features of embryo quality (Gardner score) substantiates the use of the AI for embryo assessment. The AI score provides further insight into components of the Gardner score, and may detect morphological features related to clinical pregnancy beyond those evaluated by the Gardner method.

Trial registration number: Not applicable

O-223 Fatty acid supplementation into warming solutions improve the developmental competence of mouse, bovine, and human oocytes and embryos after vitrification

K. Ohata[1], K. Ezoe[1], T. Miki[1], S. Kouraba[2], N. Fujiwara[1], A. Yabuuchi[1], K. Kato[3]

[1]Kato ladies clinic, R&D division, Tokyo, Japan ;
[2]Towako Medical Research Center, R&D division, Ishikawa, Japan ;
[3]Kato ladies clinic, Gynecology, Tokyo, Japan

Study question: Does fatty acid (FA) supplementation into vitrification and warming solutions influence the developmental competence of oocyte and embryo after vitrification and warming?

Summary answer: FA supplementation during the warming process improves the developmental competence of vitrified-warmed mouse oocytes and embryonic-morphologies after vitrification at the cleavage-stage in bovines and humans.

What is known already: Vitrified metaphase II stage oocytes exhibit a diminished ability to develop into blastocysts and live births. Previous studies have shown reduction in intracellular lipid content as one of the factors associated with reduced developmental competence of oocytes after vitrification as the intracellular lipid content of oocytes is affected by vitrification. FAs derived from break down of lipids are primarily transferred to the mitochondria, where it plays a crucial role in cellular metabolism. However, the effects of FA supplementation in warming solutions on the cytoplasmic lipid content and subsequent embryo development are unknown.

Study design, size, duration: A chemically defined FA mixture was added to the vitrification and/or warming solutions. Oocytes collected from C57BL6/N (n=80) were randomly divided into three groups (fresh, n=634; non-FA (control), n=961; FA, n=1,686), and were vitrified-warmed with/without FA. Lipid composition, developmental competence, and gene expression levels were compared among the groups. Bovine embryos (fresh, n=420; control, n=524; FA, n=492) and discarded human day-2 embryos (control, n=87; FA, n=92) were used to examine the developmental competence of embryos.

Participants/materials, setting, methods: Lipids in the ooplasm were stained with Nile red and the fluorescence intensity was analysed. The developmental competence of mouse oocytes was examined by performing intracytoplasmic sperm injection. Expressions of FA metabolism-related genes were measured. The bovine embryos were vitrified at the four-cell stage and cultured to the blastocyst stage after warming. Cryopreserved discarded human embryos were warmed and cultured. The obtained blastocysts were then placed on fibronectin-coated dishes to examine the outgrowth formation.

Main results and the role of chance: Lipid content of mouse oocytes was significantly lower in the control group compared to that in the fresh group ($P<0.05$). On the contrary, lipid contents of FA and fresh groups were comparable ($P=0.24$). Blastocyst formation rate was significantly higher in the FA group than that in the control group (55.7% and 44.8%, respectively; $P<0.05$). To examine the optimal timing for FA supplementation, FA was added to the vitrification solution (FAvit), warming solution (FAthaw), and/or both solutions (FAvit-thaw). Blastocyst formation rate was significantly higher in the FAthaw group than that in the control group (59.8% and 50.0%, respectively; $P<0.05$). The mRNA expressions of *Acaa2* and *Hadha* in mouse embryos were significantly higher in the FAthaw group compared to that in the control group ($P<0.05$). Moreover, FA supplemented warming solutions significantly improved the blastocyst formation rate in bovines (control, 53.5%; FAthaw, 64.5%; $P<0.05$). Developmental rate to the expanded blastocyst stage was slightly improved in human embryos (control, 53.7%; FAthaw, 63%; $P=0.38$) and the proportion of Grade A in inner cell mass and trophectoderm was significantly higher in the FAthaw group than that in the control group ($P<0.05$). There were no differences in the outgrowth abilities between the control and FAthaw groups.

Limitations, reasons for caution: Since the experiments of the current study on human embryos were performed *in vitro* using discarded embryos, in vivo developmental ability was not evaluated. Therefore, to validate the application of our findings in human assisted reproductive technologies, further clinical trials (ART) are warranted.

Wider implications of the findings: FA supplementation into the warming solutions improved the developmental competence of vitrified–warmed oocytes and cleaved embryos by activating the β-oxidation pathway. These results indicate that FA supplementation into warming solutions is a potential strategy to improve clinical outcomes in human ART.

SELECTED ORAL COMMUNICATIONS

SESSION 79: AGE, DISEASE, AND THEIR IMPACT ON MALE FERTILITY

01 July 2021 Stream 2 14:00 - 15:15

O-224 Paternal ageing impacts blastulation and pregnancy outcomes at different levels of maternal age: a clustering analysis of 21,960 injected oocytes and 3837 ICSI cycles

A. Setti[1,2], D. Braga[1,2], P. Guilherme[3], L. Vingris[3], A. Iaconelli Jr.[4], E. Borges Jr.[2,4]

[1]Fertility Medical Group, Scientific research, Sao Paulo, Brazil ;
[2]Sapientiae Institute, Scientific research, São Paulo, Brazil ;

[3]Fertility Medical Group, IVF lab, Sao Paulo, Brazil ;
[4]Fertility Medical Group, Clinical department, Sao Paulo, Brazil

Study question: Are the morphological parameters and development of in vitro cultured embryos, and intracytoplasmic sperm injection (ICSI) outcomes influenced by maternal and paternal ageing?
Summary answer: The slopes of maternal age on blastulation, blastocyst quality, and implantation, pregnancy and miscarriage rates significantly changed (worsened) for every year increase in paternal age.
What is known already: Due to the vast literature demonstrating that female age interferes with intracytoplasmic sperm injection (ICSI) outcomes, there is an imposition, in numerous countries, regarding maternal age limit for assisted reproduction. Despite several studies have underscored the negative impact of paternal age and lifestyle factors on reproductive health, the influence of paternal age on ICSI outcomes is still a matter of debate. The aim of this study was to investigate if the effect of paternal age on embryo development differs at different values of maternal age, thus creating a rationale for the data to reach physicians, patients, and public health recommendations.
Study design, size, duration: This historical cohort study included 3837 couples undergoing their first ICSI cycle from January/2014 to October/2020. A total of 21960 oocytes were injected and embryos were evaluated until day 5 of development. The main effects of maternal and paternal ages, as well as the effect of their product (interaction term) on embryo growth and development, and on pregnancy outcomes were investigated taking into account clustering of data (multiple embryos per cycle), using generalized mixed models.
Participants/materials, setting, methods: The study was performed in a private university-affiliated in vitro fertilization center. Zygotes were morphologically evaluated 17h post ICSI. For days 2 and 3 of development, the number of blastomeres, blastomere symmetry, percentage of fragmentation and presence of multinucleation were recorded. On day 5 of development, successful blastulation, and inner cell mass and trophectoderm qualities were recorded. Pregnancy was calculated per transfer, and miscarriage was defined as pregnancy loss before 20 weeks gestation.
Main results and the role of chance: The coefficients for the interaction term were statistically significant for blastocyst development (B: - 0.005, OR: 0.995, CI: 0.994 – 0.996, $p < 0.001$), top-quality blastocyst (B: - 0.003, OR: 0.997, CI: 0.996 – 0.999, $p < 0.001$), implantation rate (B: - 0.041, OR: 0.960, CI: 0.947 – 0.973, $p < 0.001$), pregnancy rate (B: - 0.004, OR: 0.996, CI: 0.995 – 0.997, $p < 0.001$), and miscarriage rate (B: 0.011, OR: 1.012, CI: 1.005 – 1.018, $p = 0.001$). These values describe the changes in slopes such that, the slope of one independent variable (e.g. maternal age) on the dependent variable (e.g. implantation rate) changes by the value of B (- 0.041) for every unit change on the other independent variable (e.g. paternal age). No significant results were observed for the influence of the interaction term on embryo morphological features on days 1, 2 and 3 of development. Two post hoc power analyses were calculated, given α of 5%, sample size of 21960 zygotes and 3315 ICSI cycles with embryo transfer and effect sizes for blastulation and pregnancy outcomes, respectively. The achieved power was superior to 99% in both analyses.
Limitations, reasons for caution: The retrospective and monocentric nature of the study are its major limitations.
Wider implications of the findings: Our results underscore the importance of both maternal and paternal ages for blastulation and successful pregnancy. Main effects of paternal and maternal ages should no longer be interpreted as the relationship between each independent variable and a given outcome, but rather be conditional on the values of the interaction term.
Trial registration number: Not applicable

O-225 Effects of SARS-Corona virus 2 on IVF treatment parameters: A cohort study of post COVID-19 patients

Y. Kabalkin[1], M. Gil[1], E. Lifshitz[1], A. Moav[1], M. Kabessa[1], S. Jaber[1], E. Esh Broder[1], Y. Bentov[1], B. Assaf[1], A. Solnica[1], A. Walfisch[1], H. Holzer[1], A. Hershko Klement[2]

[1]Hadassah Medical Centre, Ob Gyn, Jerusalem, Israel ;
[2]The Hebrew University Medical school, The IVF unit- Hadassah Mt. Scopus, Kiryat Ono, Israel

Study question: Does recovery from SARS–Corona virus 2 (SARS–CoV-2) infection negatively effect IVF cycle parameters?
Summary answer: Female IVF treatment parameters were comparable to the pre-Covid-19 infection cycle performance. Sperm concentration and motility demonstrated lower mean counts following Covid-19 infection.
What is known already: Corona-virus disease-19 (Covid-19) is a global pandemic caused by SARS–Corona virus 2 (SARS–CoV-2). The virus primarily affects the respiratory system, but other systemic and immune mediated effects have been reported. The spikes of SARS-CoV-2 have strong affinity for the Angiotensin converting enzyme (ACE) 2 receptor, leading to an increased Angiotensin II (Ang II) mediated pro-inflammatory response. ACE2 receptors exist in the human reproductive tract (more in males) and pose a regulatory role together with Ang II. So far, reports have been inconsistent regarding testicular effects. Other implications involving fertility and fertility treatment post infection are scarce.
Study design, size, duration: In this retrospective cohort study, IVF cycle performance was compared before and after Corona-virus disease-19. Patients were included only in cases where an IVF cycle was initiated within 3 months of Covid-19 recovery, between March 2020-December 2020.
Participants/materials, setting, methods: The study was conducted in a University affiliated IVF unit. Post Covid- 19 cycle parameters were compared to previous cycles of the same individual prior to infection. If previous cycles were not available, parameters were compared to non-exposed patients of same age, same treatment and identical indication. Sperm concentration and motility were compared before and after infection. Non exposure was defined by a lack of past Covid-19 diagnosis and a negative PCR throughout the treatment.
Main results and the role of chance: All together, including the matched cycles, we compared 40 cycles which started within 3 months of recovery: 26 fresh stimulation cycles and 14 frozen thawed transfer cycles. In 28 of these cycles the patient could serve as its own control. Mean age for the female partner was 33.2 years ±6.5 years. Eight male partners presented post infection and provided fresh samples for a cycle involving fertilization. We compared stimulation parameters including maximal Estradiol level, stimulation length, FSH dosage, number of oocytes retrieved, fertilization rates, number of embryos created, high quality embryo number and endometrial thickness. All of these were comparable to non-exposed cycles (generalized estimating equations, p values >0.1). No complications were recorded, specifically no thromboembolic events or respiratory complications. A total of 8 patients conceived: 1 was a chemical pregnancy, 1 extra-uterine pregnancy, 3 miscarriages and 3 ongoing, of those 1 was complicated by early bleeding. Male sperm analyses showed a trend towards lower post disease parameters, not reaching a statistical significance: 23mil/ml compared to 13.6 and 20.7% progressive motility compared to 12.3% (p values 0.09 and 0.17, respectively).
Limitations, reasons for caution: Current results are based on a small sample size, still insufficient for deducing definite conclusions or guidelines. Pregnancy outcome following IVF treatment in Covid-19 recoverees should further be studied. By the time of the conference, the number of cases is expected to be significantly higher.
Wider implications of the findings: This study provides preliminary data regarding the effects of SARS-COV-2 infection on IVF treatment outcomes. Despite the small sample size, treatment parameters seem unaffected, however, sperm performance seems to be compromised. Health policy and patients' decisions regarding whether or not to postpone IVF procedures necessitates additional data.
Trial registration number: Not applicable - retrospective

O-226 The microscopic se men improvement after surgical varicocele repair

Study question: Evaluation of the effect of varicocele correction on conventional and microscopic seminal parameters and evaluation of which factors might predict sperm improvement after surgical treatment.
Summary answer: The detailed morphologic sperm evaluation has been identified as a novel parameter expressing the post-surgical semen amelioration after varicocelectomy.
What is known already: Generally, varicocele develops during puberty and occurs more often on the left side for anatomic reasons. However, its diagnosis is commonly delayed, especially in asymptomatic cases, until the man consults an andrologist for couple infertility. A causative relationship between varicocele and impairment of semen quality has been largely investigated in the context of male infertility. Despite the florid literature available on this topic, the clinical benefit in terms of semen quality improvement after varicocele surgical repair remains controversial.
Study design, size, duration: An observational, retrospective clinical trial was carried out including patients undergoing surgical treatment for varicocele at the Day Surgery of the Urology Operative Unit of the Santa Maria Nuova Hospital-IRCCS of Reggio Emilia from September 2011 to March 2020. Primary outcome was the detailed morphologic microscopic sperm evaluation. Secondary outcomes were conventional semen analyses. Each patient was considered two times (before and after the surgery) and evaluated by both physical examination and ultrasonography.
Participants/materials, setting, methods: The inclusion criteria considered the patients with diagnosis of varicocele at ultrasound examination, attending surgical resolution and with at semen analyses before and after the surgery, were excluded patients with diagnosis of varicocele without surgical indication, and/or semen analyses performed only before or only after the surgery. In the statistical analysis a logistic multivariate regression analysis was performed in order to evaluate the change before and after surgery.
Main results and the role of chance: The post-surgical semen analysis was performed after a mean of 183.7 + 112.5 days since the surgery for a total of 121 males (mean age 24.6 + 4.1 years) enrolled. The surgical treatment leads to a significant increase in sperm concentration (p=0.015) and percentage of progressive and total motility (p=0.022 and p=0.039, respectively), with a significant decrease in the percentage of immobile sperms (p=0.013). In particular, semen concentration improved in 71.7% of patients (p=0.010). Considering the detailed morphologic microscopic evaluation, a significant improvement was detected: head abnormalities showed a significant reduction, considering microcephaly (3.3 + 3.6 versus 2.2 + 2.9%, p=0.015), macrocephaly (1.4 + 0.6 versus 1.2 + 0.9%, p=0.043) and cytoplasmic appendix (1.4 + 0.8 versus 0.9 + 1.2%, p=0.041). Moreover, surgery led to a significant reduction of tails abnormalities, considering absence (0.6 +2.3 versus 0.1 + 0.7, p=0.048) and coiled tail (5.2 + 1.5 versus 6.6 + 2.0, p=0.037). Thus, surgical varicocele resolution leads to a significant improvement in specific morphological semen parameters. The multivariate logistic analysis identified the ultrasound varicocele degree before surgery as a main predictor of the sperm concentration improvement (p=0.016). The semen parameters improvement was higher for varicocele of I and II degree (p=0.008).
Limitations, reasons for caution: The retrospective study design precluded from carrying out a case-control study to compare the surgical techniques. Moreover, the study design limited the availability of patients' clinical data in order to performed a more comprehensive predictive analysis.
Wider implications of the findings: Using a complex statistical approach, it emerged that the greatest improvement in semen quality was obtained in case of mild varicocele, increasing the knowledge on the therapeutic potential of surgery. This result has clinical implications, since it could help to select those patients 'to treat or not to treat'.
Trial registration number: none

O-227 Pre-treatment semen parameters in haematological malignancies. An analysis of sequential samples.

T. Lukaszewski[1], E. Williamson[1], P. Sangster[2], E. Yasmin[1]

[1]Univeristy College London Hospital, Reproductive Medicine Unit, London, United Kingdom ;
[2]Univeristy College London Hospital, Urology, London, United Kingdom

Study question: Does Leukaemia affect spermatogenesis more adversely than Hodgkin's lymphoma and is the effect consistent in sequential samples?
Summary answer: LLeukaemia is associated with a higher incidence of azoospermia, oligozoospermia and asthenozoospermia compared to Hodgkin's lymphoma. These findings were consistent in sequential samples.
What is known already: Hodgkin's lymphoma (HL) and leukaemias are common haematological malignancies that affect young men. Although not all treatments for these malignancies are gonadotoxic, there is evidence that malignancy affects sperm quality. Our own analysis in over 3000 men revealed that a diverse group of malignancies affected semen parameters adversely. There is concern that a single sample analysis may not reveal the true state due to varied period of abstinence and naturally occurring variation in semen quality. Leukaemia and lymphoma are systemic diseases; leukaemia usually runs a more torrid course whilst HL a more indolent course and therefore may variably affect spermatogenesis.
Study design, size, duration: A retrospective analysis was performed on 125 men with leukaemia and 303 men with HL. Only those men who had sequential semen analyses (1 and 2) within a month were included. Volume, sperm concentration and motility were the selected parameters in samples 1 and 2. Time period was April 1980 to January 2021.
Participants/materials, setting, methods: We included all post-pubertal men diagnosed with 2 most common haematological malignancies (Hodgkin's lymphoma and leukaemia) in our database. Patient's demographics, cancer diagnosis and semen parameters were extracted from a secure electronic database and analysed using MS Excel. Cancer diagnoses were obtained from referral letters from oncologists. Differences between samples 1 and 2 were tested using Fisher's test, and odds ratios (OR) were calculated for the two malignancy groups.
Main results and the role of chance: We analysed 250 samples in 125 men with leukaemia and 606 samples in 303 men with HL. The mean intervals between the two semen samples were similar; 4.4 (1-30) and 3.8 (1-30) days. There were 95.7% of men <40 years in the HL group and 90.4% in the leukaemia group. There was no significant difference in the incidence of low volume (<1.5ml), sperm concentration or motility between samples 1 and 2 in both groups. Oligospermia was more frequently associated with leukaemia (OR 2.22, CI 95%, 1.44-3.43). Although the incidence of severe oligozoospermia was similar between the two cancer groups (OR 0.99, 95% CI 0.55 - 1.99), azoospermia was observed to have a greater association with leukaemia than HL (OR 3.22, 95% CI 1.57-6.63). There was also a greater association of asthenozoospermia with leukaemia compared to HL (OR 2.76, 95% CI 1.76-4.35). As there was consistency between samples 1 and 2 in both groups, odds ratio calculation for sample 2 revealed similar results as for sample 1.
Limitations, reasons for caution: As we selected men with at least two semen samples on two separate occasions, we had to exclude men with single samples which substantially reduced the number of participants. Types of leukaemia and the stage of disease in HL were not analysed.
Wider implications of the findings: Our findings are pertinent when counselling men about fertility preservation even in the absence of planned gonadotoxic treatment. Awareness about increased azoospermia incidence may help plan oncoTESE procedures. Our findings could form a basis for studies examining spermatogenesis pathways in haematological malignancies.
Trial registration number: not applicable

O-228 The SSRI antidepressant Sertraline inhibits CatSper calcium channels in human sperm

R. Rahban[1], A. Rehfeld[2], C. Schiffer[3], C. Brenker[3], D. Louise Egeberg Palme[2], T. Wang[3], J. Lorenz[3], K. Almstrup[2], N.E. Skakkebaek[2], T. Strünker[3], S. Nef[1]

[1]University of Geneva, Department of Genetic Medicine and Development, Geneva, Switzerland ;
[2]University of Copenhagen- Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark ;
[3]University Hospital Münster, Centre of Reproductive Medicine and Andrology, Münster, Germany

Study question: Do Selective Serotonin Reuptake Inhibitor (SSRI) antidepressants affect the function of human sperm?
Summary answer: The SSRI-antidepressant Sertraline (e.g. Zoloft) inhibits the sperm-specific Ca^{2+} channel CatSper and affects human sperm function *in vitro*.
What is known already: In human sperm, CatSper translates changes of the chemical microenvironment into changes of the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) and swimming behavior. CatSper is promiscuously activated by oviductal ligands, but also by synthetic chemicals that might disturb the fertilization process. It is well known that SSRIs have off-target actions on Ca^{2+}, Na^+, and K^+ channels in somatic cells. Whether SSRIs affect the activity of CatSper is, however, unknown.
Study design, size, duration: We studied the action of the seven drugs belonging to the most commonly prescribed class of antidepressants, SSRIs, on resting $[Ca^{2+}]_i$ and Ca^{2+} influx via CatSper in human sperm. The SSRI Sertraline was selected for in-depth analysis of its action on steroid-, prostaglandin-, pH-, and voltage-activation of human CatSper. Moreover, the action of Sertraline on sperm acrosomal exocytosis and penetration into viscous media was evaluated.
Participants/materials, setting, methods: The activity of CatSper was investigated in sperm of healthy volunteers, using kinetic Ca^{2+} fluorimetry and patch-clamp recordings. Acrosomal exocytosis was investigated using *Pisum sativum* agglutinin (PSA) and image cytometry. Sperm penetration in viscous media was evaluated using the Kremer test.
Main results and the role of chance: Four SSRIs increased $[Ca^{2+}]_i$, two out of which also attenuated ligand-induced Ca^{2+} influx via CatSper. In contrast, Sertraline decreased $[Ca^{2+}]_i$ and almost completely suppressed ligand-induced Ca^{2+} influx via CatSper. Remarkably, the drug was about four-fold more potent to suppress prostaglandin- versus steroid-induced Ca^{2+} influx. Sertraline also suppressed alkaline- and voltage-activation of CatSper, indicating that the drug directly inhibits human CatSper. Finally, Sertraline suppressed ligand-induced acrosome reaction and sperm penetration into viscous media.
Limitations, reasons for caution: This is an *in vitro* study. Future studies have to assess the physiological relevance *in vivo*.
Wider implications of the findings: The off-target action of Sertraline on CatSper in human sperm might impair the fertilization process. In a research setting, Sertraline may be used to selectively inhibit prostaglandin-induced Ca^{2+} influx.

[3]Copenhagen University - Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark ;
[4]Zealand University Hospital, The ReproHealth Research Consortium, Køge, Denmark ;
[5]Copenhagen University - Hvidovre Hospital, Department of Gynaecology and Obstetrics - Fertility Clinic, Hvidovre, Denmark

Study question: Does reducing estradiol levels with letrozole co-treatment during ovarian stimulation with gonadotropins for IVF impact endocrinological and reproductive outcome markers in expected normal responders?
Summary answer: Letrozole co-treatment maintained follicular phase physiological serum estradiol levels, increased gonadotropin and androgen levels, and increased progesterone in the luteal phase.
What is known already: Ovarian stimulation for IVF causes supraphysiologic estradiol levels, which exert pituitary suppression reducing gonadotropin stimulation of the corpus luteum. Furthermore, stimulation may increase progesterone in the late follicular phase, reported to impair clinical outcomes, through a putative effect on endometrial maturation and embryo-endometrial asynchrony. Co-treatment with the highly selective aromatase inhibitor letrozole during ovarian stimulation has been shown to reduce estradiol levels and FSH consumption in poor responders, but conflicting data in relation to oocyte yield and implantation rates. The impact of letrozole co-treatment on hormonal changes and reproductive outcome after co-treatment in normal responders remains to be clarified.
Study design, size, duration: A multicentre double-blinded randomised placebo-controlled trial conducted in 4 fertility clinics at university hospitals in Denmark from August 2016 to November 2018. 159 women were randomised and 129 completed the study; 67 women in the letrozole group and 62 women in the placebo group. The study was conducted in accordance with the Helsinki Declaration and the ICH-Good-Clinical-Practice. Data collection and reporting followed the guidelines of CONSORT to achieve transparent reporting of trials.
Participants/materials, setting, methods: Women with expected normal ovarian reserve received an antagonist IVF protocol with fixed-dose FSH and fresh single embryo transfer. Co-treatment consisted of once-daily 5 mg letrozole or placebo from the start of stimulation until the day of triggering final oocyte maturation with human chorionic gonadotropin. Serum was collected on 7 visits from stimulation start to 8 days after oocyte retrieval. Clinical pregnancy was determined with a viable foetus by vaginal ultrasound at gestational week 7.
Main results and the role of chance: The proportion of patients with progesterone >1.5 ng/ml in the late follicular phase was similar in the letrozole versus placebo group with 6% versus 0%, respectively (OR 0, 95 % CI [0;1.6], P =.12). Mid-luteal progesterone levels >30 ng/ml were observed in 59% versus 31%, respectively, of subjects in the letrozole and placebo group (OR 3.3, 95% CI [1.4;7.1], P =.005). Letrozole treatment decreased estradiol levels by 69% (95 % CI [60%;75%], P <.0001) and increased luteinizing hormone (LH), testosterone, and androstenedione levels significantly in both the follicular and luteal phase. Follicle-stimulating hormone (FSH) concentration was elevated in the letrozole group at stimulation day 5 and at trigger day, and overall FSH consumption was diminished. The ongoing pregnancy rate did not differ between the letrozole and placebo group (31% versus 39% (risk-difference of 8%, 95% CI [-25%;11%], P =.55). Letrozole had no significant additional side effects apart from those frequently seen during ovarian stimulation, though a trend towards less nausea and vomiting was observed in the letrozole co-treated group versus the placebo group (28% versus 44% (risk-difference of 16%, 95% CI [-2%;33%], P =.11).
Limitations, reasons for caution: The diurnal variation of progesterone has been confirmed since this study was completed, hence the timing of the blood samples was not standardized . However, bias is unlikely due to the randomized design. The study was not powered to show an effect on ongoing pregnancy rates.
Wider implications of the findings: Letrozole co-treatment during ovarian stimulation with gonadotropins maintained serum estradiol at physiological levels, increased follicular phase levels of gonadotropins and androgens, and luteal progesterone levels. These data indicate that letrozole co-treatment may ameliorate the detrimental impacts of gonadotropin stimulation during IVF in normal responders.

Trial registration number: NCT02939898 and NCT02946684

O-230 RCT comparing Recombinant-hcg trigger with Dual-trigger (GnRH-agonist and recombinant-hcg) in improving clinical outcome in ICSI cycles in women with Diminished Ovarian Reserve

A. Jindal[1], M. Singh[2]

[1]*Bhopal Test Tube Baby Centre, Infertility, Bhopal, India ;*
[2]*BTTB Centre, Infertility, Bhopal, India*

Study question: Does use of Dual-trigger (GnRH-agonist with recombinant-hcg) improve the clinical outcome in women with diminished ovarian reserve as compared to Recombinant-hcg trigger?
Summary answer: Yes, the use of Dual-trigger (GnRH-agonist with recombinant-hcg) improve the clinical outcome in women with diminished ovarian reserve as compared to Recombinant-hcg trigger.
What is known already: The population of poor responders has grown exponentially over the years and their management of ovarian stimulation remains one of the most challenging aspects. In GnRH antagonist down-regulated IVF-ICSI cycles, dual triggering for the final oocyte maturation with GnRH-a and a reduced dose of hCG improves the rate of fertilization and clinical pregnancy in women with diminished ovarian reserve. Further more, the benefit of lowered cycle cancellation rate would also enable greater percentage of patients with diminished ovarian reserve to reach the final stage of their ART treatment, thereby enhancing their chances of achieving a successful pregnancy .
Study design, size, duration: This RCT included GnRH antagonist ICSI cycles from 2018-2019. 82 women with diminished ovarian reserve (AMH ≤ 1.1 ng/ml and AFC ≤5) were included. The primary outcome measured was the oocyte fertilization rate, implantation rate and clinical pregnancy rate per oocyte retrieval cycle. Secondary outcome measured was embryo transfer cancellation rate and abortion rate per oocyte retrieval cycle.
Participants/materials, setting, methods: 82 women with diminished ovarian reserve undergoing fresh embryo transfer were included and randomly divided in two groups - Group-A (hCG trigger/control group: n = 41); and Group-B (dual trigger/study group: n = 41). Both patient groups underwent controlled ovarian stimulation using antagonist. The final oocyte maturation was triggered either by recombinant hCG (Group-A) or by a combination of recombinant hCG and GnRH-agonist (Dual trigger) (Group-B).
Main results and the role of chance: The dual-trigger group had significantly higher fertilization rate (62.8 vs. 37.6%), higher clinical pregnancy rate (31.4% vs. 18.1%) as compared to the recombinant-hCG trigger group. In addition, the abortion rate(12.1% vs. 21.3%) and embryo transfer cancellation rate (8.3% vs. 16.1%) were both significantly lower in the dual trigger group. The baseline characteristics for the control and the study group were similar and there was no significant difference in the patient age, serum AMH level, and cause of infertility. The total r-FSH dose, duration of stimulation, endometrial thickness, and serum hormone profile on the day of trigger were also similar between the control and the study group. The main advantage of triggering with GnRH-a is that it induces a mid-cycle FSH surge which resembles the natural ovulatory cycle hormonal changes. Study shows that in GnRH antagonist ART cycles, dual triggering with GnRH-a and hCG could significantly improve the rate of fertilization and clinical pregnancy in diminished ovarian reserve women. Furthermore, the benefit of lowered cycle cancellation rate would also enable greater percentage of patients with diminished ovarian reserve to reach the final stage of their ART treatment thereby enhancing their chance of achieving a successful pregnancy as well as reducing their mental stress.
Limitations, reasons for caution: The main limitation of our study is the low patient number. Triggering with GnRH-a has become a significant part of contemporary ART practice, especially in high responders, oocytes donors and oncology patients. However, more RCTs are required in order to justify the use of GnRH-agonists in poor responders in ART cycles.
Wider implications of the findings: Results of our study concurred with other studies of dual triggering, calls for a possible paradigm shift in ovulation-triggering agent for GnRH-antagonist cycles. Diminished ovarian reserve patients are constituting a large part of clinical ART practice and for such patients, obtaining maximum mature oocytes and good embryos is vitally important.
Trial registration number: not applicable

O-231 In vitro maturation of human immature (GV) oocytes after controlled ovarian hormonal stimulation with recombinant AMH in the maturation medium

J. Bedenk[1], N. Jančar[1], E. Vrtačnik-Bokal[1], I. Virant-Klun[2]

[1]*University Medical Centre Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia ;*
[2]*University Medical Centre Ljubljana, Clinical Research Centre, Ljubljana, Slovenia*

Study question: Does the addition of recombinant AMH to the *in vitro* maturation (IVM) medium improve the maturation of GV oocytes after controlled ovarian hormonal stimulation?
Summary answer: Our results show that the addition of recombinant AMH to the *in vitro* maturation medium improves the maturation rate of GV oocytes.
What is known already: Anti-Müllerian hormone (AMH) is an important hormone involved in the process of sex differentiation during embryonic development. At the transition to the 21. century, more and more researchers have studied the role of AMH in ovarian function, especially its impact on folliculogenesis. AMH is becoming one of the main biomarkers of ovarian reserve and ovarian-specific disease, however, little is known about its effect on human oocyte maturation. Therefore, we matured immature GV (germinal vesicle) oocytes in IVM medium with recombinant AMH to assess its effect compared to the conventional IVM procedure with FSH and hCG.
Study design, size, duration: In this two-year prospective study, we compared the maturation rate of four groups of immature (GV) oocytes matured in maturation medium with added i) AMH (n=15), ii) AMH+FSH+hCG (n=44), iii) FSH+hCG (conventional; n=22), and iv) hormone-free maturation medium (control; n=15). Each oocyte was matured *in vitro* for a maximum of 28 hours and monitored by time-lapse microscopy to assess the time of GV breakdown (MI) and extrusion of the polar body (MII).
Participants/materials, setting, methods: Ninety-six GV oocytes of 46 patients (aged < 38 years, involved in the ICSI programme) after short antagonist protocol of controlled ovarian hormonal stimulation were included after written informed consent. IVM of oocytes was performed in the MediCult IVM System (LAG and IVM medium, Cooper Surgical, Denmark) with added hormones, and in a CO_2 incubator equipped with the PrimoVision time-lapse microscope (Vitrolife, Sweden).
Main results and the role of chance: IVM medium with added recombinant AMH gave the best result with all (100 %) oocytes matured *in vitro.* In conventional IVM medium with FSH and hCG, the oocyte maturation rate was poorer, with 68 % of oocytes matured *in vitro*. An even lower oocyte maturation rate (34 %) was observed in IVM medium with AMH, FSH and HCG, which might be explained by the antagonistic action of these hormones. In a group of control oocytes, 25 % of oocytes matured *in vitro*. The mean time to GV breakdown (MI stage) was 3.7 hours and to polar body release (MII stage) 20,5 hours. The time to MI stage was quite comparable in all groups of oocytes (3.5, 3.8 and 3.7 hours). There was a tendency for the polar body to be released later if AMH was added to the maturation medium (21.5 and 20.2 vs. 19.9 hours) but differences were not statistically significant, as revealed by Student's t-test. In the control group of oocytes, these times were prolonged (4.2 and 22.2 hours) due to slow spontaneous maturation. These preliminary results demonstrate that AMH could directly affect the oocyte maturation *in vitro*.
Limitations, reasons for caution: The limitation is the relatively small number of oocytes included; GV oocytes accounted for less than 10 % of all oocytes in the *in vitro* fertilisation (ICSI) programme. Moreover, the proportion of GV oocytes spontaneously matured to MI stage before the start of the experiment and were therefore not included.
Wider implications of the findings: Based on our data, we believe that AMH directly affects human oocyte maturation *in vitro*. Despite the common knowledge that AMH regulates the recruitment of growing ovarian follicles, it appears that the addition of AMH to the maturation medium can improve the human oocyte maturation *in vitro*.
Trial registration number: 0120-546/2018/6

O-232 Higher clinical pregnancy rate after oxytocin-receptor antagonist administration around the time of embryo transfer: A systematic review and meta-analysis of eleven RCTs

K. Neumann[1], G. Griesinger[2]

[1]*Kinderwunsch Praxisklinik, Fleetinsel, Hamburg, Germany ;*

[2]Sektion für gynäkologische Endokrinologie und Reproduktionsmedizin, Universitäres Kinderwunschzentrum, Luebeck, Germany

Study question: Does the administration of an oxytocin-receptor antagonist around time of embryo transfer in IVF impact the likelihood to achieve a clinical pregnancy?
Summary answer: Administration of oxytocin-receptor antagonists around embryo transfer increases the likelihood of clinical pregnancy achievement.
What is known already: Uterine contractions occurring around time of embryo transfer have been described as one possible mechanism of failure of implantation of an embryo in the context of in-vitro fertilization (IVF). Hence the utilization of oxytocin-receptor antagonists was evaluated in randomized clinical trials (RCT) as a therapeutic approach. The compound Atosiban was studied by most RCTs (summarized in Huang *et al.* 2017). Recently further studies have become available which also investigated the novel agents Barusiban and Nolasiban. This systematic review collates the evidence of all drugs functioning as oxytocin-receptor antagonists which have been investigated in RCTs on IVF treatment so far.
Study design, size, duration: Multiple literature databases were searched for randomized controlled studies comparing the outcome of IVF cycles with administration of an oxytocin-receptor antagonist in the time period before, during or after embryo transfer versus placebo or *nil* in IVF patients. Meta-analyses were performed using standard procedures in the software program RevMan v.5.4. All analyses were done per randomized patient, wherever feasible.
Participants/materials, setting, methods: Eleven RCTs were identified and included in the meta-analysis. Seven utilized the agent Atosiban, one Barusiban and three Nolasiban. These drugs were administered either intravenously, subcutaneously or orally. The patient populations were heterogenous (fresh cycle, frozen-thawed cycle, endometriosis, implantation failure or general IVF-population) between trials. Only four studies reported live birth rates whereas all RCTs reported clinical pregnancy rate.
Main results and the role of chance: Administration of an oxytocin-receptor antagonist around embryo transfer increases the likelihood of live birth (relative risk: 1.1, 95% CI: 0.99-1.22, p=0.06, I^2=31%, four RCTs, n=2,510). Accordingly, the ongoing pregnancy rate is increased (relative risk: 1.14, 95% CI: 1.03-1.26, p=0.01, I^2=18%, four RCTs, n=2,510) as well as the clinical pregnancy rate (relative risk: 1.31, 95% CI: 1.13-1.51, p=0.0002, I^2=61%, eleven RCTs, n=3,611) by administration of an oxytocin-receptor antagonist. The risk to suffer a miscarriage, however, is not influenced by an oxytocin-receptor antagonist administration (relative risk: 0.90, 95% CI: 0.72-1.12, p=0.35, I^2=0%, seven RCTs, n=2,936). The risk of multiple pregnancy is not different between groups (relative risk: 1.05 95% CI: 0.81-1.36, p=0.73, I^2=5%, seven RCTs, n=3,014) as is the risk for an ectopic pregnancy (relative risk: 0.88 95% CI: 0.43-1.8, p=0.73, I^2=0%, four RCTs, n=2,714).
Limitations, reasons for caution: Methodological rigor is heterogenous between trials and some of the evidence is of poor quality. Evaluation of included studies is still ongoing and queries are pending. Additionally, there is heterogeneity between patient populations and definition of outcomes; only four RCTs report ongoing pregnancies and live births.
Wider implications of the findings: The administration of oxytocin-receptor antagonists around embryo transfer increases the pregnancy rate and may be a promising approach to enhance the likelihood to achieve a live birth per embryo transfer.
Trial registration number: n.a.

O-233 Micronized progesterone plus dydrogesterone versus micronized progesterone alone for luteal phase support in frozen-thawed cycles: a prospective cohort study

T. Ho[1], T. Pham[2], K. Le[3], T. Ly[3], H. Le[3], D. Nguyen[2], V. Ho[1], V. Dang[1], T. Phung[3], R. Norman[4], B. Mol[5], L. Vuong[6]

[1]My Duc Hospital, IVFMD and HOPE Research Center, Ho Chi Minh, Vietnam ; [2]My Duc Hospital, HOPE Research Center, Ho Chi Minh, Vietnam ; [3]My Duc Hospital, IVFMD Centre, Ho Chi Minh, Vietnam ; [4]The University of Adelaide, Robinson Research Institute and Adelaide Medical [5]school, Adelaide, Australia ; [5]Monash University, Department of Obstetrics & Gynaecology, Clayton, Australia ; [6]University of Medicine and Pharmacy at Ho Chi Minh City, Department of Obstetrics and Gynecology, Ho Chi Minh City, Vietnam

Study question: Does the addition of oral dydrogesterone to vaginal progesterone as luteal phase support improve pregnancy outcomes during frozen embryo transfer (FET) cycles compared with vaginal progesterone alone?
Summary answer: Luteal phase support with oral dydrogesterone added to vaginal progesterone improves live birth rates and reduces miscarriage rates compared with vaginal progesterone alone.
What is known already: Progesterone is an important hormone that triggers secretory transformation of the endometrium to allow implantation of the embryo. During in vitro fertilization (IVF), exogenous progesterone is administered for luteal phase support. However, there is wide inter-individual variation in absorption of progesterone via the vaginal wall. Oral dydrogesterone is effective and well tolerated when used to provide luteal phase support after fresh embryo transfer. However, there are currently no data on the effectiveness of luteal phase support with the combination of dydrogesterone with vaginal micronized progesterone compared with vaginal micronized progesterone after FET.
Study design, size, duration: Prospective cohort study conducted at an academic infertility center in Vietnam from 26 June 2019 to 30 March 2020.
Participants/materials, setting, methods: We studied 1364 women undergoing IVF with FET. The luteal support regimen was either vaginal micronized progesterone 400 mg twice daily plus oral dydrogesterone 10 mg twice daily (second part of the study) or vaginal micronized progesterone 400 mg twice daily (first 4 months of the study). The primary endpoint was live birth after the first FET of the started cycle, with miscarriage <12 weeks as one of the secondary endpoints.
Main results and the role of chance: The vaginal progesterone + dydrogesterone group and vaginal progesterone groups included 732 and 632 participants, respectively. Live birth rates were 46.3% versus 41.3%, respectively (rate ratio [RR] 1.12, 95% confidence interval [CI] 0.99–1.27, p=0.06; multivariate analysis RR 1.30 (95% CI 1.01–1.68), p=0.042), with a statistically significant lower rate of miscarriage at <12 weeks (3.4% vs 6.6%; RR 0.51, 95% CI 0.32–0.83; p=0.009). Birth weight of both singletons (2971.0 ± 628.4 vs. 3118.8 ± 559.2 g; p=0.004) and twins (2175.5 ± 494.8 vs. 2494.2 ± 584.7; p=0.002) was significantly lower in the progesterone plus dydrogesterone versus progesterone group.
Limitations, reasons for caution: The study were the open-label design and the non-randomized nature of the sequential administration of study treatments. However, our systematic comparison of the two strategies was able to be performed much more rapidly than a conventional randomized controlled trial. In addition, the single ethnicity population limits external generalizability.
Wider implications of the findings: Oral dydrogesterone in addition to vaginal progesterone as luteal phase support in FET cycles can reduce the miscarriage rate and improve the live birth rate. Carefully planned prospective cohort studies with limited bias could be used as an alternative to randomized controlled clinical trials to inform clinical practice.

01 July 2021 Stream 4 14:00 - 15:15

O-234 Using serum metabolomics to identify biomarkers of viable early, intrauterine pregnancy: an untargeted 1H NMR-based approach

C. Hill[1], M. Phelan[2], A. Horne[3], K. Gemzell-Danielsson[4], N. Tempest[1], D. Hapangama[1]

[1]University of Liverpool, Department of Women's and Children's Health, Liverpool, United Kingdom ; [2]University of Liverpool, Department of Biochemistry and Systems Biology, Liverpool, United Kingdom ; [3]University of Edinburgh, Department of Gynaecology and Reproductive Sciences, Edinburgh, United Kingdom ;

[4]Karolinska Institutet, Department of Women's & Children's Health, Stockholm, Sweden

Study question: Which metabolites are associated with a viable intrauterine pregnancy (VIUP) when compared to other early pregnancy outcomes (failed intrauterine and ectopic pregnancies)?
Summary answer: Serum levels of four metabolites (phenylalanine, alanine, glutamate and glutamine) were significantly altered in VIUPs compared to other early pregnancy outcomes.
What is known already: Around 10% of all intrauterine pregnancies are lost in the first trimester. A further 1-2% of pregnancies are located outside the endometrial cavity; these ectopic pregnancies are the leading cause of maternal mortality in the first trimester of gestation. Early miscarriages may also cause significant morbidity when bleeding or infection occurs. The symptoms of miscarriages and ectopic pregnancy are often similar (pain and bleeding), however, such symptoms are also common in VIUPs. To date, no biomarkers have been identified to differentiate VIUPs from non-viable and ectopic pregnancies.
Study design, size, duration: This is a prospective cohort study that included 332 pregnant women at less than ten weeks of gestation, who attended the early pregnancy assessment unit (EPAU) at Liverpool Women's Hospital with pain and/or bleeding.
Participants/materials, setting, methods: Blood samples were collected from the 332 pregnant women prior to final clinical diagnosis of pregnancy outcome. Serum samples were subjected to NMR metabolomics profiling (14 spectra that did not meet the recommended minimum reporting standards were removed from subsequent analysis). 1D ^{1}H-NMR spectra were acquired at 37 °C on a 700 MHz spectrometer. Relative metabolite abundances underwent statistical analysis using MetaboAnalyst 5.0 (*p*-value FDR adjusted).
Main results and the role of chance: Final pregnancy outcomes were as follows: one hydatidiform mole (0.3%), 48 ectopic pregnancies (14.4%), three pregnancies of unknown location (PULs, 0.9%), 78 failed pregnancies of unknown location (FPULs, 23.4%), 47 miscarriages (14.1%), two vanishing twin pregnancies (0.6%) and 153 VIUPs (45.8%). Due to small sample numbers, the hydatidiform mole, PULs and vanishing twin pregnancies were excluded from further analysis. To compare VIUPs to other pregnancy outcomes, ectopic pregnancies, FPULs and miscarriages were grouped together. Univariate analysis of serum metabolite concentrations identified four metabolites (phenylalanine, alanine, glutamate and glutamine) as significantly different in VIUPs compared to other pregnancy outcomes. Multivariate partial least squared discriminant analysis provided only weak correlation between the serum metabolome and pregnancy outcome. In summary, we have identified differences in the metabolome of women with VIUPs compared to other common pregnancy outcomes, which may provide diagnostic utility.
Limitations, reasons for caution: In this study, women with VIUPs presented with pain and/or bleeding. The presence of symptoms may influence the metabolome of this group versus VIUPs without symptoms, thus limiting the translation of our findings. Furthermore, environmental factors were not controlled (e.g. fasting status), making it likely that cohort heterogeneity was enhanced.
Wider implications of the findings: This study identifies a metabolite profile associated with VIUPs. These findings may be useful in the development of a diagnostic test to confirm VIUPs and thus exclude potentially life-threatening pregnancy outcomes. Such a test would be invaluable in clinical emergencies.

Study question: Does ERICA's prognosis ranking based on ploidy, predict early miscarriage following positive biochemical pregnancy test?
Summary answer: The lower ERICA grades embryos, the higher the likelihood of early miscarriage, irrespective of age group.
What is known already: The vast majority of early miscarriages are due to aneuploidy, but preimplantation genetic testing for aneuploidy (PGTA) is potentially invasive, expensive, time-consuming and usually necessitates cryopreservation. Current methods for embryo selection based on morphology and morphokinetics are poorly correlated with ploidy. ERICA is a deep-learning non-invasive tool for embryo ranking, trained to identify ploidy, and has previously been shown to be similar or better than experienced embryologists in assessing implantation potential. AI-based tools capable of embryo ranking and assessment could help save laboratory time and costs, avoiding risk to embryos from invasive techniques.
Study design, size, duration: Retrospective analysis of 599 blastocysts transferred over 12 months in which ERICA was used to assist embryologists during the embryo selection process. ERICA's prognosis based on ploidy potential is presented as groups labelled as "optimal", "good", "fair", or "poor". Embryo transfers (ET) reaching biochemical pregnancy (beta-hCG ≥ 20iu) were considered for the study. Early pregnancy loss (EPL) was defined as a biochemical pregnancy failing to develop a gestational sac and/or failure to show heartbeat (FHR).
Participants/materials, setting, methods: ETs resulting in biochemical pregnancies at two IVF clinics were followed-up to FHR till 8 weeks gestation. EPLs were divided into groups according to the presence or absence of a pregnancy sac. ERICA's suggested prognosis during the embryo selection process was tested against pregnancy outcomes. Further analysis of pregnancy outcomes and their relation to ERICA's labels was also performed based on age groups. Z-test for two proportions was used to assess statistical significance.
Main results and the role of chance: 506 ETs were performed for 599 embryos (mean 1.2 embryos), from which 285 resulted in positive pregnancy tests (56.3%). Thirty-one (10.9%) EPLs happened before the identification of a gestational sac (GS). Ten pregnancies failed to develop FHR after initial GS identification (3.9%), for an overall EPL of 14.4%. The average age in this group was 35.4 years. When evaluated using ERICA's labels "optimal", "good", "fair, and "poor", chances of miscarriage before GS were 8.9% (8/89); 14.1% (11/78); 18.5% (5/27); and 18.7% (9/48) respectively, where denominator represents total number within a label (i.e. EPL/n). When including all EPLs, chances of miscarriage according to the same labels were 11.2%; 17.9%; 22.2%; and 22.9% respectively.

ERICA's performance to anticipate the risk of EPL showed statistical significance when the optimal label was compared against all other labels (Z -1.786, $p < 0.05$), and against the poor prognosis label (Z=-1.653, $p<0.05$). After stratifying the dataset according to age groups, increasing miscarriage rates were maintained as ERICA's prognosis for an embryo worsened, regardless of age groups. The most notable performance was for ≤35-year-olds, where embryos ranked as optimal had an EPL rate of 14.3% in contrast to lowest ranked embryos having a 33.3% EPL rate.
Limitations, reasons for caution: The retrospective nature of this study along with its sample-size might limit the reach of our conclusions, in particular for older patients. The results we present must still be confirmed prospectively, and on a larger dataset.
Wider implications of the findings: Most EPLs are attributed to genetic factors, hence ERICA's training for embryo ranking was based on ploidy. We conclude that ERICA's AI is able to identify embryos at a higher risk of EPL non-invasively. Cytogenetic studies from products of miscarriage would help to confirm the hypothesis.
Trial registration number: Not applicable

O-236 The clinical and morphokinetic factors indicating a risk of pregnancy loss after a euploid embryo transfer

K.B. Yuksel[1], G. Ozer[1], I.N.B. Duzguner[1], Y. Kumtepe[1], H. Yelke[1], S. Kahraman[1]

[1]Istanbul Memorial Hospital, ART and Reproductive Genetics Center, Istanbul, Turkey

Study question: Are there any clinical and morphokinetic factors which may affect the pregnancy outcome after a euploid embryo transfer?
Summary answer: Body mass index (BMI), endometriosis, the history of recurrent pregnancy losses and the number of previous frozen-thawed unsuccessful embryo transfer (FET) cycles impact pregnancy outcomes.
What is known already: Preimplantation genetic testing for aneuploidy (PGT-A) is largely used for various indications to detect chromosomal abnormalities in assisted reproductive technologies (ART). The most common reason for the first trimester pregnancy losses is chromosomal abnormalities. However, the factors that cause pregnancy loss after a euploid embryo transfer are not fully understood.
Study design, size, duration: The pregnancy results of all single euploid embryos tested with next generation sequencing (NGS) in Istanbul Memorial Hospital between January 2017 and March 2020 were evaluated in this single center retrospective cohort study. The cases that resulted in pregnancy below the age of 43 were analyzed according to outcomes; biochemical pregnancy loss (Group 1), clinical pregnancy loss (Group 2) and live birth (Group 3).
Participants/materials, setting, methods: The transfer of 2041 single euploid embryos resulted in 1492 pregnancies. The clinical and morphokinetic parameters observed using time lapse imaging (TLI) were compared among the three groups.
Main results and the role of chance: The overall pregnancy rate was 73.1%, the rates of biochemical pregnancy losses and clinical losses were 9.7% and 11.4% respectively. The live birth rate was 58.5%. The indications for PGT-A were as follows; recurrent pregnancy losses (RPL) (14.9%), recurrent implantation failure (RIF) (11.7%), advanced maternal age (AMA) (28.6%), a history of abnormal fetal karyotype or single gene defects (12.1%). In 32.6% cases PGT-A was performed to reduce time to pregnancy.

There were no differences in terms of female age, AMH, the diagnosis or the duration of infertility, the mean numbers of oocytes retrieved, mature and fertilized oocytes. However, BMI values, the presence of severe endometriosis, including adenomyosis, the history of recurrent pregnancy losses and the number of previous unsuccessful FET cycles were significantly higher in Groups 1 and 2.

When pregnancy losses were evaluated according to PGT indications, patients with a history of RPL had a significantly higher pregnancy loss rate (27.8%) compared to the other groups: AMA (19.6%), RIF (19.4%), genetic factors (21.6%) and cases where PGT was performed to reduce time to pregnancy (16.4%) ($p<0.05$).

When morphokinetic parameters were evaluated, they were found to be not significantly different in the three groups ($p>0.05$).
Limitations, reasons for caution: The retrospective nature of the data is the major limitation of the study. On the other hand, the strength of the study is the large number of PGT-A tested embryos from a single center which used the same laboratory conditions.
Wider implications of the findings: PGT-A is widely used to avoid pregnancy losses. However, BMI values, the presence of severe endometriosis, including adenomyosis, the history of recurrent pregnancy losses and the number of previous unsuccessful FET cycles should be taken into consideration during counselling and/or treatment.
Trial registration number: not applicable

O-237 A non-invasive approach for aneuploidy analysis in clinical miscarriages

N. Balaguer Cuenca[1], L. Rodrigo[2], E. Mateu-Brull[1], I. Campos-Galindo[2], N. Al-Asmar[3], C. Rubio[4], C. SImón[5], M. Milán[1]

Study question: Is maternal cell-free DNA (cfDNA) testing a feasible alternative to the analysis of the product of conception (POC) in clinical miscarriages?
Summary answer: This study demonstrates that genome-wide cfDNA testing in the maternal bloodstream constitutes a reliable tool to analyse chromosome aneuploidies in clinical miscarriages.
What is known already: It is well established that 50-70% of clinical miscarriages are caused by numerical chromosomal anomalies (aneuploidies), mostly trisomies. To date, conventional cytogenetic and advanced molecular techniques are used for the analysis of POC to identify the genetic cause of miscarriage, providing valuable information for genetic counselling. However, both approaches are based in the direct analysis of the abortive tissue, which entails several limitations due to the risk of culture failure and/or maternal cell contamination. To solve these drawbacks, maternal cfDNA testing emerges as a promising alternative due to the accumulated evidence.
Study design, size, duration: This was a retrospective study conducted in a reference genetic laboratory from January to December 2020. Before carrying out the foetal tissues collection that precludes the POC analysis, a blood sample was drawn to evaluate possible aneuploidies by cfDNA testing. Using NGS+STR POC results as the gold standard, results derived from both studies were compared to assess the percentage of concordance and the cases of non-informativeness (foetal fraction (FF) <2%), false positives, and false negatives.
Participants/materials, setting, methods: A total of 12 cases were included in the study. cfDNA testing in the mother's blood was performed by using Illumina's technology platform. Genetic testing for POC was done using an NGS technology (Thermo Fisher Scientific, USA) for 24 chromosome aneuploidy screening. Short-tandem repeat (STR) analysis allowed us to detect or rule out maternal cell contamination (MCC) and some types of polyploidies.
Main results and the role of chance: The non-informative rate for both analysis techniques was 9.1% (1 out of 12 cases: 1 low FF for cfDNA testing and maternal cell contamination for POC analysis). The median cfDNA FF was 9.0%. Using the molecular POC analysis as gold standard, the concordance rate between both studies was 90.0% (9 out of 10 cases;1 monosomy X, 1 trisomy (T) 21, 1 T22, 1 T11 and 5 patients with no alteration detected). No mosaics or structural rearrangements were identified by either of the two analysis techniques. The only discordant result was a case in which cytogenetics of POCs identified a triploidy. This discordancy is expected since triploidies are outside the scope of cfDNA testing. Also, foetal sex was correctly assigned in all informative cases. The sensibility and specificity of the study were estimated at 80.0 (4/5) and 100.0% (6/6), respectively. Statistics analysis suggested that no significant difference was found between both techniques regarding the aneuploidy detection ability ($P=0.5$). These promising results indicate that genome-wide cfDNA-based screening provides a non-invasive approach for determining whether foetal aneuploidy could explain the loss in patients experiencing early o recurrent pregnancy loss (RPL).
Limitations, reasons for caution: The sample size prevents drawing more significant conclusions regarding the diagnosis power similarity between both testing techniques. Therefore, a larger cohort will be essential to improve confirm the cfDNA testing performance. Current cfDNA testing technology fails in polyploidy identification, which is a potential cause of pregnancy loss.
Wider implications of the findings: CfDNA testing could be an alternative to POC analysis in clinical miscarriage. If optimized, cfDNA testing could be used contingently with the molecular POC analysis in cases where maternal cell contamination is present. As a result, the overall success rate in the POC program could be substantially improved.

O-238 Preterm birth after recurrent pregnancy loss: A systematic review and meta-analysis

C. Wu[1], K. Nichols[2], M. Carwana[3], C. Nicholas[4], C. Maratta[5]

[1]University of Ottawa, Reproductive Endocrinology and Infertility, Ottawa, Canada ;
[2]Women & Infants Hospital, Obstetrics and Gynecology, Providence, U.S.A. ;
[3]University of British Columbia, General Pediatrics, Vancouver, Canada ;
[4]University of Ottawa, Plastic and Reconstructive Surgery, Ottawa, Canada ;
[5]University of Toronto, Paediatric Critical Care Medicine, Toronto, Canada

Study question: What is the impact of recurrent pregnancy loss on the risk of preterm birth?

Summary answer: Women with RPL were found to be at increased odds of having preterm deliveries (<37 weeks gestation) in their subsequent live pregnancies.

What is known already: Recurrent pregnancy loss (RPL) occurs in up to 5% of all women with miscarriages. The emotional, physical, and financial burden associated with RPL is unequivocal, and over the years, much research has gone into the management of RPL. However, relatively little is known about the perinatal outcomes following RPL. Past research in the area reports conflicting data on the association between RPL and preterm birth (PTB) in a subsequent pregnancy.

Study design, size, duration: A systematic search was performed across the-PubMed, EMBASE and Google Scholar databases for relevant studies published up until October 2020. Observational cohort and case-control studies comparing the risk of preterm birth (PTB) among women with and without a history of RPL were included. Effect estimates were pooled using a DerSimonian and Laird random-effects meta-analysis model. Study appraisal was performed using the Newcastle-Ottawa scale.

Participants/materials, setting, methods: We included studies where the study population consisted of women with a history of RPL (defined as 2 or more pregnancy losses), where the comparator group consisted of women without a history of RPL, and where the outcomes assessed included PTB (defined as birth prior to 37 completed weeks gestation). Two reviewers independently extracted data in duplicate. Publication date, population, exposure and outcome data were extracted.

Main results and the role of chance: A total of 12 retrospective observational studies met inclusion criteria, and were included in the systematic review and meta-analysis (N = 37,046 women with a history of RPL). Incidence of PTB among the RPL groups ranged from 5.8% to 19.6%, and from 1.5-14.0% in the non-RPL groups. A pooled OR of 1.59 with 95% CI 1.40-1.80 was observed in our random-effects meta-analysis with an I^2 of 84%. Subgroup analyses were completed for the pooled risk of only 2 RPL (pooled odds ratio [OR] 1.35; 95% CI 1.08-1.69; I^2=84.7%); ≥2 RPL (pooled OR 1.42; 95% CI 0.91-2.22; I^2=68.9%); and ≥3 RPL (pooled OR 1.86; 95% CI 1.51-2.29; I^2=79.5%).

Limitations, reasons for caution: Inconsistent adjustment for confounders and significant between-study heterogeneity were noted in this study.

Wider implications of the findings: Despite significant heterogeneity among studies, we found that women with a history of RPL had significantly higher odds of delivering preterm infants in their subsequent pregnancies.

P-001 Effect of mild α-chymotrypsin treatment of highly viscous semen samples on fertilization rates

A. Schallmoser[1], J. Verguts[2], J.P. Allam[1], N. Sänger[1]

[1]University WHospital Bonn- Germany, Reproductive Medicine, Bonn, Germany ; [2]Jessa Hospital- Hasselt- Belgium, Department of Gynecology, Hasselt, Belgium

Study question: The main objective of this study was to examine the influence of mild α-chymotrypsin treatment of highly viscous semen samples on the fertilisation rate after artificial reproductive treatment (ART).
Summary answer: The use of mild α-chymotrypsin treatment of semen samples in case of hyperviscosity does not appear to impact negatively on the fertilization rates after ART.
What is known already: Highly viscous semen reduces sperm motility significantly and can contribute to infertility. When processing semen samples, few techniques exist to induce liquefaction in case of seminal hyperviscosity such as different washing steps and mechanical treatment. The use of α-chymotrypsin seems controversial due to possible negative effects on fertilisation rates after IVF.
Study design, size, duration: All patients were recruited at the Department of Gynecological Endocrinology and Reproductive Medicine, University Hospital of Bonn, Germany from July first 2018 till June first 2019. Anonymized data on age, number of previous pregnancies and deliveries were retrospectively collected. The study group consisted of a cohort of 52 couples meeting the inclusion criteria of highly viscous semen and were compared to a cohort control group of 88 couples.
Participants/materials, setting, methods: The fertilization rate of 52 ART cycles was examined following IVF using a low dose of α-chymotrypsin to induce liquefaction of highly viscous semen and was compared to a control group of 88 ART cycles. Data was analyzed using SPSS version 25. A Mann Whitney U test was used to compare continuous parameters between groups.
Main results and the role of chance: The study group consisted of a cohort of 52 couples meeting the inclusion criteria of highly viscous semen and were compared to a cohort control group of 88 couples. The Fertilization rate between the two groups was not significant ($p<0.146$, Mann-Whitney U test), with a rate of 57.95 in the study group compared to 57.53 in the control group. Our analysis showed no significant differences in male and female age, male abstinence period, semen volume, sperm concentration, total sperm count, and total progressive sperm count between the two groups. We observed a significant difference [$p=0.025$] in the progressive motility and a borderline significance in the total progressive sperm count [$p=0.052$] between α-chymotrypsin treated samples and the non α-chymotrypsin treated samples. Analyzing the clinical and biochemical pregnancy parameters of the study group (n=41) and the control group (n=66) per fresh embryo transfer procedures (n=107) we found no significant differences. Freeze all cycles were excluded from the study. No significant differences concerning previous pregnancies and childbirth were detected.
Limitations, reasons for caution: The study is a pilot study as the majority of the studies using α-chymotrypsin was conducted up to three decades ago, comparison of data must be interpreted in the light of the fact that since then, IVF has seen a rapid evolution of technology and culture techniques.
Wider implications of the findings: The use of mild α-chymotrypsin treatment of semen samples in case of hyperviscosity does not appear to impact negatively on the fertilization rates after ART and could be regarded as an additional method to induce liquefaction of highly viscous semen samples in IVF...
Trial registration number: not applicable

P-002 Prediction model for salvage microdissection testicular sperm extraction in patients with failed conventional testicular sperm extraction

E. Caroppo[1], F. Castiglioni[2], C. Campagna[2], E.M. Colpi[2], E. Piatti[2], G. Gazzano[3], G.M. Colpi[2]

[1]Asl Bari, Andrology Outpatients Clinic, Bari, Italy ; [2]Procrea Institute, Andrology Unit, Lugano, Switzerland ; [3]IRCCS Istituto Auxologico, Anatomia Patologica, Milano, Italy

Study question: Is there any intra-surgical parameter able to predict the outcome of salvage microdissection testicular sperm extraction (mTESE) in patients with previous failed TESE?
Summary answer: Among all the variables under consideration, only the seminiferous tubules (ST) caliber pattern found at high magnification was able to significantly predict the mTESE outcome...
What is known already: Several studies have demonstrated that no clinical or hormonal parameters are able to predict the outcome of a salvage mTESE performed in patients with previous sperm retrieval failure (SRF). It has been previously demonstrated that a prediction model with the combination of two intra-surgical parameters such as the STs caliber, defined as dilated tubule (DT), slightly dilated tubules (SDT) and not dilated tubules (NDT), and testis histology had an excellent discrimination ability (AUC 0.93) to distinguish between cases with and without the outcome, but such prediction model has not been tested in patients undergoing salvage mTESE.
Study design, size, duration: A prediction model was built on a dataset of 63 patients, 29-50 years old, undergoing unilateral (15) or bilateral (48) salvage mTESE after failed TESE from 2015 through 2019, with a resulting N=111 testes under consideration. Two models were compared, one with STs and histology as covariates, the other with STs alone: the second model was chosen due to better discrimination...
Participants/materials, setting, methods: we assessed internal validity with a bootstrapping procedure for a realistic estimate of the performance of the prediction model in similar future patients with NOA undergoing salvage mTESE. We repeated the entire modeling process in 259 samples drawn with replacement from the original sample, and determined the performances (AUC, sensitivity, specificity) of the selected prediction model. Calibration (correspondence between the predicted and observed probabilities) was visually assessed by inspecting the calibration belt...
Main results and the role of chance: Sperm retrieval was successful in 24 out of 63 patients (38%): age, testis volume and hormonal parameters did not vary among patients with successful sperm retrieval (SSR) or SRF. The prevalent histological pattern was Sertoli cell only syndrome (69.6%), while hypospermatogenesis, maturation arrest and hyalinosis were found in 4.5%, 23% and 1.8% of cases. The STs pattern was heterogeneous, with DTs being found only in 23.4% of testes. Sperm were found in 69% of DTs, 29% of SDTs, and 5% of

NDTs. The prediction model correctly classified 82.88% of patients and explained the 26.5% variability of the outcome. The STs pattern significantly predicted the mTESE outcome with a sensitivity of 62% and a specificity of 90.2%, PPV 69.2%, NPV 87%. Both SDT (OR 0.105, 95% CI 0.034-0.317, p<0.0001) and NDT (OR 0.024, 95% CI 0.004-0.128, p<0.0001) were negatively associated with the chance of retrieving sperm, the resulting prediction equation being Log (SSR)= 0.81 – 2.2 SDT – 3.7 NDT. The model had a clearly useful discrimination (AUC 0.813). The optimism corrected AUC was 0.7977, and the model was well calibrated (p=1.00) with both the 80% and 95% calibration belts encompassing the bisector over the whole range of the predicted probabilities

Limitations, reasons for caution: The STs caliber pattern was subjectively evaluated at high magnification (24-36x) by comparing the individual ST appearance with the surrounding ones, however such evaluation was performed by the same experienced urologist with more than 1000 mTESE procedures performed to date.

Wider implications of the findings: No clinical data but the STs appearance at high magnification could discriminate between patients with and without chances of SSR. These results reinforce the evidence supporting the superiority of mTESE compared to conventional TESE in retrieving sperm, particularly in lower prognosis patients with NOA such as those with previous SR.

Trial registration number: Not applicable

P-003 Transposon insertion profiling by sequencing (TIPseq) identifies novel LINE-1 insertions in human sperm

T. Berteli[1], F. Wang[1], W. McKerrow[2], P. Navarro[3], D. Fenyo[2], J. Boeke[2], F. Kohlrausch[1], D. Keefe[1]

[1]New York University- Langone Medical Center, Department of Obstetrics and Gynecology, New York, U.S.A. ;
[2]New York University, Institute for Systems Genetics, New York, U.S.A. ;
[3]Faculty of Medicine of Ribeirao Preto- University of Sao Paulo, Human Reproduction Division- Department of Gynecology and Obstetrics, Ribeirão Preto, Brazil

Study question: Do human sperm contain novel LINE-1 insertions and are they affected by paternal age?

Summary answer: Human sperm contain novel LINE-1 insertions. Their location or number are not affected by paternal age.

What is known already: LINE-1 comprises 17% of the human genome and some LINE-1s are the only autonomous retrotransposons in humans. Retrotransposons influence genomic instability and/or regulation if new retrotransposition events disrupt coding or regulatory regions in the host genome. Demethylation during germ cell development de-represses retrotransposons. Advanced paternal age is associated with genomic instability. Previously we showed that sperm LINE-1 copy number decreases with paternal age. We hypothesize that human sperm exhibit de novo retrotransposition and that sperm from older men contain increased novel LINE-1 insertions.

Study design, size, duration: Cross-sectional case–control study with semen samples collected between February to July 2020.

Participants/materials, setting, methods: Normospermic sperm samples (n=10; 5 <35 years old and 5 ≥45 years old) obtained from consenting men undergoing IVF at NYU Fertility Center were submitted to a novel method, single cell Transposon Insertion Profiling by Sequencing (scTIPseq) to identify and map LINE-1 insertions in human sperm. TIPseqHunter, a custom bioinformatics pipeline, compared the architecture of sperm LINE-1 to known LINE-1 insertions from the European database of human specific LINE-1 (L1Hs) retrotransposon insertions in humans (euL1db).

Main results and the role of chance: TIPseq identified 17 novel insertions in sperm, 8 from older (≥ 45 years) and 9 in younger men (<35 years). New insertions were mainly intergenic or intronic, including *AC007402* (2/10), *TMEM163* (2/7), *CTTNBP2NL* (3/5), *AC107023* (3/3), *TMC2* (2/19), *MacroD2* (2/6), *RAB3C* (3/4), *LINC02664* (1/1), *AC079052* (2/3) and *AC017091* (4/4). One novel insertion (<35 years old) hits a known regulatory element. Only one sample (≥ 45 years old) did not exhibit any new insertion. The location or number of novel insertions did not differ by paternal age.

Limitations, reasons for caution: The small sample-size and use of normospermic specimens limit interpretation of paternal age effect on LINE-1. Besides, the novel insertions could be polymorphic sites that have low allele frequency and thus have not yet been described.

Wider implications of the findings: This study for the first time reports novel LINE-1 insertions in human sperm, demonstrating that scTIPseq method is a feasible technique, and identifying new contributions to genetic diversity in the human germ line. Further studies are needed to evaluate the impact of these insertions on sperm function.

Trial registration number: Not applicable

P-004 Effect of varicocelectomy on sperm DNA fragmentation rates in infertile men with clinical varicocele: a systematic review and meta-analysis

F. Tenori. Lir. Neto[1], M. Roque[2], S. Esteves[3]

[1]Instituto de Medicina Integral Prof. Fernando Figueira, Department of Urology, Recife, Brazil ;
[2]Mater Prime, Department of Reproductive Medicine, São Paulo, Brazil ;
[3]ANDROFERT, Andrology and Human Reproduction Clinic, Campinas, Brazil

Study question: Does varicocelectomy improve sperm DNA quality in men with infertility and clinically detected varicoceles?

Summary answer: Varicocelectomy reduces sperm DNA fragmentation (SDF) rates in infertile men with clinical varicocele.

What is known already: Varicocele has been linked to male infertility through various non-mutually exclusive mechanisms, including an increase in reactive oxygen species (ROS) production that may lead to sperm DNA damage. Damage to sperm DNA may result in longer time-to-pregnancy, unexplained infertility, recurrent pregnancy loss, and failed intrauterine insemination or in vitro fertilization/intracytoplasmic sperm injection. Therefore, interventions aimed at decreasing SDF rates, including varicocele repair, have been explored to improve fertility and pregnancy outcomes potentially, either by natural conception or using medically assisted reproduction.

Study design, size, duration: Systematic review and meta-analysis

Participants/materials, setting, methods: We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. Our systematic search included PubMed/Medline, EMBASE, Scielo, and Google Scholar to identify all relevant studies written in English and published from inception until October 2020. Inclusion criteria were studies comparing SDF rates before and after varicocelectomy in infertile men with clinical varicocele. Articles were included if the following SDF assays were utilized: SCSA, TUNEL, SCD test, or alkaline Comet.

Main results and the role of chance: Thirteen studies fulfilled the inclusion criteria and were selected for the analysis. The estimated weighted mean difference of SDF rates after varicocelectomy was -6.58% (13 studies, 95% CI -8.33%, -4.84%; I^2=90% p<0.0001). Subgroup analysis revealed a significant decrease in SDF rates using SCSA (eight studies, WMD -6.80%, 95% CI -9.31%, -4.28%; I^2=89%, p<0.0001), and TUNEL (three studies, WMD -4.86%, 95% CI -7.38%, -2.34%; I^2=89%, p<0.0001). The test for subgroup difference revealed that pooled results were conservative using the above SDF assays. Comet and SCD tests were used in only one study each; thus, a meta-analysis was not applicable. The studies were further categorized by the surgical technique (microsurgical versus non-microsurgical). This subgroup analysis showed a significant decrease in SDF rates using microsurgical technique (10 studies, WMD -6.70%, 95% CI -9.04%, -4.37%; I2=91%, p<0.0001). After varicocelectomy, SDF rates were also decreased when non-microsurgical approaches were used, albeit the effect was not statistically significant (2 studies, WMD -6.84%, 95% CI -10.05%, 1.38%; I2=86%) (Figure 3). The heterogeneity was not materially affected by performing analyses by the above subgroups, suggesting that the SDF assay and surgical technique do not explain the inconsistency in the treatment effect across primary studies.

Limitations, reasons for caution: There were no randomized controlled trials comparing varicocelectomy to placebo for alleviating SDF levels. Heterogeneity was high, which may be explained by the low number of included studies. Pregnancy data are not available in most studies, thus the impact of reduced SDF after varicocelectomy on pregnancy rates unclear.

Wider implications of the findings: Our study indicates a positive association between varicocelectomy and reduced postoperative SDF rates in men with clinical varicocele and infertility, independentetly of the assays used to

measure SDF. These findings may help counsel and manage infertile men with varicocele and high SDF levels.
Trial registration number: not applicable

P-005 Magnetic-activated cell sorting in couples undergoing preimplantation genetic testing for aneuploidies (PGT-A) using autologous oocytes shows slightly lower aneuploidy rates compared to standard semen processing

M. Gi. Julia[1], I. Hervas[1], A. Navarro-GomezLechon[1], F. Quintana[2], D. Amoros[3], A. Pacheco[4], C. Gonzalez-Ravina[5], R. Rivera-Egea[6], N. Garrido[1]

[1]IVI Foundation, Andrology and Male Infertility, Valencia, Spain ; [2]IVIRMA Bilbao, Andrology Laboratory, Bilbao, Spain ; [3]IVIRMA Barcelona, Andrology Laboratory, Barcelona, Spain ; [4]IVIRMA Madrid, Andrology Laboratory, Madrid, Spain ; [5]IVIRMA Sevilla, Andrology Laboratory, Sevilla, Spain ; [6]IVIRMA Valencia, Andrology Laboratory, Valencia, Spain

Study question: Does the selection of non-apoptotic sperm via magnetic-activated cell sorting (MACS) reduce the aneuploidy rate of embryos from couples undergoing ICSI cycles with PGT-A using the patients' own oocytes?
Summary answer: It does. The aneuploidy rate in the MACS group was 4.34% lower than the one obtained using semen samples processed according to standard clinical practice.
What is known already: MACS is a successful tool in eliminating proapoptotic sperm from a semen sample. However, the true effect of this technique on reproductive outcomes and the quality of the resulting embryos are a matter of controversy. Some studies report that its use improves the percentage of good quality blastocysts in women older than 30 years old compared to standard ICSI. Randomized clinical trials that compare MACS to a control sample consider parameters of embryo quality such as morphology at day 3 or day 5, symmetry of the blastomeres, blastocysts' stage of expansion, but they do not consider embryo ploidy.
Study design, size, duration: Retrospective, multicentre, observational cohort study. 14,145 patients and 18,710 cycles were evaluated in the reference group. In the MACS group, 615 patients and 974 cycles were considered. Data were exported from cycles performed in Spanish IVIRMA clinics between January 2008 and February 2020.
Participants/materials, setting, methods: Unselected males in couples undergoing PGT-A cycles, then subdivided into male factor (MF) - total progressive motile sperm count lower than 5 million - and non-male factor (NMF) infertility. Statistical analysis performed using R v.4.0.0. Means were calculated and compared using two-tailed paired t-test, while proportions were compared using Fisher's exact test and the chi-squared test and the appropriate correction for multiple comparisons. The aneuploidy rates for each group were compared using Fisher's exact test.
Main results and the role of chance: In the control group 73,228 biopsied embryos, from which 71,439 were informative in the PGT-A. In the MACS group 3,919 biopsied embryos, from which 3,843 were informative. The aneuploidy rate, computed per informative embryo, was 68.87% (68.40%, 69.34%) in the reference group and 64.53% (62.43%, 66.64%) in the MACS group. Both comparisons were statistically significant (p-value <0.00001). According to these results, an embryo in the PGT-A programme using non-apoptotic sperm selected through MACS and autologous oocytes had a 5% less chance of being aneuploid than those embryos fertilised with standardly selected sperm (relative risk of 0.95 (0.91-0.98) p=0.006769). Embryos conceived from NMF patients whose semen had been processed using MACS had a 4.27% lower aneuploidy rate than the reference (65.52% (63.16%, 67.88%) vs 69.79% (69.20%, 70.37%) respectively). This difference was statistically significant. Those embryos conceived using semen from patients with MF using MACS also showed a lower aneuploidy rate than the reference with MF (0.28% (55.48%, 65.08%) vs (64.94% (63.35%, 66.23%) respectively), although this difference was not statistically significant. Thus, the decrease in aneuploidy rate observed when comparing MACS and reference groups undergoing PGT-A cycles using autologous oocytes remained approximately the same in both MF and NMF semen samples.
Limitations, reasons for caution: The retrospective nature of the study subjects the data to biases or inaccuracies in their annotation in the clinics' informatic platform from which they were exported. However, the statistical analysis aimed at controlling these biases as much as possible.
Wider implications of the findings: The vast amount of data compiled for this study confirms that the selection of non-apoptotic sperm through MACS slightly decreases the aneuploidy rate of embryos compared to semen samples processed according to the clinics' standards. This would be interesting for patients who are considering undergoing PGT-A cycles in the future.
Trial registration number: Not applicable

P-006 Simultaneous determination of bisphenol A and S in the samples of human seminal fluid

S. Fialková[1], T. Král[1], J. Kohoutek[2], K. Franzová[3], M. Ješeta[3], J. Navrátilová[2]

[1]Faculty of science- Masaryk University, Experimental biology, Brno, Czech Republic ; [2]Faculty of science- Masaryk University, RECETOX Centre, Brno, Czech Republic ; [3]Faculty of Medicine - Masaryk University and University Hospital Brno, Center of Assisted Reproduction- Department od Gynecology and Obstetrics, Brno, Czech Republic

Study question: Can we quantitatively determine concentrations of endocrine disruptors namely bisphenol A and S in seminal fluid?
Summary answer: We developed selective analytical method to simultaneously screen for the presence of bisphenol A (BPA) and S (BPS).
What is known already: The male reproductive system involves processes, which may be influenced by the disruption of the endocrine system by chemicals called endocrine disruptors (EDs). There is a growing evidence that EDs such as bisphenol A and S may be responsible for the decline in male reproductive health. To date, the claimed adverse effects on male fertility are largely based on the results from studies assessing the relationship between urinary BPA and BPS concentration and semen parameters. The best evidence of an adverse effect of BPA and BPS directly on spermatozoa could be provided by measuring bisphenols concentration directly in seminal fluid.
Study design, size, duration: To selectively and quantitatively analyzed bisphenols in any biological matrix advanced analytical tools and selective sample preparation protocols must be employed. In this study we developed targeted analytical method based on liquid chromatography tandem mass (LC-MS/MS) detection to measure bisphenol A and S in seminal fluid samples obtained from IVF clinic. A total of 140 samples were analysed.
Participants/materials, setting, methods: BPA and BPS was extracted from 140 seminal fluid samples using solvent extraction followed by preconcentration step. Samples were analyzed on Agilent 6495 Triple Quadrupole (Agilent Technologies, Santa Clara, CA) operating in the ESI-negative mode. Two MS/MS transitions were used for quantitative LC-MS/MS analyses. Chromatographic separation was achieved on Waters™ ACQUITY™ UPLC™BEH C18 (100 × 2.1 mm, 1.7 µm) column using gradient elution with a mixture of 0.1mM ammonium fluoride and methanol as mobile phases.
Main results and the role of chance: We developed selective sample preparation method for detection of BPA and BPS in seminal fluid followed by LC-MS/MS detection. The method validation was performed based on FDA guidelines. Validation criteria included limit of detection (LOD), limit of quantitation (LOQ), accuracy and precision. Due to the lack of the certified reference material the validation criteria of the method were assessed in pool of spiked seminal samples. The accuracy of the LC-MS/MS method was evaluated as a percent recovery of the amount of target analyte added into the sample. Recovery rates were above 80 % for both analytes. LOD was 0.04 ng/mL for BPA and 0.01 ng/mL for BPS. LOQ was 0.14 ng/mL and 0.02 ng/mL for BPS. Measured BPA concentration ranged from 0.04 ng/mL to 1.62 ng/mL. For BPS, the concentration ranged from 0.01 ng/mL to 0.47 ng/mL. BPA and BPS were detected in 64 % and 81 % of samples, respectively. Interestingly, BPA showed lower detection frequency compared to BPS. These results are consistent with other studies performed on urine samples.
Limitations, reasons for caution: The limitation of the developed method is the time-consuming sample preparation and analysis cost.
Wider implications of the findings: These results document for the first time the presence of BPS in seminal fluid. Knowing the concentration of BPA and BPS in seminal fluid is crucial for mitigating the associated health risks and

initiating intervention and prevention strategies. Our future work will evaluate the influence of BPS concentration on spermatozoa.
Trial registration number: AZV NV18-01-00544; CZ.02.2.69/0.0/0.0/19_074/0012727

P-007 Effect of swim-up on sperm morphology

R. Ganeva[1], D. Parvanov[1], M. Handzhiyska[1], G. Stamenov[2]

[1]"Nadezhda" Women's Health Hospital, Research and Development, Sofia, Bulgaria ;
[2]"Nadezhda" Women's Health Hospital, Obstetrics and Gynecology, Sofia, Bulgaria

Study question: To evaluate the effect of swim-up on the percentage of certain morphological defects in the semen population
Summary answer: Swim-up preparation led to significantly lower percentage of spermatozoa with cytoplasmic droplets, thick neck and also multiple defects.
What is known already: Swim-up is routinely used sperm preparation technique in ART practice. It is widely known that swim-up enhances sperm quality in terms of motility and sperm morphology. However, the effect of swim-up on the frequency of occurrence of the specific sperm morphological abnormalities is still missing.
Study design, size, duration: This observational study involved 30 teratozoospermic patients of Nadezhda Women's Health hospital between December 2020 and January 2021. Sperm morphology was evaluated before and after swim-up preparation.
Participants/materials, setting, methods: Native semen was liquefied and was subjected to swim up. Semen analysis performed according to WHO 2010. Native semen and swim up samples from the same men were subjected to Kruger strict morphological evaluation.

The analyzed sperm morphological defects included: head defects (large, small, tapered, pyriform, round, amorphous and double heads); midpiece defects (bent, asymmetrical, thin, thick, presence of cytoplasmic droplet); tail defects (short, hairpin, bent, coiled tail and terminal droplet) and multiple defects.
Main results and the role of chance: Wilcoxon paired test showed that the percentage of morphologically normal spermatozoa was significantly higher in the swim-up samples in comparison to the native semen (8.5±4.2% vs 4.9±3.2%, $p<0.05$). In addition, the percentage of spermatozoa bearing multiple defects was found to be significantly lower in the swim-up samples than in the native semen (25.8±11.6% vs 37.0±15.0%, $p<0.05$). Two specific sperm morphological defects were found to be significantly lower after swim-up preparation: the presence of cytoplasmic droplets (6.0±1.0% vs 8.6±1.5%, $p<0.05$) and the thick neck (9.7±5.5% vs 12.8±5.8%, $p<0.05$). No significant different were observed in the other morphological defects between swim up samples and native semen ($p>0.05$).
Limitations, reasons for caution: Results obtained from this study need to be confirmed by larger group of samples.
Wider implications of the findings: Our study showed a significant reduction of certain midpiece defects after swim-up. The observed selection of spermatozoa without thick necks and cytoplasmic droplets explains the effectiveness of swim-up on ART. In addition, the obtained results can serve as a guide for future validation of new sperm preparation techniques.
Trial registration number: Not Applicable

P-008 The diameter of standard seminiferous tubules varies with the different histological patterns in patients with non-obstructive azoospermia

G. Colpi[1], E.M. Colpi[1], C. Campagna[1], E. Piatti[1], F. Castiglioni[1], G. Gazzano[2], E. Caroppo[3]

[1]Procrea Institute, Andrology Unit, Lugano, Switzerland ;
[2]Irccs Auxologico Italiano, Anatomia Patologica, Milano, Italy ;
[3]Asl Bari- PTA F JAIA, Andrology Outpatients Clinic, Conversano Ba, Italy

Study question: Does the standard, not-dilated seminiferous tubules (STs) diameter vary according with different testis histology patterns in patients with non-obstructive azoospermia (NOA)?
Summary answer: The standard STs diameter differed significantly among cases with different testis histology: hypospermatogenesis (HYPO) had the highest STs diameter compared to the other histological subgroups.
What is known already: During microdissection testicular sperm extraction (mTESE), the identification of dilated STs, as subjectively evaluated at high magnification by comparing their apparent caliber with that of the surroundings, is crucial to identify residual foci of intact spermatogenesis and to retrieve sperm. Previous studies have demonstrated that dilated STs contain sperm in most cases, but it is not clear why in some cases an apparent normal tubular caliber does not correspond to spermatogenesis integrity. Aim of the present study was to assess whether different histology patterns could affect the STs diameter.
Study design, size, duration: We retrospectively evaluated 168 patients with NOA undergoing unilateral (N=91) or bilateral (N=77) mTESE from 2018 through 2019. One or more biopsy samples representative of the overall appearance of the testicular parenchyma were taken from one (for unilateral mTESE) or both testes (for bilateral mTESE), was fixed in Bouin's solution and sent to the pathologist. Histological analysis was conducted by the same experienced pathologist, who examined at least 100 different tubule sections per biopsy sample.
Participants/materials, setting, methods: Each tubule section (N=100 per sample) was evaluated at 10X magnification with a micrometer to measure the tubule diameter, then the mean ST diameter was computed. The basal membrane (BM) thickening was evaluated in every section, and a score was assigned by multiplying the degree of BM fibrosis (mild=1, moderate=2, severe=3) for the number of sections (e.g. BM score for moderate fibrosis in 50 sections=2x50=100). Leydig cells hyperplasia (LCH), if present, was also annotated.
Main results and the role of chance: The median + interquartile range STs diameter was 140; 110-185 mm, while the median BM score was 100; 10-150. Sertoli cell only syndrome (SCO) was found in 51.1% of cases, focal SCO (FSCO) in 4,7%, early (EMA) and late (LMA) maturation arrest in 10.2 and 2.73% respectively, HYPO in 26.17% and hyalinosis (HL) in 5% of cases. LCH was found in 46.88% of samples. STs diameter, BM score and LCH differed significantly among the different histological patterns: STs diameter was 125; 100-148 in SCO, 162; 102-187 in FSCO, 130; 100-175 in EMA, 145; 130-195 in LMA, 205; 170-240 in HYPO and 57.5; 42.5-100 in HL. HYPO samples also had the lowest BM score (20;1-100; $p<0.0001$) and LCH prevalence (23.8%, $p<0.0001$) compared to the other histological subgroups (HS). A multinomial logistic regression for prediction of different histological subgroups was run with STs diameter, BM score and LCH as candidate predictors: the model explained the 29% of variability of the outcome and correctly classified 69% of cases. STs diameter significantly predicted FSCO (RR 1.02, 95% CI 1.0-1.04), LMA (RR 1.02, 95% CI1-1.04) and HYPO (1.03, 95%CI 1.02-1.04), while BM score significantly predicted HL (RR 1.07, 95%CI 1.02-1.13).
Limitations, reasons for caution: The STs were carefully cut before extraction in order to preserve their structural integrity, however the accuracy of such a method of estimating the STs diameter needs to be assessed by further studies.
Wider implications of the findings: The identification of dilated STs remains the best strategy to retrieve sperm by mTESE, since larger STs diameters are mostly associated with the more favorable histological patterns. However, dilated STs may be also found in cases with LMA, which explains why in some cases dilated STs do not contain sper.
Trial registration number: not applicable

P-009 A modified sperm chromatin dispersion test, LensHooke® R10, for quick and accurate determination of human sperm DNA fragmentation

L.S. Chang[1], H.C. Lee[1], C.T. Hsu[2], H.M. Tsao[3], C.C. Huang[3], M.S. Lee[3]

[1]Bonraybio Co.- Ltd, Clinical Medicine Dept., Taichung, Taiwan R.O.C. ;
[2]Bonraybio Co.- Ltd, Executive Office, Taichung, Taiwan R.O.C. ;
[3]Lee Women's Hospital, IVF Center, Taichung, Taiwan R.O.C.

Study question: The performance and efficiency of the LensHooke® R10 test kit were evaluated by the clinical examination for precision, accuracy, and time.
Summary answer: The LensHooke® R10 based on sperm chromatin dispersion test offers not only quick testing for sperm DNA fragmentation but also reliable and accurate test results.
What is known already: Sperm chromatin dispersion (SCD) test, one of the most commonly used testing for sperm DNA fragmentation (SDF), can be conducted promptly and without the need for expensive laboratory instruments.

However, the main disadvantage of the SCD test is inter-observer variability in categorizing the size of characteristics halos surrounding the core of sperm. Moreover, it takes more than one hour to accomplish whole assay procedures making this testing an inefficient diagnostic tool. These may hinder its broad availability among andrology laboratories or prevent it from being routinely used for the evaluation of male infertility.

Study design, size, duration: A total of 108 participants was included in this prospective study. Data was collected from the reproductive medicine center between June and December 2020.

Participants/materials, setting, methods: This study included 108 consecutive male partners of couples attending for assisted reproductive treatment. SDF was simultaneously tested by using LensHooke® R10 (R10) and Halosperm® G2 (G2) respectively. We evaluated the correlation and agreement between two SCD-based test kits. The repeatability and reproducibility of the SCD kits were assessed by intra-and inter-observer agreement experiments. The sensitivity, specificity, positive predictive value, negative predictive value for the R10 was determined by receiver operator characteristics (ROC) curve analysis.

Main results and the role of chance: The R10 produced more clear sperm core and dispersed chromatin, therefore highly recognizable images can be easily and accurately categorized when scoring of SDF. It took 50% less time for SDF testing by the R10 compared to the G2 (38.26 ± 9.85 minutes vs. 76.52 ± 19.7 minutes, P< 0.0001). The SDF% results showed a strong correlation for the R10 and G2 with Spearman's coefficients of rank correlation (rho) above 0.8 (P<0.0001, N=108). The R10 showed 89.8% accuracy with 87.9% sensitivity, 90.8% specificity, 82.9% PPV, and 93.7% NPV on the measurement of SDF% at the threshold value of 22%. Intraclass correlation coefficients (ICC) >0.9 showed a strong agreement between two observers on the testing of SDF using the R10. ICC >0.9 showed a high intra-observer agreement within 4 repeated testing on SDF using the R10. The R10 showed an intra-observer's precision of coefficient variation, CV <10% for SDF%. In addition, SDF% test results obtained by the R10 for asthenospermic (31.8% ± 16.7%), teratospermic (22.9% ± 14.4%), and oligoasthenoteratozoospermic samples (36.6% ± 14.4%) were significantly higher than that observed in normozoospermic samples (15.3% ± 10.2%, p< 0.05), was comparable with the G2.

Limitations, reasons for caution: The sample size of 4 semen specimens used to evaluate the intra-and inter-observer agreement was a limitation. Besides, evaluating the relationship between the SDF and clinical outcome of ART is necessary for further study.

Wider implications of the findings: The new in vitro diagnostics reagent, LensHooke® R10, is a simple and quick test kit that offers reliable and accurate test results of sperm DNA fragmentation, can be routinely used in male infertility evaluation.

Trial registration number: CS2-20012

P-010 Timing of TESE does not affect laboratory outcomes

C. Goktas[1], M. Basar[2], M. Fetahovic[3], H. Spahovic[4], E. Goktas[5], U. Goktolga[6]

[1]bahceci bih ivf centar, Embryology, sarajevo, Bosnia - Herzegovina ;
[2]Bahceci Umut Ivf Center, Embryology, Istanbul, Turkey ;
[3]bahceci bih ivf centar, Andrology, Sarajevo, Bosnia - Herzegovina ;
[4]bahceci bih ivf centar, urology, Sarajevo, Bosnia - Herzegovina ;
[5]bahceci bih ivf centar, Nursing Department, Sarajevo, Bosnia - Herzegovina ;
[6]T.C Uskudar University, Gynecology obstetrics, Istanbul, Turkey

Study question: What is the outcome of intracytoplasmic sperm injection (ICSI) using testicular spermatozoa obtained on the day of oocyte pick-up (OPU) or the day before OPU.

Summary answer: Testicular spermatozoa were obtaining the one day before OPU does not affect fertilization rate, top quality embryo on day 3, and blastocyst utilization rate.

What is known already: Usually, TESE is performed just before OPU. OPU is generally cancelled if no sperm is retrieved. The use of fresh testicular spermatozoa, obtained the day before OPU could offer the couple and the caring team both medical and practical advantages. The benefits of this approach, however, has not been evaluated in detail. An uncontrolled preliminary study has revealed that regular fertilization and pregnancy rates could be achieved with sperm extraction performed one day before OPU.

Study design, size, duration: This was a single-center retrospective study in Bahceci BIH IVF center. Sixty-six patients suffering from azoospermia from January 2015 to December 2020 were evaluated. TESE was performed either on the OPU day (43 patients; group A) or one day before OPU (23 patients; group B).

Participants/materials, setting, methods: In this study, primary outcomes were motile spermatozoa at ICSI, fertilization, top quality embryo on day 3, and blastocyst utilization rate. Statistical analyses were performed with chi-squared tests.

Main results and the role of chance: There is no statistical difference fertilization rate (72.3% vs. 72.2, p>0.05), top quality embryo rate on day 3 (58.3% vs 58.3%, p>0.05) and blast utilization rate (43.98% vs 49.58%, p>0.05) between group A and B, respectively.

Limitations, reasons for caution: The retrospective nature of this study may not eliminate potential bias. On the contrary, the strength of our study is that all procedures were performed by the same operators, so there are no operator-dependent differences. More research is needed to prove our findings.

Wider implications of the findings: TESE procedure can be performed one day before OPU without compromising success.

Trial registration number: 1

P-011 Automated sperm morphology assessment using artificial intelligence technology

A. Agarwal[1], M.K. Panne. Selvam[1]

[1]Cleveland Clinic, American Center for Reproductive Medicine, Cleveland, U.S.A.

Study question: Can LensHooke X1 PRO semen analyzer be used to evaluate sperm morphology in men with infertility?

Summary answer: Morphology results generated by X1 PRO are highly reliable when normal sperm forms are ≥4% and therefore they can be reported in such cases .

What is known already: Most laboratories rely on manual evaluation of sperm morphology smears, which is a time-consuming procedure and its results are subjected to a relatively high variability. However, in recent years the computer-assisted semen analyzers are being increasingly used to evaluate sperm morphology. The X1 PRO semen quality analyzer was designed for in vitro diagnostic use to analyze sperm concentration, total, progressive and non-progressive motility as well as sperm morphology based on WHO 5th edition criteria. Evaluation of sperm morphology using X1 PRO based on AIOM (Artificial Intelligence Optical Microscopic)-based technology requires no fixation steps or staining unlike the manual method.

Study design, size, duration: This cross-sectional study used 31 semen samples from 8 normozoospermic healthy volunteers and 5 infertile men with a minimum abstinence period between 2 - 3 days. While the 8 healthy semen donors produced a total of 26 ejaculates, which were split into 88 aliquots, the 5 infertile patients produced 5 ejaculates that were split into 13 aliquots.

Participants/materials, setting, methods: A total of 101 aliquots were prepared from the native semen samples either by dilution or concentration using seminal plasma of the respective donors. Automated semen analysis was performed by the X1 PRO semen analyzer and the results of sperm morphology were compared with manual morphology results using Diff-Quik staining. Statistical analysis was carried out to calculate the positive predictive value (PPV) and negative predictive value (NPV) of X1 PRO semen analyzer.

Main results and the role of chance: The X1 PRO sperm morphology results show a weak non-significant (P=0.2441) correlation (r=0.119) with the manual results. However, X1 PRO demonstrated a high PPV (97.7%) and a low NPV (9.1%) for correct assessment of sperm morphology (≥4%) when compared to manual results. Due to its high PPV, laboratories can report the morphology results generated by X1 PRO in all such cases when normal sperm forms are ≥4%. However, a manual evaluation is necessary in patients with abnormal morphology (<4%).

Limitations, reasons for caution: One of the limitation of this study is that X1 PRO morphology values did not correlate with manual results. The low NPV seen in our study is due to the inclusion of very few samples with abnormal sperm forms (<4%) in the analysis.

Wider implications of the findings: The X1 PRO's combination of speed, ease of use, accuracy and portability makes it a good choice of device for small medical offices to large IVF centers. High PPV of X1 PRO allows it to correctly identify normal sperm forms for diagnostic use.

Trial registration number: 18-771

P-012 A new sperm preparation technique for ICSI

K. Yildiz[1], U. Ucar[1], D. Deniz[1], A. Akinc. Bak[1], O. Atasoy[1], R. Pabuccu[2]

[1]Dogufertil IVF Center, Embryology Laboratory, MALATYA, Turkey ; [2]Centrum Clinic, Embryology Department, Ankara, Turkey

Study question: Is there any difference in this technique(swim-in) according to clinical results in ICSI cycles?
Summary answer: Fertilization rates are significantly better with this new technique(swim-in). There is no difference in pregnancy and ongoing pregnancy rates between swim-in and DGS techniques.
What is known already: Sperm separation is crucial in assisted reproductive technologies, based on different principles like migration, filtration, or density gradient centrifugation techniques. However, there are some studies that centrifugation steps and using gradient solutions may increase sperm DNA fragmentation. On the other hand, multiple contacts to different plastic surfaces such as pipettes, plastic tubes, etc., and also pipetting the ejaculate in sperm preparation may have detrimental effects. The ideal sperm separation technique should be non-invasive, not time-consuming, easy, and cost-effective, not cause sperm damage or non-physiological alterations of the separated sperm cells, eliminate dead spermatozoa and other cells, including leukocytes.
Study design, size, duration: This is a prospective randomized study between 01/02/2019...01/01/2021. Sperms were prepared either with this new technique that we call "swim-in"(n=359) or with density gradient centrifugation(n=404) before microinjection (ICSI). Fertilization rates, clinical pregnancy rates, and on-going pregnancy rates were compared between groups. Sperm motility is less than %20 patients are not included in the study. t-test and Chi-square test used. p<0.05 significant.
Participants/materials, setting, methods: For this new centrifugation free technique(swim-in), a Braun injector, 21G green needle, and sperm washing medium are used. First, we pulled a 0.5 ml sperm wash medium in a Braun injector. After sperm liquefaction, we put Braun injector with the needle in the sperm cap perpendicularly and waited 30 minutes at 37-degree Celcius. Sperms swam through the needle to the injector used for ICSI. For DGC sperms were prepared according to the 2015 WHO manual. Main results and the role of chance: We try to make a centrifugation-free, gentle, cost-effective, and easy sperm preparation technique and called it a swim-in technique. Groups were comparable according to mean age, collected oocyte numbers, and oocyte maturation ratios. Fertilization rates are %73,2(1786/2438) vs %66,9(2167/3237) respectively for swim-in and DGC groups. Clinical pregnancy rates are %45,1 vs %42,3 respectively for swim-in and DGC groups. On-going pregnancy rates are %41,5 vs %39,6 for swim-in and DGC respectively. There is a significant difference between the two techniques according to fertilization rates but no difference according to clinical pregnancy and ongoing pregnancy rates.
Limitations, reasons for caution: Sperms can move by their own motility from ejaculate to the sperm washing medium for that reason with severe sperm problem patients are not suitable for this technique.
Wider implications of the findings: This technique is centrifugation free so there are no detrimental g-forces. The needle used may mimic the physiological environment like Uterine Tube. Alternative sperm washing mediums like follicular fluid or chemical attractor progesterone rich medium can be used. DNA fragmentation rates and live birth rates should be established for future aspect.
Trial registration number: not applicable

P-013 Sperm freezing does not affect live birth rates: results from 6,594 cycles in normozoospermic patients

M. Torra[1], M. Tutusaus[2], D. Garcia[1], R. Vassena[1], A. Rodríguez[1]

[1]Euvitro SL, Research, Barcelona, Spain ; [2]Eugin, UPF Barcelona School of Management, Barcelona, Spain

Study question: Does sperm cryopreservation influence the reproductive outcomes of normozoospermic patients undergoing elective ICSI?
Summary answer: After controlling for confounders, the use of cryopreserved semen from normozoospermic patients does not affect pregnancy and live birth rates after ICSI.
What is known already: Sperm cryopreservation with slow freezing is a common practice in ART. While frozen-thawed semen typically presents reduced motility and vitality, its use for ICSI is generally considered adequate in terms of reproductive outcomes. Nevertheless, most studies comparing reproductive outcomes between fresh versus cryopreserved sperm include patients with oligo- and/or asthenozoospermia, where the altered quality of the sample can partially mask the full effect of freezing/thawing. The objective of this study is to ascertain whether ICSI using fresh or cryopreserved semen from normozoospermic patients results in similar fertilization rates and reproductive outcomes.
Study design, size, duration: Retrospective cohort of 6,594 couples undergoing their first elective ICSI cycle between January 2011 and December 2019, using normozoospermic partner semen (fresh or cryopreserved). All cycles involved a fresh embryo transfer, either at cleavage or blastocyst stage. Cycles were divided in 4 groups: fresh semen with partner's oocytes (FSPO, n=1.878), cryopreserved semen with partner's oocytes (CSPO, n=142), fresh semen with donor oocytes (FSDO, n=2.413), and cryopreserved semen with donor oocytes (CSDO, n=2.161).
Participants/materials, setting, methods: A slow freezing protocol using GM501 SpermStore medium (Gynemed, Lensahn) was used for all sperm cryopreservation. Sperm washing, capacitation, and selection prior to ICSI were performed equally for fresh and frozen-thawed samples, using pellet swim-up in IVF® medium (Vitrolife, Göteborg). Fertilization rate (FR), pregnancy (biochemical, clinical, and ongoing) and live birth (LB) rates were compared among study groups using Pearson's Chi square and Student's t-test. A p-value <0.05 was considered statistically significant.
Main results and the role of chance: Male and female age, sperm concentration and motility after ejaculation, and number of oocytes inseminated were similar between study groups compared (FSPO vs. CSPO, FSDO vs. CSDO). As expected, oocyte donation cycles resulted in higher LB rate than cycles in which partner's oocytes were used (30.04% vs 18.17%, p<0.001). In cycles using partner's oocytes, no significant differences were observed between fresh and cryopreserved sperm in FR, pregnancy and LB rates (p>0.05 for all outcomes). However, in oocyte donation, the mean FR after ICSI using cryopreserved semen (73.6 ± 19.6) was lower than the FR obtained with fresh semen (75.1 ± 19.2), p=0.010. Similarly, in oocyte donation cycles, the biochemical pregnancy rate was significantly lower when using cryopreserved semen (48.5% in CSDO vs. 52.3% in FSDO, p=0.009), while clinical, ongoing pregnancy and LB rates were similar between both semen status (p>0.05). In oocyte donation, a subgroup analysis including only the ICSI cycles with embryo transfer at blastocyst stage (n=1.187 for FSDO, n=337 for CSDO) confirmed that the LB rate was comparable between fresh and cryopreserved semen groups (34.7% vs 35.6% respectively, p=0.76), without significant differences in pregnancy rates neither (p>0.05 for all outcomes).
Limitations, reasons for caution: Caution should be exerted when extrapolating these results to different protocols for sperm cryopreservation and selection, or to IVM and classical IVF cycles, which were excluded from analysis. Due to the retrospective nature of the study, some uncontrolled for variables may affect the results.
Wider implications of the findings: Sperm cryopreservation does not affect pregnancy and live birth rates in normozoospermic patients, although it may lower slightly fertilization rates. In line with previous studies including patients with an apparent male factor detected after routine semen analysis, sperm cryopreservation is a safe and convenient technique.
Trial registration number: not applicable

P-014 Effect of microsurgical varicocelectomy on fertility outcome and treatment plans of patients with severe oligozoospermia: An original report and meta-analysis

A. Majzoub[1], H. Elbardisi[1], A. Almalki[2], S. Alsaid[1], M. Arafa[1]

[1]Hamad Medical Corporation and Weill Cornell Medicine -Qatar, Department of Urology, Doha, Qatar ; [2]Hamad Medical Corporation and Qatar University, Department of Urology, Doha, Qatar

Study question: Does microsurgical subinguinal varicocelectomy (MSV) improve semen parameters and fertility outcomes of patients with severe oligozoospermia (SO) and clinical varicocele?

Summary answer: MSV significantly improves semen parameters of patients with SO and can broaden their fertility treatment options. What is known already: Varicocele ligation has been proven to restore semen parameters and improve pregnancy rates in men with clinically palpable disease. However, its effect in men with SO is less clearly elucidated. Patients with SO are candidates for in vitro fertilization and intracytoplasmic sperm injection. Improvements in semen quality following varicocele ligation in this patient population may broaden their fertility options. While few studies indicate an improvement in semen parameters, reports revealing a negative outcome following surgery in this patient group were also published.

Study design, size, duration: This original report and meta-analysis examined the impact of MSV on semen parameters and fertility outcomes of men with SO. A retrospective chart review of 85 patients was conducted on patients with SO who underwent MSV. A literature search was carried out according to the PRISMA guidelines using the key words "severe oligozoospermia" and "varicocele". 8 scientific articles (including the current study) reporting the impact of MSV on men with SO were included.

Participants/materials, setting, methods: Changes in semen parameters postoperatively were compared with pre-operative results. The reported natural pregnancy rates were also calculated. The Wilcoxon signed-rank test was used to compare semen and hormone values before and after varicocelectomy. The Chi-squared test was used to assess the changes in TMSC groups after surgery. The meta-analysis was performed using comprehensive meta-analysis software (Biostat, Englewood, NJ, USA). Statistical significance was set at =0.05. The random-effects model was used to adjust for heterogeneity.

Main results and the role of chance: The original study reported significant improvements in sperm concentration ($p < 0.001$), total motility ($p = 0.003$), progressive motility ($p = 0.002$) and TMSC ($p < 0.001$) was following the surgery. in semen parameters following surgery. 78 patients had a pre-operative TMSC < 5 million. Following surgery, 9 (11.5%) patients had a TMSC between 5-9 million, while 14 (17.9%) patients had a TMSC > 9 million. The meta-analysis shows a statistically significant increase in sperm count following surgery (MD 5.64, 95% CI, 4.195-7.090, $p = 0.00$) with an acceptable degree of heterogeneity (Q value= 8.75, p= 0.188, I^2= 31.5%). Similarly, the total motility significantly increased by 7.77% (p= 0.001) following surgery (95% CI, 3.248-12.297), however, with considerable heterogeneity among the reported results (Q value= 34.4, p< 0.001). TMSC was assessed by three studies, including ours. The meta-analysis shows a significant increase in TMSC following surgery (MD 8.44 million sperm, 95% CI, 4.648-12.228, p <0.001) (Q Value= 2.53, p= 283, I^2=20.7%).

A total of 6 studies reported the natural pregnancy rate of patients with SO who underwent surgery. Out of 530 patients with preoperative SO, 146 patients achieved natural pregnancy following surgery indicating that the reported pregnancy rate was 27.5%.

Limitations, reasons for caution: One limitation to the original study is its relatively small sample size. However, this was compensated by conducting a meta-analysis and reporting the outcome of 601 patients with SO who underwent varicocele ligation. Another limitation is the retrospective nature of the study design.

Wider implications of the findings: 29.5% of SO patients in the original study became eligible for IUI following varicocelectomy. Meta-analysis showed that 27.5% of patients achieved natural conception following surgery. Such information is beneficial during patient counselling and needs to be measured against the financial and clinical implications in order to make sound treatment decisions.

Trial registration number: NA

P-015 Characterization of ultrastructural morphology of human sperms by field-emission scanning electron microscopy using the NanoSuit method

S. So[1], Y. Takaku[2], I. Ohta[3], F. Tawara[4], T. Hariyama[2]

[1]Hamamatsu University School of Medicine, Department of Reproductive and Perinatal Medicine, Hamamatsu City, Japan ;
[2]Hamamatsu University School of Medicine, Preeminent Medical Photonics Education and Research Center- Institute for NanoSuit Research, Hamamatsu City, Japan ;
[3]Hamamatsu University School of Medicine, Laboratory for Ultrastructure Research- Research Equipment Center, Hamamatsu City, Japan ;
[4]Tawara IVF Clinic, Reproductive Medicine, Shizuoka City, Japan

Study question: Can the NanoSuit method to observe sperm cells in wet conditions help treat male infertility using a field emission scanning electron microscope (FE-SEM)?

Summary answer: Compared with the conventional fixation method, the NanoSuit method can easily prepare FE-SEM samples without causing contraction and denaturation of human sperm cells.

What is known already: Evaluation of sperm morphology by optical microscopy is important for identifying male infertility. FE-SEM observation is useful for a more detailed evaluation of sperm morphology; however, a lot of the morphological information of the cells is lost by chemical fixation, dehydration, and freeze-drying. The NanoSuit method enables FE-SEM observation of unfixed cells under a high vacuum environment by electron beam polymerization of extracellular substances called NanoSuit. It has been reported that a sample prepared by the NanoSuit method retains the morphological information of live cells better than a sample prepared by the conventional fixation method.

Study design, size, duration: This laboratory study was conducted with informed consent and IRB approval. Semen parameters were within the WHO normal reference range.

Participants/materials, setting, methods: The conventional fixation method sample was prepared by fixing (glutaraldehyde and osmium), dehydration (ethanol and t-butyl alcohol), and freeze-drying. The NanoSuit method sample was introduced into the FE-SEM directly without conducting the above treatments. For observation, a JSM-7100F (JEOL, Japan) was used at an acceleration voltage of 1.0 kV. The vacuum level of the observation chamber was 10^{-3} to 10^{-6} Pa.

Main results and the role of chance: Sperm head segmentation (acrosome, equatorial segment, and post acrosome), midpiece, and tail including endpiece could be clearly identified in the FE-SEM sample prepared by the NanoSuit method. Transmission electron microscopy revealed the existence of a thin polymerized extra layer, the NanoSuit, on the surface of the sperm. It is suggested that the presence of the NanoSuit layer enables FE-SEM observation of the unfixed sperm. The conventional fixation method causes a statistically significant contraction in the sperm head size compared to that calculated from optical micrographs (13.5 μm^2 vs. 11.6 μm^2, $p<0.001$). Furthermore, wheat germ agglutinin (WGA), a lectin, which is known to have the ability to bind to the sperm surface, did not bind to the fixed FE-SEM samples. This means that the original cell surface properties are lost in the fixed sperm sample. On the other hand, the FE-SEM sample prepared by the NanoSuit method did not show a statistically significant contraction of the sperm head compared to that calculated from optical micrographs (13.2 μm^2 vs 12.9 μm^2, $p=0.416$); it also revealed a detailed binding pattern of gold-labelled WGA to the sperm surface. These results indicate that the NanoSuit method can prepare FE-SEM samples without sperm contraction and denaturation.

Limitations, reasons for caution: Characteristic sperm morphology in patients with male infertility should be investigated in future studies.

Wider implications of the findings: The NanoSuit method does not use chemical carcinogens and can prepare an FE-SEM sample in a shorter time than the conventional fixation method. The evaluation of ultrastructural morphology of unfixed sperms by this method may be useful for the identification of new morphological features and the evaluation of male infertility.

Trial registration number: not applicable

P-016 Using artificial intelligence to predict semen upgrading after microsurgical varicocele repair

J. Ory[1], M. Tradewell[1], T. Lima[1], U. Blankstein[2], V. Madhusoodanan[1], J. Moryousef[3], S. Lau[2], K. Jarvi[2], R. Ramasamy[1]

[1]University of Miami, Department of Urology, Miami, U.S.A. ;
[2]University of Toronto, Department of Surgery- Division of Urology, Toronto, Canada ;
[3]McGill University, Faculty of Medicine, Montreal, Canada

Study question: Can we use artificial intelligence models to predict semen upgrading after microsurgical varicocele repair?

Summary answer: A machine learning model performed well in predicting clinically meaningful post-varicocelectomy semen upgrade using pre-operative hormonal, clinical, and semen analysis data.

What is known already: Varicocele repair is recommended in the presence of a clinical varicocele together with at least one abnormal semen parameter,

and male infertility. Unfortunately, up to 50% of men who meet criteria for repair will not see meaningful benefit in outcomes despite successful surgery. Nomograms exist to help predict success, but these are based out of single-center databases, do not incorporate hormonal data, and are rarely designed to predict pre-defined, clinically meaningful improvements in semen parameters.

Study design, size, duration: Data were collected from an international, multi-center retrospective cohort. A total of 240 men were identified. Data from 160 men from Miami, USA and 80 men from Toronto, Canada were included. Data was collected from 2006 to 2020.

Participants/materials, setting, methods: We collected pre and postoperative clinical data following varicocele surgery. Clinical upgrading was defined as an increase in sperm concentration that would allow a couple to access new reproductive technologies/techniques. The tiers used for upgrading were 0-1million/cc (Intracytoplasmic Sperm Injection), 1-5 million (In Vitro Fertilization), 5-15 million (Intrauterine Insemination), and >15 million (Natural conception). Artificial intelligence models were trained and tested using R to predict which patients upgraded after surgery.

Main results and the role of chance: 51% of men underwent bilateral varicocele repair. The majority of men had grade 2 varicocele on the left, and (when present) a grade 1 varicocele on the right. Overall, 47% of men experienced an upgrade following varicocele surgery, 47% did not change, and 6% downgraded. The data from Miami were used to create a random forest model for predicting clinically significant upgrade in sperm concentration. The most informative model parameters were preoperative FSH, sperm concentration, and surgical laterality. The model identified three clinical categories: men with unfavorable, intermediate, and favorable features to predict varicocele upgrade. On external validation using data from Toronto, the model accurately predicted upgrade in 87% of men with favorable features, and in 49% and 36% of men with intermediate and unfavorable features, respectively. Overall, the model performed well on external validation with an AUC of 0.72 and good calibration.

Calibration plots, using cross-validation, define how well the predicted probabilities match the actual probability of sperm concentration upgrade. The random forest model was run twelve times. All model characteristics are the mean of ten model runs with the highest and lowest performing runs removed.

The model was translated to an online calculator that can be used by clinicians.

Limitations, reasons for caution: One limitation to our study is that we were not able to predict total motile sperm count (TMSC), which has been shown to perform slightly better than concentration at predicting assisted reproduction outcomes. By focusing on clinically significant upgrading, this difference should be minimized.

Wider implications of the findings: Predicting the chances of clinically significant semen upgrading after varicocele repair is essential for patients and clinicians to understand. Several men undergo surgery with no subsequent benefit, which may lead to a delay in definitive treatment with IVF/IUI. Understanding their chances will help couples make better informed decisions moving forward.

Trial registration number: not applicable

P-017 The maintenance of testicular architecture and germ cell in adult testis tissue under organ culture condition based on the gas-liquid interface method

M. Komeya[1], H. Odaka[1], T. Matsumura[2], H. Yamanaka[1], T. Sato[2], M. Yao[1], N. Masumori[3], T. Ogawa[2]

[1]Yokohama City University Graduate School of Medicine, Urology, Yokohama, Japan ;
[2]Yokohama City University Association of Medical Science, Laboratory of Biopharmaceutical and Regenerative Sciences- Institute of Molecular Medicine and Life Science, Yokohama, Japan ;
[3]Sapporo Medical University, Urology, Sapporo, Japan

Study question: Can the gas-liquid interface organ culture system that achieved in vitro spermatogenesis in mice also support in vitro spermatogenesis in human adult testis?

Summary answer: Although the progression of spermatogenesis was not observed, germ cells were maintained without the degeneration of the architecture in both fresh and cryopreserved testicular tissues.

What is known already: Although the research on in vitro spermatogenesis have been conducted for 100 years, only the organ culture system using gas-liquid interface method achieved in vitro spermatogenesis in mice. It has not been verified whether this culture system can be applied to other mammals including humans and induce spermatogenesis.

Study design, size, duration: Testicular tissue was obtained from the transgender patients receiving sex reassignment surgery. Testicular specimens were either immediately processed for cultivation or cryopreserved, using a vitrification freezing protocol. Organ culture of testicular fragments was performed in three different media for a maximum period of 3 weeks to evaluate the short-term changes in the cultured tissues (viability, proliferation and maintenance of germ and somatic cells).

Participants/materials, setting, methods: Fresh and cryopreserved-thawed testis fragments (1–2 mm^3) were cultured using the organ culture system in alpha-MEM with knock-out serum replacement (K group), alpha-MEM with lipid-rich BSA (A group) and DMEM with FBS (D group). Luteinizing hormone, follicle stimulating hormone and testosterone were supplemented. The number of germ cells (using DDX4), proliferative activity of germ cells (using EdU assay) and intratubular cell apoptosis (by TdT-mediated dUTP Nick End Labeling) were evaluated by immunohistochemical staining weekly.

Main results and the role of chance: The architecture of the seminiferous tubules was maintained until the second week of culture in both the fresh and the cryopreserved culture group. The number of DDX4-positive germ cells per seminiferous tubule in groups D, K, and A was 49 ± 24, 55 ± 21, 50 ± 26 cells/tubule in 1 day, 32 ± 13, 42 ± 7, 36 ± 21 cells/tubule in 1week, respectively. The numbers gradually decreased to 26 ± 8, 24 ± 6 and 27 ± 18 cells/tubule, in 2 weeks, respectively, with no difference among the groups. The number of intratubular EdU-positive cells of groups D, K, and A was 0.2 ± 0.2, 2.8 ± 2.1, 1.1 ± 0.8 cells/tubule at 1 day, 0.1 ± 0.2, 0.5 ± 0.6, 0.3 ± 0.6 cells/tubule at 1 week, respectively. The values were 0.01, 0.05, and 0.03 at 2 weeks. Thus, EdU-positive cells drastically decreased from the first week of culture. The number of DDX4-positive germ cells and the intratubular EdU-positive cells in the cryopreserved culture group was not different from that in the fresh culture group.

Limitations, reasons for caution: Current organ culture systems are incomplete, being unable to induce human in vitro spermatogenesis. Further research is needed to improve culture condition with the aim of producing fertile sperm of infertile adult male patients.

Wider implications of the findings: Our organ culture system could maintain testis structure and germ cells. By using the testis tissues of the transgender patients, which are available with their consent, we will promote the investigation of the culture condition necessary for germ cell proliferation and differentiation.

P-018 Observational study on the behaviour of the seminal sample in donors: seasonal variation according to parameters

B. Amoroch. Llanos[1], R. Hernánde. Jornet[1], E. Sellé. Soriano[1], E. Martíne. Díaz-Jiménez[1], I. Pére. Cano[2], M. Muño. Cantero[3]

[1]IVIRMA-Alicante, Andrology Laboratory, Alicante, Spain ;
[2]IVIRMA-Alicante, IVF Laboratory, Alicante, Spain ;
[3]IVIRMA-Alicante, Reproductive Unit, Alicante, Spain

Study question: What is causing the decline in semen quality worldwide?

Summary answer: Our results indicated significant differences, finding a decrease in sperm concentration/mobility in summer compared to the other seasons, with greater differences being observed in spring.

What is known already: Infertility is an increasing global problem and it is estimated that approximately 15 to 20% of all couples experience it at some point in their reproductive life. Among all causes, the male factor is becoming increasingly important as seminal quality is steadily declining globally. Knowing that the spermatogenesis process is very sensible to temperature fluctuations we could focus on the ambient temperature as one of the causes.

Study design, size, duration: Taking into account that donors are selected for having an optimal seminal quality, a retrospective study (January 2006 / February 2020) was proposed at IVI Alicante from 160 seminal samples to determine whether environment actually affects spermatogenesis and semen quality. It was evaluated whether there is variation in donors in mobility/volume / concentration depending on the season and quarter of the year in which the sample was obtained; and relation to the age of the donor.

Participants/materials, setting, methods: The inclusion criteria were sperm donors between 18 and 35 years old, anonymously, with good physical health, full capacity to act, and with seminal samples with characteristics to survive sperm thawing, complying with the requirements according to Spanish law on ART 2006. Exclusion criteria were based mainly on poor sperm survival after thawing. The statistical analysis was performed with the R statistical software, version 4.0, linear and multiple regression, establishing significant differences when p <0.05.
Main results and the role of chance: The results indicated significant differences, finding in summer a decrease in concentration and sperm motility (p <0.05) compared to autumn and winter and obtaining the best quality in spring. The concentration and mobility decrease from 63.4 million sperm / ml and 49.6% in spring to 44.4 million (p = 0.009) and 39.9% mobility in summer (p = 0.0075). We found the same results comparing them by quarters, having 62.7 million / ml and 49.3% between April-June, up to 44.9 million (p = 0.003) and 39.3% mobility between July-September (p = 0.03), showing that July and September there is a decrease in both concentration and mobility. This association has not been significantly affected by age. Thus, we conclude that high temperatures affect seminal concentration and mobility.
Limitations, reasons for caution: More studies can be done to increase the number of donors and confirm our findings.
Wider implications of the findings: According to other studies, carried out in Denmark, Israel and China, with different latitudes and temperature-humidity, the same trend has been observed in sperm quality, decreasing the quality in summer and being optimal in spring-winter, so the temperature could be a variable to take into account when studying semen.
Trial registration number: Not applicable for non clinical-trials

P-019 Sperm parameter and ICSI / IVF outcomes after sperm selection using microfluidic sperm separator and density gradient centrifugation with swim-up in split semen sample

R. Higashiyama[1], M. Kishimoto[1], S. Komure[1], S. Mizuta[1,2], K. Kitaya[1], T. Takeuchi[1], H. Matsubayashi[1,2], T. Ishikawa[1,2]

[1]Reproduction Clinic Osaka, Lab, Osaka-shi, Japan ;
[2]Reproduction Clinic Tokyo, Lab, Tokyo, Japan

Study question: To analyze whether microfluidic sperm selection (MSS) by ZyMōt™ improves sperm DNA fragmentation rate and embryonic development compared to density gradient centrifugation with swim-up (DGCS).
Summary answer: MSS by ZyMōt™ selects sperm for clinical use with less DNA damage significantly compared to DGCS.
What is known already: Conventional sperm preparation methods, such as density gradient centrifugation and the swim-up method utilize centrifugation during processing, may damage the sperm. MSS may allow for improved selection of normal sperm compared with conventional sperm preparation as it yields sperm with a lower DNA fragmentation rate. However, there are few clinical studies by sibling oocytes study compared to DGCS.
Study design, size, duration: This prospective study was performed between March 2020 and May 2020 at a reproductive center. All patients involved gave written consent, and institutional review board approval was granted. A total of 575 metaphase II oocytes were collected from 49 cycles. Wife's age was 34.7 ± 3.9 years old. Raw sperm concentration and motile sperm concentration was 63.1 ± 78.7M/mL, and 41.6 ± 67.7M/mL, respectively.
Participants/materials, setting, methods: Patients who performed ART for the first or second time were divided into two groups according to MSS and DGCS. Sperm DNA fragmentation rate (SDFR) and motile sperm concentration were compered between MSS and DGCS. SDFR was measured by sperm chromatin structure assay (SCSA) using a flow cytometer. Sibling oocytes were randomized into MSS-IVF, DGCS-IVF, MSS-ICSI, and DGCS-ICSI. Rate of two pronuclear (2PN) oocytes, blastocysts development, and good-quality blastocysts were compared between each group.
Main results and the role of chance: SDFR was 13.5 ± 11.8% for raw semen. SDFR was significantly lower after MSS (3.6 ± 4.1%) than that for raw semen and after DGCS (17.4 ± 14.8%) (P <0.01). Motile sperm concentration after MSS (19.0 ± 28.3M/mL) was significantly higher after than after DGCS (15.4 ± 15.3M/mL) (P<0.01). The number of IVF performed was 145 for MSS and 132 for DGCS. IVF results (MSS vs DGCS) were 2PN rate (73.1% vs 72.0%), blastocysts development rate (65.3% vs 55.4%), and good quality blastocysts rate (43.2% vs 34.9%). The number of ICSI performed was 149 for MSS and 149 for DGCS. ICSI results (MSS vs DGCS) were 2PN rate (77.9% vs 79.2%), blastocysts development rate (68.8% vs 65.8%), and good quality blastocysts rate (35.8% vs 30.6%). No significant difference was observed between MSS and DGCS for each parameter both IVF and ICSI.
Limitations, reasons for caution: The participants were limited to those who collected semen of 2mL or more and motile sperm concentration of above 1M/mL, because semen sample needed to be divided to MSS and DGCS.
Wider implications of the findings: This is the first study to conducted in sibling oosytes study with MSS and DGCS, in both IVF and ICSI. MSS is effective in collecting sperm with less DNA damage compared to DGCS. Motile sperm concentration after using MSS is sufficient to perform IVF as well as DGCS.
Trial registration number: not applicable

P-020 AZFc partial microdeletions of the Y chromosome is associated with severe oligozoospermia among Iranian men

Z. AzarAfshar[1,2], M.A. Sadigh. Gilani[3], A. Ghaheri[4], M.R. Zamanian[2]

[1]University of Science and Culture- ACECR-, Faculty of Basic Sciences and Advanced Technologies in Biology, Tehran, Iran ;
[2]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Genetics, Tehran, Iran ;
[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Andrology, Tehran, Iran ;
[4]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Epidemiology and Reproductive Health, Tehran, Iran

Study question: Are AZFc partial deletions correlated with severe oligozoospermia in Iranian men? Can we consider them as risk factors for infertility?
Summary answer: The frequency of total partial AZFc microdeletions was significantly higher in the oligozoospermia group compared to control group (8% vs. 3%, P = 0.028).
What is known already: Among many factors affecting male infertility, the second most common genetic factor is Y chromosome microdeletion. Some studies on partial AZFc microdeletions (especially on three major types; gr/gr, b1/b3 and b2/b3) have associated them with impaired spermatogenesis (azoospermia and oligozoospermia) in infertile men from different ethnicities. This finding is attributed to differences in alterations in pattern of *DAZ/CDY1* copy numbers as spermatogenesis related genes.
Study design, size, duration: 200 oligozoospermic (sperm count <5 mil./mL) and 200 fertile men were included as case and control groups, respectively. Individuals with karyotype abnormalities, complete microdeletions in AZF regions, infections, hypogonadism, history of chemotherapy and radiation, cryptorchidism or history of orchiopexy were not included. The study was approved by the Royan Institute Ethics Committee. Written informed consents were obtained from each participant.
Participants/materials, setting, methods: Total DNA from peripheral blood was used to amplify six sequence-tagged sites (STS) markers through multiplex PCR to detect AZFc partial deletions according to previous studies. Patterns of deletion in *DAZ* and *CDY1* copies were determined through PCR- RFLP.
Main results and the role of chance: The frequency of AZFc partial microdeletions was 8% in oligozoospermic men (16/200) which was significantly higher compared to 3% in control group (6/200) (P = 0.028). Hence, partial deletions may be considered as a risk factor for the male infertility in Iranian population. Also, gr/gr showed a higher frequency in oligozoospermic group (4%) compared to controls (1.5%) (P=0.126). The combination of *DAZ1/2+CDY1b* was the most observed deletion pattern in 8 oligozoospermic men with gr/gr deletion (75%), while among 3 controls with gr/gr, *DAZ3/4+CDY1a* (2 out of 3) and *DAZ3/4+CDY1b* (1 out of 3) were detected. Therefore, *DAZ1/2+CDY1b* can be correlated to oligozoospermia.
Limitations, reasons for caution: In order to achieve stronger statistical results, a larger sample size is of more help.
Wider implications of the findings: Risk of vertical transmission to male offspring and expansion in the size of deletions should be considered when providing ART services to infertile men. Genetic counseling is suggested in oligozoospermic men.
Trial registration number: -

P-021 An accurate and reliable screening for SARS-CoV-2 in human sperm samples by RT-PCR: A requirement to evaluate the viral contamination risk during SARS-CoV-2 pandemic

Study question: How to ensure a reliable and accurate detection of SARS-CoV-2 in seminal plasma and spermatozoa fractions of human sperm samples?
Summary answer: This RT-PCR assay showed high sensibility, repeatability and reproducibility for SARS-CoV-2 detection in seminal plasma and spermatozoa fractions, with a detection limit of 17 genomes/reaction.
What is known already: SARS-CoV-2 pandemic brings numerous concerns, such as the safety of gametes for patients undergoing assisted reproductive technologies, fertility preservation or sperm donation. Transient viremia and expression of SARS-CoV-2 receptors in testis and accessory glands bring the question of the presence of the virus in sperm samples. Moreover, the contamination during sperm collection may be possible. The few available studies about this issue mostly showed the absence of SARS-CoV-2 detection in semen of COVID-19 patients, except one reported study. All these studies performed SARS-CoV-2 detection with RT-PCR assays approved for naso-pharyngeal swabs, without a process specifically validated for semen fractions.
Study design, size, duration: Method validation was conducted between July 2020 and January 2021. SARS-CoV-2 direct detection was performed according to the French Society of Microbiology guidelines (SFM). Repeatability (n=6), reproducibility (n=3), limit of quantification (n=2) and of detection (n=6) were evaluated in seminal plasma (SP) and spermatozoa samples isolated after density gradient centrifugation and cryopreserved. In addition, variability of the whole analytical method efficiency was evaluated in samples of men with normal (n=6) or altered sperm parameters (n=6).
Participants/materials, setting, methods: Samples were surplus semen obtained from men undergoing routine semen analysis after granting informed consent. Assays were performed on SP and frozen spermatozoa fractions. After automated RNA extraction (MGISP-960, MGI-Tech®), real-time RT-PCR was performed using the one-step multiplex TaqPath COVID-19 kit (ThermoFisher®) targeting three viral regions (ORF1, nucleocapsid-N and spike-S proteins). An exogenous internal control was added before RNA extraction. Positive samples and dilution ranges were prepared with a standard (SARS-CoV-2 inactivated virus, QnosticTM Randox®).
Main results and the role of chance: RT-PCR assay applied for human sperm samples has been previously validated and is routinely used for SARS-CoV-2 detection in naso-pharyngeal swabs. We evaluated the efficiency of RNA extraction and RT-PCR for SARS-CoV-2 detection in semen fractions. The qualitative and quantitative performance of the whole analytical method was validated with an accuracy profile for SP and spermatozoa fractions. Overall, for repeatability, the standard deviation (SD) of the cycle threshold (Ct) was lower than 0.40 for the strong positive sample and 0.50 for the low positive one. An exception was observed for the S target of the low positive SP samples (SD=3) which was consistent with S being the less sensitive target of the assay. For reproducibility, SD of the Ct was lower than 0.30 for the strong positive sample and 0.80 for the low positive, except for the S target of the low positive (SD=1.5). The linearity range was determined for N target, the most sensitive target of the RT-PCR assay. It layed between 5200 and 52 SARS-CoV-2 genomes/reaction. The limit of detection of the RT-PCR assay was 17 viral genomes/reaction. Equal efficiency of the assay was observed for SP and spermatozoa independently of semen parameters (normal and altered sperm parameters). Limitations, reasons for caution: Our detection method was validated for the whole process: RNA extraction (reagents and system), RT-PCR (reagents and thermocycler QuantStudio 5™) and for both SP and frozen spermatozoa fractions. Variability might be observed with a different extraction system or a different type of biological sample.
Wider implications of the findings: This validated RT-PCR assay enables accurate and reliable screening of SARS-CoV-2 in SP and spermatozoa fractions, mandatory to investigate the presence of the virus in semen samples of patients undergoing assisted reproductive techniques, fertility preservation or sperm donation, and to ensure viral safety in the cryobanking process during covid-19 pandemic.
Trial registration number: EudraCT 2020-A01409-30

P-022 Improvement in sperm concentration and motility after oral antioxidant supplementation in infertile men with varicocele who have not undergone surgical repair: systematic review and meta-analys

P. Ioannidou[1], J. Bosdou[1], D. Papanikolaou[2], D. Goulis[3], A. Lambropoulos[4], G. Grimbizis[4], E. Kolibianakis[1]

[1]Aristotle University of Thessaloniki, Unit for Human Reproduction- 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece ;
[2]Aristotle University of Thessaloniki, 2nd Department of Urology, Thessaloniki, Greece ;
[3]Aristotle University of Thessaloniki, Unit of Reproductive Endocrinology- 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece ;
[4]Aristotle University of Thessaloniki, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece

Study question: Does oral antioxidant supplementation improve sperm quality in infertile men with varicocele who have not undergone surgical repair?
Summary answer: Oral antioxidant supplementation improves sperm concentration and motility in infertile men with varicocele who have not undergone surgical repair. What is known already: Benefit from oral antioxidant supplementation has been shown in infertile men with varicocele following surgical repair. Similarly, oral antioxidant supplementation has been suggested in infertile men with varicocele who have not undergone surgical repair. However, its effect currently remains controversial.
Study design, size, duration: A literature search was performed until January 2021 aiming to identify prospective studies evaluating the use of oral antioxidant supplementation alone or in combination in men with varicocele who have not undergone surgical repair.
Participants/materials, setting, methods: Seven prospective studies were identified, published between 1987 and 2018, including 278 infertile men with varicocele who had not undergone surgical repair. The number of patients included ranged from 20 to 65. Sperm analysis, evaluating sperm concentration, motility and morphology was performed in these studies before and after oral antioxidant supplementation. Meta-analysis of weighted data was performed using random effects model. Results are reported as weighted mean difference (WMD) with 95% confidence interval (CI).
Main results and the role of chance: Seven studies were included in the systematic review. Oral antioxidant supplementation was performed by a combination of pentoxifylline, zinc and folic acid (single study), a combination of l-carnitine, fumarate, acetyl-l-carnitine, fructose, CoQ, vitamin C, zinc, folic acid and vitamin B12 (single study), a combination of L-Carnitine, vitamin C, coenzyme Q10, vitamin E, vitamin B9, vitamin B12, zinc , and selenium, l-carnitine (single study), or sole treatment with acetyl-l-carnitine (single study), L-Carnitine (single study), Coenzyme Q10 (single study) or zinc sulfate (single study). For the purpose of meta-analysis, the effect of oral antioxidant supplementation was evaluated after three months of treatment.

Oral antioxidant supplementation significantly increased sperm concentration (WMD +5.65x106/ml 95% CI: +1.11 to +10.12 p=0.01, random effects model) and motility (WMD +4.30%, 95% CI: +0.86 to +7.74 p=0.01, random effects model) in infertile men with varicocele who had not undergone surgical repair.

On the other hand, no significance difference was observed in sperm morphology (WMD +3.9%, 95% CI: -0.16 to +8.04 p=0.06, random effects model) and volume (WMD +0.53ml, 95% CI: 0.0 to +1.0 p=0.052, random effects model).
Limitations, reasons for caution: The number of relevant trials and that of patients included is small to allow for solid conclusions to be drawn. Moreover, although different oral antioxidants have been administered in infertile who had not undergone surgical repair, subgroup analysis was not feasible.

Wider implications of the findings: Currently, limited evidence supports the use of oral antioxidants in the treatment of men with varicocele, who have not undergone surgical repair. Although the benefit in sperm concentration and motility appears to be modest, it might be important regarding achievement of pregnancy in these men.
Trial registration number: not applicable

P-023 Innovative ultra-rapid vitrification method for five or fewer testicular spermatozoa from non-obstructive azoospermic men after microsurgical testicular sperm extraction (Micro-TESE)

A. Tanaka[1], Y. Yanagihara[1], M. Nagayoshi[1], T. Yamaguchi[1], I. Tanaka[1], A. Itakura[2]

[1]Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan ;
[2]Juntendo University School of Medicine, Department of Obstetrics and Gynecology, Bunkyo-ku, Japan

Study question: What technique can be used to successfully cryopreserve five or fewer testicular spermatozoa from non-obstructive azoospermic men?
Summary answer: This method for cryopreserving five or fewer spermatozoa from non-obstructive azoospermic men showed a recovery rate above 90% and a survival rate of about 70%.
What is known already: Clinical outcomes of ICSI when using only five or fewer testicular spermatozoa after cryopreservation have been unsuccessful and are considered to be inferior to those using testicular fresh spermatozoa from Micro-TESE. A possible cause of these poor results has been the lack of a successful freezing technique. In these cases, repeated Micro-TESE and simultaneous oocyte pick up has been the only available treatment.
Study design, size, duration: Evaluation of the efficiency of cryopreservation by modified permeable cryoprotectant-free vitrification method (HTF supplemented with 0.1M sucrose and 10% SPS) for five or fewer testicular spermatozoa from 113 non-obstructive azoospermic men using Micro-TESE was conducted retrospectively at St. Mother Clinic between 2011 and 2018.
Participants/materials, setting, methods: This study included 113 non-obstructive azoospermic men. Each motile spermatozoon was carefully aspirated tail first into the pipette, put into a 2-µl microdroplet media of the vitrification medium near the tip of the Cryotop (Kitazato Corporation, Tokyo, Japan) submerged in liquid nitrogen vapor for 2 min and then immediately plunged in liquid nitrogen. The vitrified spermatozoa were warmed by dipping them into a droplet media. Successfully recovered motile sperm were selected and used for ICSI.
Main results and the role of chance: Number of patients, transfer cycles and collected sperms were 113, 192 and 560. Mean age of patients and their wives were 32.0±3.7y and 28.4±5.8y. Clinical pregnancy rate, miscarriage rate, live birth rate and number of live offspring were 24.0% (46/192), 19.6% (9/46), 19.3% (37/192) and 37 (Male: Female = 17: 20). Sperm recovery rate and survival rate were 90.3% (506/560) and 70.4% (356/506). Fertilization rate and mean number of transferred embryos were 51.6% (99/192) and 1.73 (1-2). Mean gestational weeks and mean body weight at birth were 39.23±5.27w and 2852.31±314.28g. No congenital anomalies were observed in any of the babies.
Limitations, reasons for caution: The maximum number of spermatozoa to which this method can be applied successfully is about 10. When the number of aspirated spermatozoa is over 10, some of them change direction and reach the mineral oil, and once this happens, they cannot be expelled out of the pipette.
Wider implications of the findings: This technique is very useful for the cryopreservation of very small numbers of testicular spermatozoa (fewer than 10) in order to avoid or reduce Micro-TESE interventions.
Trial registration number: N/A

P-024 Health and lifestyle detrimental conditions may impact the association between patient age and semen parameters in male populations

M.C. Guglielmo[1], M. Vitali[1], R. Iemmello[1], I. Caliari[1], S. Maruccia[2], M.R. Mignin. Renzini[1], M. Da. Canto[1], J. Buratini[1,3]

[1]CMR - Centro di Medicina della Riproduzione - Biogenesi, Istituti Clinici Zucchi-Monza- Italy, Monza Milano, Italy ;
[2]Istituti Clinici Zucchi, Urology Department, Monza, Italy ;
[3]Sao Paulo State University, Department of Structural and Functional Biology, Sao Paulo, Brazil

Study question: Can health and lifestyle detrimental conditions impact the relationship between paternal age and semen quality parameters in a male population?
Summary answer: Health and lifestyle detrimental conditions can attenuate the negative relationship between age and sperm concentration in a male population.
What is known already: Paternal age has increased in parallel with maternal age but its contribution in couple subfertility deserves further investigation. Previous studies suggest that paternal ageing is associated with reduced semen volume and impaired sperm morphology and motility, but not with reduced sperm concentration. Several health and lifestyle conditions such as diabetes, hypertension and smoking can negatively affect semen quality. Since the distribution of these conditions is not homogeneous throughout men's reproductive life, one can hypothesize that their presence may confound the association between paternal age and semen quality parameters in male populations.
Study design, size, duration: This is a retrospective study with data from 5565 men examined in a single fertility clinic between 2015 and 2020. The impact of health and lifestyle conditions was assessed by comparing the effects of age on semen parameters in two different patient populations: the overall patient population and a subpopulation excluding patients with detrimental health or lifestyle characteristics, both divided in 4 age groups (A: 25-34, B: 35-39, C: 40-44 and D: ≥45 years).
Participants/materials, setting, methods: The study includes 5565 men aged 24 to 72 years providing semen samples to assess volume, progressive motility and concentration (WHO) in a single fertility clinic. Patients presenting diabetes, heart/circulatory diseases, andrological disorders, genital neoplasms, cystic fibrosis, Y microdeletions, abusive alcohol intake, smoking and/or recreational use of drugs were excluded from the healthy subpopulation. The effect of age on semen parameters was assessed by ANOVA (motility and volume) or Kruskal-Wallis one-way ANOVA (concentration). Main results and the role of chance: Of 5565 men included in the study, 2150 (38.6%) did not present any of the detrimental health and lifestyle conditions described above. In the overall patient population, semen volume [Mean±SD (mL); A: 3.14 ± 1.55, B: 3.01 ± 1.53, C: 2.83 ± 1.52, D: 2.65 ± 1.58; p<0.001] and sperm progressive motility [Mean±SD (%); A: 33.1 ± 18.0, B: 31.7 ± 17.7, C: 31.4 ± 17.5, D: 28.4 ± 17.5; p<0.001] gradually and significantly decreased with paternal age. The same effect was observed in the patient subpopulation excluding detrimental health and lifestyle conditions [(mL; A: 3.21 ± 1.58, B: 3.05 ± 1.51, C: 2.89 ± 1.59, D: 2.78 ± 1.50; p<0.001); (%; A: 35.85 ± 17.4, B: 33.7 ± 17.4, C: 32.2 ± 17.1, D: 30.3 ± 16.5; p<0.001)]. However, sperm concentration significantly decreased with paternal age in the subpopulation excluding detrimental health and lifestyle conditions [(Mean±SD) million/mL; A: 43.19 ± 41.0, B: 38.8 ± 38.6, C: 38.4 ± 34.6, D: 36.6 ± 33.9; p<0.001], but not in the overall population (million/mL; A: 38.17 ± 40.9, B: 36.7 ± 34.7, C: 35.3 ± 35.1, D: 35. 1± 37.5; p=0.088).
Limitations, reasons for caution: This study is limited by its retrospective nature and by the accuracy of data on health and lifestyle conditions provided by the patients. Differences between age groups not controlled for in the study could also impact the results.
Wider implications of the findings: Ours findings suggest that health and lifestyle conditions may confound the effects of age on semen and sperm quality. Therefore, these data constitute a useful reference for the accurate assessment of the impact of male age on fertility.
Trial registration number: not applicable

P-025 Sperm selection using a modified "swim up" technique in absence of sperm centrifugation improve sperm DNA fragmentation and decreases miscarriage rate

Y. Cabell. Vives[1,2], P. Belchin[3], C. Lopez-Fernandez[4], M. Fernandez-Rubio[3], J. Guerrero-Sanchez[2], M. Sanche. d. Burgos[3], A. Garcia-Enguidanos[5], D. Ordonez[5], E. Izquierdo[5], J. Gosalvez[4]

[1]Hospital Ruber Juan Bravo Quironsalud, Scientific, Madrid, Spain ;
[2]Overture Life, Embryology, Alcobendas- Madrid, Spain ;
[3]Hospital Ruber Juan Bravo Quironsalud, Embryology, Madrid, Spain ;

[4]Universidad Autonoma de Madrid, Biology, Ciudad Universitaria de Cantoblanco, Spain ;
[5]Hospital Ruber Juan Bravo Quironsalud, Gynaecology, Madrid, Spain

Study question: Is it useful to avoid sperm centrifugation in laboratory routine work to improve sperm quality and reproductive outcome in Assisted Reproduction Techniques (ART)?
Summary answer: Exclusion of sperm centrifugation for sperm selection using neat sperm samples (IO-lix), increases sperm quality in the collected subpopulation decreasing miscarriage rate after using ICSI.
What is known already: Inclusion of sperm centrifugation in ART is an aggressive intervention for sperm selection with ineludible production iatrogenic damage affecting sperm integrity. The application of IMSI, PICSI or microfluidic devices avoid sperm centrifugation and may improve the quality of the subsample obtained. However, these methodologies may result time consuming, expensive or producing poor results when the quality of the sperm is limited. We have already shown that a modified swim-up avoiding centrifugation (called IO-lix) is a low-cost and efficient alternative to microfluidic devices, recovers 100 times more concentration and reduces sperm DNA fragmentation with no significant differences to other methodologies.
Study design, size, duration: This is a retrospective study from 2018 to 2020 which includes patients with an average of age of 38.2 years using their own oocytes with ICSI as fertilization technique. Two aleatory groups of patients were made: Group 1: 88 cycles with 503 fertilized oocytes and 206 blastocysts were obtained with sperm samples processed by IO-lix and Group 2: 303 cycles, 1451 fertilized oocytes and 591 blastocysts using a standard "swim up" technique to process sperm.
Participants/materials, setting, methods: A total of 391 ICSI cycles were included in this retrospective study. The male factor was similar in both groups and they showed altered SDF previously to the cycle. We compared data of the motility and SDF of sperm samples before and after applying IO-lix and we analyzed by $\chi 2$ contingence test differences on miscarriage rates between groups 1 and 2.
Main results and the role of chance: General sperm parameter changes after IO-lix showed that averaged sperm concentration observed in neat ejaculated samples was 62M/SD=46.4. Values obtained after IO-lix in the same samples were 12.3M/SD8.0. Averaged sperm motility in neat samples was 54%/SD=9.3 and 70.9%/SD=13.2 after IO-lix. Finally, sperm DNA fragmentation in neat samples was 35.8%/SD17.3, while these values decreased to 9.2%/SD=3.9 after IO-lix.

About reproductive outcome results, significant differences were not obtained on the development to blastocyst stage rate comparing both groups ($\chi 2$=0.003; p value = 0.954; Alpha 0.05).

In the case of IO-lix processed samples, the pregnancy rate was 59.42% in Group 1 and 44.72% in Group 2 ($\chi 2$=0.651; p value =0.419; Alpha 0.05).

A total of 9 miscarriages of 41 clinical pregnancies (21.95%) were observed after IO-lix, while this number increases to 59 out of 123 clinical pregnancies, which means the 47.96% of the embryo transfers, when "swim-up" was used. In this case significant differences were obtained ($\chi 2$=3.935; p value = 0.0.047; Alpha 0.05).
Limitations, reasons for caution: Being a pilot study aimed to understand the results of IO-lix in ART, correlations have not been stablished between the levels of sperm improvement after IO-lix and paired results of ART. This study would be necessary, specially to identify the possible origin of miscarriage associated to the male factor.
Wider implications of the findings: Elimination of sperm centrifugation using a combined strategy of gradients and "swim-up" for sperm isolation, reduce miscarriage rate and produce equivalent results of blastocyst development to those obtained with "swim-up". Being a cost-effective and improving laboratory workload, its use for sperm selection is recommended.
Trial registration number: Not applicable

P-026 Seminal plasma exosomes: a promising source of biomarkers for fertility evaluation

P. Piomboni[1,2], A. Luddi[1], C. Landi[3], A. Haxhiu[1], F. L. Presti[1], L. Boschi[1,2], R. Ponchia[1,2], L. Governini[1]

[1]Siena University, Molecular and Developmental Medicine, Siena, Italy ;
[2]S. Maria alle Scotte- Siena University Hospital, Assisted Reproduction Unit, Siena, Italy ;
[3]Siena University, Life Sciences, Siena, Italy

Study question: Do exosomes from seminal plasma have a role in male fertility?
Summary answer: Exosomes isolated from seminal plasma have a pivotal role during spermatogenesis and sperm maturation and may represent eligible biomarkers for male fertility/infertility.
What is known already: During their journey along the male reproductive tract, exosomes contained in seminal fluid are involved in the transfer of several molecules to the maturing sperm. Exosomes are extracellular vesicles (EVs) released by all the cells; they carry a cargo of nucleic acids, proteins and lipids. In the male genital tract, they are released at various levels and their composition differs between men of proven fertility and infertile male patients. Recent studies reported the proteomic profile of exosomes, revealing the presence of several proteins with a well know role in sperm maturation and fertilizing ability acquiring.
Study design, size, duration: This prospective study consisted of 36 Caucasian men; according to seminal parameters (WHO 2010) they were divided in normozoospermic (N; n=12), oligoasthenoteratozoospermic (OAT: n=12) and azoospermic (A; n=12). Semen samples were collected between October 2020 and January 2021 at the Assisted Reproductive Unit, Siena University Hospital (Italy) after institutional ethical approval and signed written consent from all the participants.
Participants/materials, setting, methods: Ejaculated sperm were analyzed according to WHO-2010 criteria and divided into the three groups: N, OAT and A. Exosomes were isolated by an in-house modified ExoGAG®-polymer precipitation-based protocol and characterized for size and ultrastructure by Nanoparticle tracking analysis (NTA) and transmission electron microscopy (TEM). The exosomal proteins were extracted and analyzed by 2D-electrophoresis and the identified profiles were examined by applying bioinformatic tools. The expression of selected genes was evaluated by digital droplets PCR (ddPCR).
Main results and the role of chance: The present work is readily providing an improvement of the standard ExoGAG® protocol and underlines its advantages over more conventional EVs isolation protocols used to date for recovery from seminal fluid: the number of recovered EVs and their size were finely included in the range of exosomes.

This isolation protocol provides samples suitable for proteomic analyses, representing the first 2D-electrophoresis reference map of exosome-pay loaded proteins in N respect to OAT/A groups and providing an innovative and comprehensive functional overview of its proteins. Moreover, the STRING protein-protein interaction analysis revealed the deregulation of specific pathways (e.g. signaling proteins, chromatin packaging and/or remodeling, protein folding and apoptosis) in A and OAT in comparison with N group.

Gene expression by ddPCR analysis highlighted that most of the analyzed genes are modulated in according to seminal parameters, in particular: *GAPDHS* (*Glyceraldehyde-3-Phosphate Dehydrogenase, Spermatogenic*); *SPAM1* (*Sperm Adhesion Molecule-1*) encoding a members of hyaluronidase family; *ADAM2* (*ADAM Metallopeptidase Domain-2*) that plays an important role in sperm-egg interactions; *CRISP1,2,3* (*Cysteine Rich Secretory Protein 1,2,3*) expressed in the epididymis and secreted into the epididymal lumen; *CLGN* (*Calmegin*) encoding a testis-specific chaperone protein and *PGK2* (*Phosphoglycerate Kinase-2*) expressed in the later stages of spermatogenesis.
Limitations, reasons for caution: This study represents a preliminary experiment. We suggest further comparative studies in larger study cohorts.
Wider implications of the findings: This pilot study, demonstrating the unique proteomic and transcriptomic pattern of exosomes in N/OAT/A groups, supports the importance of exosomes in sperm production and maturation. This methodological set-up is expected to open new ways for advancement in the use of exosomes as fertility biomarkers, making possible personalized approaches in ART.
Trial registration number: Not applicable

P-027 Does air pollution impact on semen parameters? Findings from a real-life cross-sectional study in white-European infertile men

F. Belladelli[1], E. Pozzi[1], L. Boeri[1], G. Fallara[1], P. Capogrosso[2], D. Cignoli[1], L. Candela[1], N. Schifano[1], M. Raffo[1], A. Colandrea[1], F. Montorsi[1], A. Salonia[1]

[1]IRCCS Ospedale San Raffaele, Division of Experimental Oncology/Unit of Urology, Milano, Italy ;
[2]ASST Sette Laghi – Circolo e Fondazione Macchi Hospital, Unit of Urology, Varese, Italy

Study question: We aimed to investigate the association between air pollutants levels and semen parameters in a cohort of white-European men seeking medical attention for couple's infertility.
Summary answer: We found that Pm10, Pm 2.5, and NO2 levels were negatively associated with sperm morphology.
What is known already: Air pollutants levels have been monitored closely for environmental and research issues in industrialized countries.
Study design, size, duration: Data from 156 infertile men consecutively assessed between 01/2019 and 12/2020 were analysed.
Participants/materials, setting, methods: Semen analyses were based on 2010 WHO reference criteria. We analysed the annual average level of the main markers of air pollution (Pm10, Pm2.5, and NO2) between 2014-2018 (Legambiente, 2020, Annual dossier series on air quality in Italy) relative to patients' addresses of the last 5 years. Health-significant comorbidities were scored with the Charlson Comorbidity Index (CCI). Descriptive statistics and linear regression analyses were used to test the association between air pollutants and semen parameters.
Main results and the role of chance: Overall, median (IQR) age and BMI were 37 (33-41) years and 25.1 (23.4-27.3) kg/m2, respectively. A CCI≥1 was found in 12 (7.7%) men, and 47 (30.1%) participants were smokers. As for sperm parameters, semen volume, sperm concentration, sperm progressive motility and normal sperm morphology were 3 (2-4) ml, 18 (5-45.5) x10^6/ml, 32 (22-45) % and 2 (1-3) %, respectively. Pm10 was negatively associated with sperm morphology (ß: -0.580, p=0.001). Furthermore, Pm10 was found to be an independent predictor for sperm morphology worsening (ß: -0.729, p= 0.006) (Fig.1A), after adjusting for age, BMI, CCI and smoking status. Similarly, Pm2.5 levels were negatively associated with sperm morphology (ß: -0.595, p=0.009) (Fig.1B). After adjusting for the same variables, the association between Pm2 and sperm morphology remained significant (ß: -0.724, p= 0.015) (Fig.1C). NO_2 levels were found to be associated with sperm morphology worsening after adjusting for age, BMI, CCI, and smoking status (ß: -0.471, p= 0.006).
Limitations, reasons for caution: It is a retrospective analysis at a single, tertiary-referral academic centre, thus raising the possibility of selection biases. Moreover, markers of air pollutions divided by residence may not completely evaluated the single patient exposure.
Wider implications of the findings: In this cross-sectional study we found that Pm10, Pm 2.5, and NO2 levels were negatively associated with sperm morphology, while they were not consistently associated with an increased risk of other abnormal sperm parameters in infertile men. Further studies are needed to characterize air pollution effects on sperm parameters.
Trial registration number: Not Applicable

P-028 Single centre retrospective analysis of endocrine stimulation therapy prior to microsurgical testicular sperm retrieval (mTESE) in men with hypogonadism and non-obstructive azoospermia (NOA)

G. Chiriaco[1], K. Naylor[1], V. Talaulikar[2], E. Williamson[3], G. Conway[4], D. Ralph[1], P. Sangster[1]

[1]University College London Hospitals UCLH, Andrology, London, United Kingdom ;
[2]University College London HospitalsUCLH, Reproductive Medicine, London, United Kingdom ;
[3]University College London Hospitals UCLH, Fertility Lab, London, United Kingdom ;
[4]University College London Hospitals UCLH, Endocrinology, London, United Kingdom

Study question: What is the role of endocrine stimulation therapy prior to mTESE in men with hypogonadism and non obstructive azoospermia (NOA)?
Summary answer: In hypogonadal men there is a positive correlation between change of serum Testosterone (ΔT) before and after stimulation, and a successful mTESE.
What is known already: NOA is the most common cause of azoospermia and it is often associated with hypogonadism and testicular failure. It is common practice for endocrine stimulation therapies such as gonadotropines or selective estrogens receptor modulators to be used prior mTESE; however there is currently paucity of data regarding their efficacy.
Study design, size, duration: Retrospective analysis on infertile men with hypogonadism (defined as T<12nmol/L) and NOA who underwent mTESE with or without prior endocrine stimulation therapy (clomiphene or human chorionic gonadotropin). Retrospective data from 2015-2020, total number of patient: 71; stimulated group (N:40) vs unstimulated group (N:31).
Participants/materials, setting, methods: Retrospective study on infertile men who underwent mTESE with or without prior endocrine stimulation therapy. Hypogonadism was defined as serum testosterone (T) level <12nm/L. We recorded demographic data, cause of testicular failure, previous testosterone therapy, duration and type of endocrine stimulation, pre-and post-stimulation hormone levels(T, FSH, LH), pre-operative hormone levels, successful sperm retrieval rate (at least 1 vial of viable sperm), average Johnsen score and total number of vials of sperm retrieved.
Main results and the role of chance: One-hundred-sixty-eight men underwent mTESE out of which 59 men received endocrine stimulation therapy for NOA between 2015-2020. Among them, we selected men with hypogonadism defined as serum T<12nmol/L which comprised 43% of the entire patient cohort. The hypogonadal group included 71 men, 28/71 had Klinefelter syndrome and 40/71 received endocrine stimulation for 13.9±9.2 months.

Testosterone levels significantly increased after endocrine stimulation (6.3±3.3nm/L vs 11.7±7.4nm/L) with mean change in serum testosterone (ΔT) of 5.7 nm/L (-5.5-23.3, N35). In the stimulated group, pre-operative serum T levels were significantly higher (11.7±7.4 vs 7.8±3.0 p:0.007) as compared to unstimulated men but the success rate of mTESE did not differ significantly (16/40-40%) vs 13/31-42%). Men with Klinefelter syndrome demonstrated significant differences with regards to age, lower T levels, higher FSH and LH levels, lower Johnsen score and success rates compared to other causes of NOA. Comparing men who had successful mTESE vs unsuccessful mTESE - higher T and lower FSH and LH seemed to correlate with successful sperm retrieval. Among men who received endocrine stimulation therapy the ΔT before and after stimulation seemed to correlate with successful sperm retrieval (AUC:0.701, SE:0.089, p:0.043). In the stimulated group a ΔT>3.5nm/L showed a significant association with successful mTESE(p:0.041).
Limitations, reasons for caution: Retrospective study limitations.
Wider implications of the findings: Our study shows a significant improvement of serum T following endocrine stimulation therapy. Overall, in hypogonadal men, the hormonal stimulation seems not to be related to a higher success rate of mTESE but our data do suggest a positive correlation between ΔT before and after stimulation, and a successful mTESE.

P-029 Identification of spermatozoa by unsupervised learning from video data

V. Thambawita[1], T.B. Haugen[2], M.H. Stensen[3], O. Witczak[2], H.L. Hammer[4], P. Halvorsen[1], M.A. Riegler[1]

[1]Simula Metropolitan Center for Digital Engineering, Department of Holistic Systems, Oslo, Norway ;
[2]Faculty of Health Sciences- OsloMet – Oslo Metropolitan University, Department of Life Sciences and Health, Oslo, Norway ;
[3]Fertilitetssenteret, Fertilitetssenteret, Oslo, Norway ;
[4]Faculty of Technology- Art and Design- OsloMet -Oslo Metropolitan University, Department of Computer Science, Oslo, Norway

Study question: Can artificial intelligence (AI) algorithms identify spermatozoa in a semen sample without using training data annotated by professionals?
Summary answer: Unsupervised AI methods can discriminate the spermatozoon from other cells and debris. These unsupervised methods may have a potential for several applications in reproductive medicine.
What is known already: Identification of individual sperm is essential to assess a given sperm sample's motility behaviour. Existing computer-aided systems need training data based on annotations by professionals, which is resource demanding. On the other hand, data analysed by unsupervised machine learning algorithms can improve supervised algorithms that are more stable for clinical applications. Therefore, unsupervised sperm identification can improve computer-aided sperm analysis systems predicting different aspects of sperm samples. Other possible applications are assessing kinematics and counting of spermatozoa.
Study design, size, duration: Three sperm-like paint images were manipulated using a graphic design tool and used to train our AI system. Two paintings have an ash colour background and randomly distributed white colour circles, and one painting has a predefined pattern of circles. Selected semen sample

videos from a public dataset with videos obtained from 85 participants were used to test our AI system.

Participants/materials, setting, methods: Generative adversarial networks (GANs) have become common AI methods to process data in an unsupervised way. Based on single image frames extracted from videos, a GAN (SinGAN) can be trained to determine and track locations of sperms by translating the real images into localization paintings. The resulting model showed the potential of identifying the presence of sperms without any prior knowledge about data.

Main results and the role of chance: Visual comparisons of localization paintings to real sperm images show that inverse training of SinGANs can track sperms. Converting colour frames into grayscale frames and using grayscale synthetic sperm-like frames showed the best visual quality of generated localization paintings of sperm frames. Feeding real sperm video frames to the SinGAN at different scaling factors, which is defining the resolution of the input image, showed different quality levels of generated sperm localization paintings. A sperm frame given to the algorithm with a scaling factor of one leads to random sperm tracking, while the scales two to four result in more accurate localization maps than scaling levels five to eight. In contrast, scales from six to eight result in an output close to the input frame. The proposed method is robust in terms of the number of spermatozoa, meaning that the detection works well for samples with a low or high sperm count. For visual comparisons, visit our Github page: https://vlbthambawita.github.io/singan-sperm/. The sperm tracking speed of our SinGAN using an NVIDIA 1080 graphic processing unit, is around 17 frames per second, which can be improved by using parallel video processing capabilities. This shows the capability of using this method for real-time analysis.

Limitations, reasons for caution: Unsupervised methods are hard to train, and the results need human verification. The proposed method will need quality control and must be standardized. Unsupervised sperm tracking SinGAN may identify blurry bright spots as non-existing sperm heads which may restrict the use of SinGAN sperm tracking for sperm counting.

Wider implications of the findings: Assessment of semen samples according to the WHO guidelines is subjective and resource-demanding. This unsupervised model might be used to develop new systems for less time-consuming and more accurate evaluation of semen samples. It may also be used for real-time analysis of prepared spermatozoa for use in assisted reproduction technology.

Trial registration number: N/A

P-030 A sperm chromatin damage >15% negatively impacts on the quality of embryos obtained from ovum donation ICSI cycles of unselected couples

A. Pachec. Castro[1], I. Hervas[2], R. Rivera-Egea[3], M. Gi. Julia[2], A. Navarro-Gomezlechón[2], N. Garrido[2]

[1]IVI Madrid, Andrology Laboratory and Sperm Bank, Madrid, Spain ;
[2]Health Research Institute La Fe, Foundation, Valencia, Spain ;
[3]IVIRMA Valencia, Andrology Laboratory and Sperm Bank, Valencia, Spain

Study question: Is embryo quality downgraded in couples with elevated sperm DNA fragmentation (SDF) in the ejaculated semen of male partner using donated eggs?

Summary answer: The rate of good quality embryos at day 3 and blastocyst-stage is statistically inferior in males with SDF>15% undergoing ICSI cycles with donated oocytes.

What is known already: The effect of a damaged paternal chromatin will be shown from the 8-cell stage of embryo development, a time which the genome of the embryo is transcriptionally active. Fertilization with a spermatozoon with fragmented DNA may impair the quality of the embryos obtained per cycle, and therefore reduce the chances of pregnancy. The use of donated oocytes is an ideal model to evaluate the real effect of SDF on embryo quality by standardizing the female factor. In addition, we have a large cohort of ovum donation cases in our history, which allows a more proper evaluation of the effect.

Study design, size, duration: Retrospective multicentric study including the clinical data of 864 couples of ovum donation program who underwent 1903 ICSI cycles between January 2000 and March 2019. The DNA fragmentation of their ejaculated spermatozoa was measured by TUNEL assay (Terminal deoxynucleotidyl transferase dUTP nick end labeling). Two study groups were created according to the SDF level: ≤15% (low) (n=1626) or >15% (high) (n=277).

Participants/materials, setting, methods: Embryos were evaluated throughout embryonic development according to classical morphological parameters at day 3 (D3), on cleavage-stage, and at day 5 (D5), on blastocyst-stage (trophectoderm (TE) and inner cell mass (ICM)), following ASEBIR guidelines, categorized from A to D. Embryos scored as A and B were considered to be good quality. The proportion of embryos was calculated according to the total number of correctly fertilized oocytes or zygotes. A $p<0.05$ was considered significant.

Main results and the role of chance: A total of 6130 embryos were evaluated. The SDF average of ≤15% group was 5.9% (95%CI 5.7-6.1) and 24.3% (95%CI 23.2-25.3) in the >15% group. The cycle-related characteristics and the seminal parameters were comparable. The proportion of optimal cleavage-stage embryo (number of A+B embryos at D3) per cycle was 21.7% (95%CI 19.0-24.5) (8.1 average cells number, 0.8 embryo fragmentation average, symmetry 1, mononucleated cells) in ≤15% SDF group versus 21.1% (95%CI 13.9-28.3) (8.2 cells number average, 1.3 embryo fragmentation average, symmetry 1, mononucleated cells) ($p<0.001$). The blastocyst-stage arrival rate (number of embryos at D5) per cycle was higher in the >15% SDF group ($p<0.001$), 53.4% (95%CI 48.8-58.1) (TE quality A:20.5%, B:42.5%, C:22.7%, D:14.8%, and the ICM quality A:26.1%, B:52.1%, C:13.2%, D:6.2%) versus 49.9% (95%CI 48.1-51.6) (TE quality A:21.1%, B:42.8%, C:21.85, D:14.1% and ICM A:26.6%, B:55.5%, C:11.1%, D:4.7%) in the low SDF group. The rate of good quality blastocyst (number of quality A+B embryos in D5) per cycle was significantly higher in the couples with low SDF (24.8% (95%CI 23.6-25.9)) than in those with elevated SDF (23.5% (95%CI20.9-26.2)) ($p<0.001$). Accordingly, the A+B blastocyst rate divided by the total number of blastocysts was 59.1% (95%CI 56.7-61.4) versus 55.9% (95%CI 49.9-62.0) ($p<0.001$), respectively.

Limitations, reasons for caution: The main limitation is that retrospective design of the study may not eliminate the potential unaccounted-for bias derived from the clinical practice of multiple centers even though both groups were statistically comparable. Also, the assessment of embryo quality is still remaining highly subjective to embryologists.

Wider implications of the findings: Although the effect size is small, it may be useful in clinical practice when an ICSI cycle yields no good-quality embryos, as one of the underlying causes of that fact. Knowing the SDF level can be a helpful tool in making subsequent clinical decisions aimed at improving outcomes for couples.

Trial registration number: Not applicable

P-031 The effect of ejaculatory abstinence period on embryological and clinical outcomes in ICSI cycles: A retrospective analysis of 3,353 cycles

G.C. Cermisoni[1], L. Pagliardini[1], A. Alteri[2], L. D. Santis[2], S. Esposito[2], S. Minetto[2], E. Papaleo[2], P. Vigano'[1], M. Candiani[2]

[1]I.R.C.C.S. San Raffaele Scientific Institute - Milan- Italy, Reproductive Sciences Laboratory- Obstetrics and Gynaecology Unit, Milan, Italy ;
[2]I.R.C.C.S. San Raffaele Scientific Institute - Milan- Italy, Obstetrics and Gynaecology Unit, Milan, Italy

Study question: Does ejaculatory abstinence period in male affect embryological and pregnancy outcomes following fresh embryo transfers in ICSI cycles?

Summary answer: Shorter ejaculatory abstinence period is associated with lower triploid zygotes rate per ICSI cycle but it does not affect clinical outcomes after fresh embryo transfers.

What is known already: Lower sperm quality may negatively impact on fertilisation rate and embryo morphokinetic parameters after ICSI and the effect of the ejaculatory abstinence period before semen collection on seminal parameters and sperm quality has been widely reported. However, the impact of ejaculatory abstinence on clinical outcomes is still controversial. WHO (World Health Organization) guideline recommended that abstinence period should be 2-7 days. Even so, there are no larger prospective trials determining the optimal timing for ejaculatory abstinence period for infertile couples.

Study design, size, duration: This is a single center retrospective observational study of 3,353 fresh cycles from January 2017 to December 2020. Semen analysis was done according to the WHO criteria. Exclusion criteria for this study were frozen gametes and cycles with no retrieved oocytes. Primary outcomes were fertilization rate and triploid zygotes rate. Secondary outcomes were blastulation rate, ongoing pregnancy rate and live birth rate per fresh embryo transfer.

Participants/materials, setting, methods: The correlation between ejaculatory abstinence and continuous outcomes was evaluated by Spearman's correlation analysis in order to detect potential non-linear associations. Generalized linear model and logistic regression were used, respectively for continuous and binary outcomes, in order to adjust for confounders such as female age, male age, number of retrieved oocytes, percentage of mature oocytes, infertility causes, seminal volume, sperm concentration and total progressive sperm motility. A p value <0.05 was considered significant.
Main results and the role of chance: The male mean age was 40.3±5.5 and mean duration of abstinence was 2.9±1.7 days. The mean age of female patients was 38.2±4.0. Higher ejaculatory abstinence period was associated with a higher sperm concentration (Spearman $p=3.1x10^{-6}$) but not with a higher total sperm progressive motility. Even so, no significant correlation with EA were observed when considering fertilization rate, blastulation rate, ongoing pregnancy and live birth rate per transfer in analyzed cycles. Triploid zygote rate was positively associated with a higher ejaculatory abstinence period. For the ejaculatory abstinence period of 1 day (n=64), 2 days (n=1523), 3 days (n=1032), 4 days (n=408), 5 days (n=174), 6 days (n=47) and ≥7 days (n=105) the mean triploid rate was 2.4%, 2.4%, 2.5%, 4.1%, 3.6%, 5.4% and 4.3%, respectively (Spearman $p=9x10^{-3}$). Triploid zygote rate was independent of semen volume, concentration and total progressive motility.
Limitations, reasons for caution: This is a large observational study with a retrospective data collection. Despite our methodological approach, the presence of biases related to retrospective design can not be excluded and it may be a reason for caution.
Wider implications of the findings: Our results demonstrate that ejaculatory abstinence period do not affect blastulation, ongoing pregnancy and live birth rates. The current findings discourage an abstinence time longer than 3 days due to its association with a higher abnormal fertilization rate.
Trial registration number: not applicable

P-032 Assessment of embryonic developmental outcome of direct unequal cleavage in patients with non-obstructive azoospermia and/or obstructive azoospermia

A. NAGANO[1], Y. Narumiya[1], N. Okutani[1], S. Mizuta[1,2], T. Takeuchi[2], K. Kitaya[1], H. Matsubayashi[1,2], T. Ishikawa[1,2]

[1]Reproduction Clinic Osaka, Department of reproductive medicine, Osaka, Japan ; [2]Reproduction Clinic Tokyo, Department of reproductive medicine, Tokyo, Japan

Study question: Does direct unequal cleavage (DC) affect embryonic development after ICSI with testicular sperm (TESE-ICSI) in patients with non-obstructive azoospermia (NOA) and/or obstructive azoospermia (OA)?
Summary answer: The incidence of DC at the first cleavage (DC1) was extremely high and DC1 negatively affected embryonic development in NOA patients.
What is known already: It has been reported that the blastocyst development of embryos with direct cleavage (DC) was significantly lower than that without DC, but the clinical pregnancy rate after blastocyst transfer was not different with or without DC. The incidence of DC has been reported to be significantly higher after ICSI with testicular sperm (TESE-ICSI) than ICSI with ejaculated sperm (Ej), but to our knowledge, there are few reports investigating that the embryos with DC after TESE-ICSI affect embryonic development.
Study design, size, duration: We conducted a retrospective cohort study using time-lapse incubators (Geri, Genea Biomedx, Australia) from September 2018 to November 2020. Of 1033 two-pronuclear (2PN) embryos from TESE-ICSI, 486 and 547 embryos were from OA (35.9±5.5 years) and NOA (33.7±5.2 years), respectively. As an age matched control, we chose 581 embryos from ICSI using Ej (36.5±4.4 years).
Participants/materials, setting, methods: DC embryos were classified as DC1 (DC at first cleavage), DC2 (DC at second cleavage), and non-DC (without DC). The incidences of DC1 or DC2 and blastocyst development rates were compared among OA, NOA and Ej groups. In TESE-ICSI group, we compared blastocyst development rates with or without DC between good and poor quality embryos on day 3. Good quality embryos were defined as 8 cells with G3 or more by the Veeck's classification.
Main results and the role of chance: DC1 incidence was significantly higher in NOA (37.3%) than OA (27.8%) and Ej (22.7%) (P<0.01), whereas DC2 incidence was not statistically different among three groups; NOA (15.7%), OA (15.0%) and Ej (13.4%). Blastocyst development rates in DC1 were 17.8%, 19.5% and 25.8% for NOA, OA and Ej, respectively, which were significantly lower compared to non-DC in corresponding three groups (65.1%, 67.7%, and 68.5%, respectively, P<0.01). In TESE-ICSI group, good-quality embryo rate on day 3 was significantly lower in DC1 (34.5%, P<0.01) than DC2 (60.9%) or non-DC (54.2%). Additionally, blastocyst development rates in DC1 and DC2 were significantly lower than non-DC regardless of embryonic grades on day 3 (35.1%, 51.0%, and 81.6% for good-quality embryos on day 3, 10.1%, 27.0%, and 49.1% for poor-quality embryos on day 3, respectively, P<0.05). When immotile sperm was used for TESE-ICSI, DC1 incidence was 40.0% (6/15), which did not show statistically differences. When performing single frozen-thawed blastocyst transfers, no pregnancies resulted from either DC1 (n=13) or DC2 (n=3) embryos in TESE-ICSI group.
Limitations, reasons for caution: We had a few data about the pregnancy rates after blastocyst transfers with DC, because embryos with DC were seldom transferred due to those lower priority. Although DC might be influenced by the sperm, we did not analyze the incidence of DC by taking the semen factors into account.
Wider implications of the findings: The incidence of DC1 was extremely high and DC1 negatively affected embryonic development in NOA patients. Therefore, it is important to observe embryos using time-lapse incubator in order to recognize embryos with/without pregnancy potential, especially for embryos with DC1 in NOA patients.
Trial registration number: Not applicable

P-033 In vitro protective effect of α-tocopherol and anthocyanin against TiO2-NPs induced genotoxicity on human spermatozoa

M. Santonastaso[1], F. Mottola[2], C. Iovine[2], N. Colacurci[1], L. Rocco[2]

[1]University of Campania "Luigi Vanvitelli", Department of Woman- Child and General and Special Surgery, Naples, Italy ; [2]University of Campania "Luigi Vanvitelli", Department of Environmental-Biological and Pharmaceutical Sciences and Technologies, Caserta, Italy

Study question: Do α-tocopherol and anthocyanin counteract human sperm DNA damage provoked by titanium dioxide nanoparticles (TiO2-NPs)? Summary answer: α-tocopherol and anthocyanin are able to counteract TiO_2-NPs genotoxicity on human sperm cells reducing oxidative stress.
What is known already: The environmental release and the extensive use of TiO_2-NPs have been implicated in poor human sperm functionality.TiO_2-NPs is genotoxic on human sperm cells causing a loss of sperm DNA integrity, an increase of apoptotic process and a reduction of genomic stability related to an over production of intracellular ROS.Antioxidants are the substances that can scavenge free radicals. α-tocopherol, present in vegetables, is the most important lipophilic antioxidant involved in restore sperm parameters in several experimental models. Anthocyanin, present in *Aronia melanocarpa*and belonging to the flavonoid family, is able to prevent damage caused by varicocele-induced ROS in rats.
Study design, size, duration: Semen samples from 132 men were obtained by masturbation following 3–5 days sexual abstinence and were examined for sperm concentration, viability, motility and morphology according to WHO 2010. The sperm cells, after purification with 45-90% double density gradient, were exposed *in vitro*to 1 µg/L of TiO_2-NPs, 1 µg/L of TiO_2-NPs whit 1 mg/L of anthocyanin and 1 µg/L of TiO_2-NPs plus 1 mg/L of α-tocopherolfor 15,30,45 and 90 minutes at 37°C.
Participants/materials, setting, methods: Sperm motility and concentration were analyzed with Makler camber while sperm viability and morphology were evaluated by Eosin-Nigrosin Test and by Testsimplets® prestained slides respectively. Antigenotoxicity was evaluated by Comet assay, TUNEL test and RAPD-PCR technique and Genomic Template Stability (GTS,%) calculation. The intracellular ROS level was assessed by DFC Assay. The data were analyzed using ANOVA test by GraphPad Prism 6 and considered significant if p-value ≤ 0.05.
Main results and the role of chance: Sperm analyses showed none statistically significant changes in sperm viability and motility (progressive and non-progressive) for each treatment. Anthocyanin and α-tocopherol counteracted sperm DNA damage induced *in vitro*by TiO_2-NPs neutralizing ROS in a time-dependent way. Comet assay displayed that both antioxidants reduced sperm DNA strand breaks produced by TiO_2-NPs, in particular the damage was no longer statistically significant starting from 30 and 90 minutes of anthocyanin-TiO_2-NPs and -tocopherol-TiO_2-NPs co-exposure respectively. The antioxidant supplementation

induced a statistically decrease of sperm DNA fragmentation provoked by TiO_2-NPs after 45 co-treatment minutes. The RAPD-PCR technique evidenced variations of bands number in the TiO_2-NPs treated sperm compared to the negative control and anthocyanin and α-tocopherol-TiO_2-NPs co-treated samples. Human sperm genomic stability increased after anthocyanin and α-tocopherol TiO_2-NPs co-exposure respect to the TiO_2-NPs single treatment, until it almost reaches the negative control at 90 minutes. Intracellular ROS percentage was significantly lower both in anthocyanin and α-tocopherol TiO_2-NPs co-treated compared to TiO_2-NPs alone starting from 45 minutes.
Limitations, reasons for caution: *In vitro* study. Wider implications of the findings: Our results showed a protective effect of anthocyanin and α-tocopherol on human DNA by neutralizing intracellular ROS induced by TiO_2NPs. We suggest anthocyanin and α-tocopherol as suitable molecules to defend human sperm DNA from oxidative stress, with a potentially role in treatmentof male infertility due to environmental factors.
Trial registration number: None

P-034 Social distancing protocol changes during the COVID-19 pandemic; the effect of at-home semen collection on intrauterine insemination outcomes

S. Vagios[1], C.R. Sacha[1], K.C. Hammer[1], V.W. Fitz[1], I. Dimitriadis[1], I. Souter[1], C.L. Bormann[1]

[1]Massachusetts General Hospital- Harvard Medical School, Obstetrics & Gynecology- Division of Reproductive Endocrinology and Infertility, Boston, U.S.A.

Study question: How have the coronavirus 2019 (COVID-19)-driven changes in semen collection protocols, from on-site to at-home collection, impacted intrauterine insemination (IUI) cycle outcomes?
Summary answer: Our data suggest that at-home semen collection within 2 hours of processing does not negatively impact semen parameters and IUI pregnancy outcomes. What is known already: There are mixed reports regarding the effect of at-home semen collection on IUI outcomes. In a study of 633 cycles, no differences in semen parameters or pregnancy rates were observed between home and clinic collections[1]. Conversely, in a smaller cohort, at-home collection was associated with worse pregnancy outcomes when IUI was coupled with gonadotropin stimulation, but not when coupled with clomiphene[2]. We previously reported no differences in semen parameters and in-vitro fertilization (IVF) embryo transfer outcomes, when cycles using semen collected at-home were compared to cycles with on-site collection[3]. However, such findings cannot necessarily be extended to the IUI setting.
Study design, size, duration: This is a retrospective cohort study of all 529 IUI cycles that took place in 2020 at an academic fertility center. Semen collected at the "clinic" was used for 143 cycles before the COVID-19 pandemic, and "at-home" collected specimens were used for the 386 cycles following the revised semen collection protocol. Participants/materials, setting, methods: Prior to the COVID-19 pandemic, semen was collected at our "clinic" and processed within ~30 minutes. Post-COVID, in order to maintain social distancing, semen was collected "at-home", at an IUI-approved cup, and transported to our center within 2 hours, while maintained to room temperature. Logistic regression models were performed to evaluate the effect of "at-home" collection on achieving pregnancy (positive pregnancy test-PPT) and clinical pregnancy (sonographic confirmation-CP), adjusting for age and anti-Mullerian hormone (AMH).
Main results and the role of chance: The mean age (SD) (years) of the female partner was 35.4 (4.2) vs. 35.4 (4.4) (p=0.978) and of the male partner 36.6 (4.4) vs. 37.1 (p=0.328) for the "clinic" vs. "at-home" groups, respectively. There were no significant differences in day-3 follicle stimulating hormone and AMH. In both groups the most common diagnoses were idiopathic and combined factors infertility (27.3% and 18.9% & 24.1% and 25.1%, respectively for the "clinic" & "at-home" groups, p=0.376). Similarly, there were no differences regarding ovarian stimulation, and gonadotropins were the most common medication used in both groups ("clinic": 44.1% vs. "at-home": 39.4%, p=0.775). Semen analysis parameters (volume, motility, forward progression, total motile count) were comparable between the 2 groups, with the exception of concentration (mil/ml) which was higher with "at-home" collection [66.1 (45.0) vs. 81.1 (63.0), p=0.009].

In unadjusted models, "at-home" collection had no significant effect on the odds for a PPT [OR (95%CI): 0.691 (0.427-1.119), p=0.133] or CP [0.751 (0.447-1.263), p=0.281]. These results persisted even when adjusting for maternal age and AMH: PPT [0.708 (0.435-1.153), p=0.165] and CP [0.773 (0.455-1.312), p=0.340]. When sub-analysis was performed within the different medication groups, the above findings persisted for both gonadotropin and oral medication cycles.
Limitations, reasons for caution: The limitations of the study include its retrospective design and the absence of livebirth data, given the limited follow up period. However, regarding the latter, one can use the ongoing clinical pregnancy rate as an accurate estimate of livebirth.
Wider implications of the findings: At-home semen collection within 2 hours of processing did not negatively impact semen analysis parameters or pregnancy outcomes following IUI. These data constitute an important addition to the current limited literature on the subject and provides an additional level of safety for our patients and staff during the COVID-19 crisis.
Trial registration number: not applicable

P-035 Mathematical model of the signaling cascade during mouse sperm capacitation

B. D. Prelle[1], P. Lybaert[1], D. Gall[1]

[1]Université Libre de Bruxelles, Laboratoire de Reproduction Humaine, Bruxelles, Belgium

Study question: Modeling the feedback loop controlling sperm capacitation to study the reversibility/irreversibility of the process
Summary answer: We demonstrate the existence of a feedback loop between pH increase and hyperpolarization, inducing bistability and possibly the reversibility of the capacitation process.
What is known already: The process of mammalian capacitation does need an influx of calcium ions through the transmembrane Catsper Channel Complex. This plasmic membrane channel, which is activated by an increase in either the intracellular pH or the membrane potential, is a sperm-specific protein that is localized in the sperm flagella. Two other sperm specific transporters, sNHE and SLO3, found in the flagella, have been shown to control protons influx and transmembrane voltage respectively, and could work together in a feedback loop keeping the sperm in a high pH state with hyperpolarized membrane.
Study design, size, duration: Mathematical model
Participants/materials, setting, methods: Not applicable
Main results and the role of chance: The results given by this minimal theoretical model are robust as the predicted qualitative behavior can accommodate to a wide span of physiological parameters variations.
Limitations, reasons for caution: The model and its parameters are mainly based on in vitro results of the literature, so that the in vivo implications should be inferred carefully.
Wider implications of the findings: The possible reversibility of the capacitation process could have major clinical implications, relevant for the optimization of sperm preparation in assisted reproductive techniques and cryopreservation procedures.
Trial registration number: not applicable

P-036 Investigation of the 2100 MHz electromagnetic field effects on sperm CatSper calcium channel

B. Ayas[1], A. Kocaman[2]

[1]Ondokuz Mayıs Univesity- Faculty of Medicine, Histology-Embryology and IVF center, Samsun, Turkey ;
[2]Ondokuz Mayıs Univesity- Faculty of Medicine, Histology-Embryology, Samsun, Turkey

Study question: Does electromagnetic field (EMF) effect sperm motility through CatSper calcium channels in rat?
Summary answer: 2100 MHz EMF may reduce sperm motility by acting on CatSper calcium channels.
What is known already: EMF exposure has become a serious concern in infertility patients. The effects of EMF through by using mobile phone and laptop have been explored previously, mostly focusing on sperm motility and DNA fragmentation. EMF activates the voltage gated calcium channels and increases calcium concentration. As a result of the EMA exposure, the sperm motility may increase. However, if this happens while sperms are in non-progressive motile phase in the epididymis, it may result with the depletion of limited energy stores.

Sperms may become immotile and they can't move forward in the progressive motile phase in the female reproductive system.
Study design, size, duration: This basic research study was an in vivo experimental approach involving the use of 50 male rats. Wistar-Albino rats (n=10) weighing ~320 -350g were included in each groups. The duration of EMF exposure was 1 hour per day for 28 days. Amlodipine (1 mg/kg, 28 days) was used as a calcium channel blocker. The experiment was held between July to December in 2020. 20 female rats were recruited for mating test.
Participants/materials, setting, methods: 50 rats were divided into five groups. Group 1; Pure control. Group 2; Sham. Group 3; EMF exposure, Group 4: EMF+Amlodipine, Group 5: Amlodipine positive control. After four weeks of exposure, rats were sacrificed and sperm were collected from cauda epididymis. Sperm motility parameters were analyzed. Intracellular calcium levels were determined with two different method, fluorescence spectrophotometer and laser scanning confocal microscope. Before sacrifice, rats were mated with female rats to evaluate mating ratios.
Main results and the role of chance: The mating score and live birth rates did not vary significantly among the groups (p>0.05). The sperm motility (A+B, 47.62±16.92 versus 34.19±14.62) and intracellular calcium levels (2.46±0.20 versus 1.85±0.18) were significantly decreased in the EMF group (p<0.05). The results of fluorescence spectrophotometer and laser scanning confocal microscopy with fluorescent attachment were consistent with each other. There were no significant differences found among the other groups in terms of investigated parameters. Statistical analysis was performed with Kruskal-Wallis test followed by the Dunn-Bonferroni's test.
Limitations, reasons for caution: The *Catsper* 1, 2, 3, 4 gene expression levels are still under analyses. These gene expression levels will be helpful to understand possible changes of the sperm motility. The determination of other motility related gene expressions may strength the results.
Wider implications of the findings: EMF exposure may have a significant effect on sperm motility parameters. Mobile phones carried very close to the reproductive organs may adversely affect the motility of sperm cells due to its emitted radiation levels
Trial registration number: not applicable

P-037 Influence of sperm selection by microfluidic device on outcomes of in vitro fertilization cycles

T. Vergueiro[1], G.N. Cecchino[2], E.O.S. Tamaru[1], R. Portela[1], L.M.F. Silva[1], M.T. Roque[2], R.R. Filho[2], J.G.A.F. Junior[1], P. Wolff[1]

[1]Genics, Department of Embryology and IVF laboratory, Sao Paulo, Brazil ;
[2]Mater Prime, Department of Reproductive Medicine, São Paulo, Brazil

Study question: Does sperm selection by a microfluidic sperm-sorting device improve laboratory outcomes of intracytoplasmic sperm injection cycles?
Summary answer: The ZyMōt™device seems a good alternative to the conventional swim-up technique, possibly increasing progressive sperm motility post processing and blastulation rate.
What is known already: It is well-known that high levels of sperm DNA fragmentation negatively impact not only early embryonic development but also embryo genome activation. Microfluidic technologies for processing sperm samples selection such as the ZyMōt™ device have been developed to sort sperm with lower rates of sperm DNA fragmentation in order to improve *in vitro* fertilization (IVF) outcomes. Moreover, it offers several advantages: working with very small volume samples, high sensitivity and low reaction times, automatic sample treatment and analysis, among others. However, the real benefits on the clinical and laboratory outcomes of IVF cycles is yet to be determined.
Study design, size, duration: We performed a retrospective study including 126 seminal samples processed between May 2019 and December 2020. These samples belong to 63 infertile couples that underwent 2 consecutive IVF cycles using the swim-up technique in the first cycle (n=63) and the ZyMōt™ device in the second (n=63). The oocytes of the female partners were recovered and inseminated, and the embryonic culture was carried out until the blastocyst stage, when the quality of these embryos was analyzed. Participants/materials, setting, methods: A total of 118 seminal samples from 59 couples were included. Four couples were excluded due to insufficient seminal volume / concentration (2) or absence of mature oocytes recovered (2). Laboratory outcomes were evaluated including semen parameters post processing, as well as fertilization, cleavage, blastulation (blastocyst among cleavage stage) and top-quality blastocyst rates. Continuous variables were analyzed by paired Student's *t*-test or Wilcoxon signed-rank test, as appropriate. Differences were considered significant when *p-value* < 0.05.
Main results and the role of chance: We did not find any difference in the percentage of non-progressive sperm motility [0 (0-33%) *vs.* 0 (0-10%); *p*=0.063] and immotile sperm [0 (0-70%) *vs.* 0 (0-80%); *p*=0.095] post processing when comparing the swim-up technique with the ZyMōtTM device. Likewise, no significant differences were detected regarding fertilization [83% (0-100%) *vs.* 89% (0-100%); *p*=0.104] and cleavage [100% (0-100%) *vs.* 100% (80-100%); *p*=0.217] rates in both groups. Nevertheless, there was a significant difference in the percentage of progressive sperm motility [100% (20-100%) *vs.* 100% (10-100%); *p*=0.012] post processing, as well as blastulation [37% ± 0.32 *vs.* 50% ± 0.3; *p*=0.031] and top-quality blastocyst [13.5% (0-100%) *vs.* 33% (0-100%); *p*=0.009] rates, favoring the ZyMōt™ device.
Limitations, reasons for caution: The retrospective design and the small sample size make the study prone to bias. Furthermore, we do not have data on sperm DNA fragmentation pre and post processing. Clinical outcomes were not evaluated due to insufficient statistical power, since embryo transfer has not yet been accomplished in several patients.
Wider implications of the findings: Besides the ZyMōt™ device has been indicated as a new tool to potentially improve laboratory and clinical IVF outcomes, it offers the advantage of being safe, fast, easy-to-use and less influenced by human errors. Further well-designed prospective studies are needed to prove its cost-effectiveness.
Trial registration number: not applicable

P-038 Clinical outcomes of 77 testicular sperm extraction treatment cycles in non-mosaic Klinefelter syndrome patients

P. Barros[1], M. Cunha[2], A. Barros[3], S. Dória[1], M. Sousa[4]

[1]Faculty of Medicine- University of Porto, Department of Genetics, Porto, Portugal ;
[2]Centre for Reproductive Genetics Prof. Alberto Barros, Department of Embryology, Porto, Portugal ;
[3]Faculty of Medicine- University of Porto and Centre for Reproductive Genetics Prof. Alberto Barros, Department of Genetics and Director, Porto, Portugal ;
[4]Institute of Biomedical Sciences Abel Salazar- University of Porto, Depart. Microscopy- Lab. Cell Biology, Porto, Portugal

Study question: What are the clinical results of patients with azoospermia and nonmosaic Klinefelter syndrome, using fresh and cryopreserved sperm?
Summary answer: The results showed a recovery rate of testicular sperm in the order of 40% and a life newborn rate of 52% when using fresh sperm
What is known already: In Klinefelter syndrome (KS), the rates of successful testicular sperm retrieval were shown to be similar either using conventional TESE or micro-TESE (Corona et al., 2017), which highlights that the variability observed between studies is due to differences in patient characteristics. There are a few works with a large number of KS patients elucidating the clinical outcomes using fresh and cryopreserved testicular sperm. However, these studies revealed contradictory outcomes, either revealing better (Greco et al., 2013; Vicdan et al., 2016) or worst (Madureira et al., 2014) results with cryopreserved testicular sperm, or finding no differences (Chen et al, 2019).
Study design, size, duration: This study includes all patients up to 2019 presenting azoospermia due to non-mosaic Klinefelter syndrome (n=76) that went for infertility consultations in a private fertility clinic. Patients were evaluated by the same Urologist. The genetic analysis of the patients was performed at an academic institution. At examination patients did not refer other complaints besides infertility, and referred to have not received any hormone replacement therapy in the past.
Participants/materials, setting, methods: The 76 azoospermic patients with non-mosaic Klinefelter syndrome (KS) were treated by testicular sperm extraction (TESE) followed by intracytoplasmic sperm injection (ICSI), using fresh and cryopreserved testicular sperm. Most patients used fresh testicular sperm, where others preferred to postpone ICSI treatment cycles and used cryopreserved testicular sperm. Aneuploidy screening in children was performed by prenatal diagnosis and MLPA (Multiplex ligation-dependent probe amplification). Full embryological, clinical and newborn outcomes are provided.
Main results and the role of chance: Of the 76 patients with non-mosaic Klinefelter syndrome, one repeated the testicular sperm extraction (TESE) procedure. Testicular sperm were recovered in 31/77 (40.3%) of the cases. Comparisons between the 31 cases with successful sperm recover (group-1) and

the 46 cases without a successful TESE (group-2) revealed no significant differences regarding age, time of infertility, testicular volume, serum levels of FSH, LH and testosterone, total number of testicular fragments analyzed, and time of search in samples. The mean male age was 34 years. In most of the cases, the testicular volume was reduced (96.1%), the levels of FSH (98.3%) and LH (94.1%) were increased, and the levels of testosterone were normal (77.6%). There were 25 intracytoplasmic sperm injection (ICSI) treatment cycles using fresh testicular sperm and 22 ICSI treatment cycles using frozen testicular sperm. The rates of fertilization (63.5% fresh sperm vs 41.6% frozen sperm), implantation (37% fresh sperm vs 13.2% frozen sperm), clinical pregnancy (60.9% fresh sperm vs 19% frozen sperm), live birth delivery (52.2% fresh sperm vs 19% frozen sperm) and newborn (65.2% fresh sperm vs 23.8% frozen sperm) were higher in the group using fresh testicular sperm. Chromosome analysis of the 21 newborn was normal.
Limitations, reasons for caution: Although presenting a high number of cases with azoospermic non-mosaic Klinefelter syndrome treated with testicular sperm extraction and intracytoplasmic sperm injection, future studies are needed with a higher number of cycles using frozen testicular sperm, in order to confirm or rebut that the freezing methodology affects negatively the clinical outcomes.
Wider implications of the findings: Data adds further information regarding testicular sperm retrieval rates and use of fresh or frozen testicular sperm in Klinefelter syndrome (KS) patients. High newborn rates were obtained only with fresh testicular sperm. Results also reassure KS patients about the safety relative to any abnormal chromosomal transmission to the born children.
Trial registration number: Not Applicable

P-039 Sperm chromatin integrity in relation to clinical pregnancy rate in an egg donation program

L. Vargas-Tominaga[1], A. Suarez[2], A. Medina[2], F. Alarcon[1], M. Gomez[1]

[1]Centro De Fertilidad Y Ginecología Del Sur CFGS, Fertility, Cusco, Peru ; [2]Centro De Fertilidad Y Ginecología Del Sur CFGS, IVF Lab, Cusco, Peru

Study question: Is DNA Fragmentation Index (DFI) determinant in clinical pregnancy rate (CPR) after ICSI?
Summary answer: DFI is determinant in CPR after ICSI
What is known already: Male fertility evaluation often leaves the clinician in uncertainty. Semen analysis is a basic examination, but insufficient. Sperm DNA is in a compact state, and its integrity is observed to be related to reproductive capacity
Study design, size, duration: A retrospective, single center study, in 65 couples underwent egg donation, ICSI and blastocyst transfer, evaluating DFI and its effect on CPR. This study was carried out since September 2017 to March 2020
Participants/materials, setting, methods: DFI was evaluated using Sperm Chromatin Dispersion test (SCD) and considering 20% or below as normal. We performed ICSI in donated eggs, cultured until blastocyst stage and transferred 1 to 3 embryos. CPR was defined as the number of patient with fetal heart beats presents in relation with the number of patients with embryo transfer. We determined CPR in both groups with normal and abnormal DFI. Fisher exact test was used to analyze the differences.
Main results and the role of chance: From these 65 couples, in 29 male partners had normal DFI and 36 abnormal. CPR was 68.97% in the first group and 41.67% in the second (p = 0.0448)
Limitations, reasons for caution: The small number of patients is a limitation
Wider implications of the findings: The results permit us to know more male patients, to consider DFI as an important variable and to prepare better our patients for procedures.
Trial registration number: 00012

P-040 Correlation between DNA fragmentation index and big halo pattern with sperm decondensation index and semen sample parameters

A.D. Crippa[1], M.C. Magli[1], A.P. Ferraretti[1], L. Gianaroli[1]

[1]SISMeR, Reproductive Medicine Unit, Bologna, Italy

Study question: Does sperm DNA integrity evaluated by DNA fragmentation index (DFI) and big halo pattern correlate with sperm decondensation index (SDI) and semen sample parameters?
Summary answer: DFI correlates with SDI and semen sample parameters in a stronger way than the big halo pattern
What is known already: The sperm chromatin dispersion test evaluates DNA integrity by measuring the susceptibility of sperm DNA containing breaks to denature when treated by an acid solution. Spermatozoa with intact DNA produce big or medium size halos of dispersed DNA loops, whereas small halos or no halos indicate fragmented DNA. The DFI calculates the proportion of spermatozoa with fragmented DNA. Data have been published documenting the negative effect of sperm DFI on embryo viability, suggesting that its evaluation could contribute to the prediction of the male reproductive potential
Study design, size, duration: A prospective study between 2011 to 2019 included 300 patients attending our clinic for fertility treatment. All sperm samples were analyzed according to WHO criteria, and the results from the DNA integrity analysis were related to the semen sample indices
Participants/materials, setting, methods: Of the 300 males included in the study, 118 were normozoospermic, 16 were oligozoospermic (O), 63 were asthenozoospermic (A), 9 were teratozoospermic, 7 were AT, 51 were OA, 5 were OT, and 31 OAT. The DNA integrity was assessed by the Halosperm test, and DNA decondensation by the aniline blue assay. A big halo was defined as a dispersion greater or equal to the length of the minor diameter of the core
Main results and the role of chance: DFI showed negative correlations with progressive motility (r= -0.532, p= 2.816 E-23), total motility (r= -0.598, p= 1.688 E-30) and morphology (r= -0.338, p= 2.954 E-9). Accordingly, when compared with normozoospermic, DFI was significantly higher in A and T samples (29.5 ±12.0 and 36.5±4.8 respectively, p<0.002) with the highest levels found in samples with combined defects (45.2±12.5 in AT, p<0.002; 51.3±17.2 in OAT, p<0.002). DFI also showed a negative correlation with the big halo pattern (r= -0.656, p= 2.934 E-38) and a positive correlation with the SDI (r= 0.429, p= 7.314 E-15). For the big halo, negative correlations were found with progressive motility (r= 0.429, p= 7.314 E-15) and morphology (r= 0.407, p= 4.077 E-13) resulting in a lower incidence in T samples (27.0±9.6, p<0.002) that was especially relevant in AT (18.3±14.5, p<0.002), OT (33.0±10.2, p<0.02) and OAT samples (20.6±15.8, p<0.002). SDI presented a negative correlation with total motility (r= -0.403, p= 3.849 E-13) and was fond to be increased in A samples (32.4±11.8, p<0.002) as well as in samples with double defects (38.9±19.2 in AT samples and 38.8±15.9 in OA samples, p<0.002) and triple defects (42.6±16.8 in OAT, p<0.002)
Limitations, reasons for caution: The study did not evaluate the lifestyle and reproductive history of the patients
Wider implications of the findings: Although the effects of sperm DNA damage on reproductive outcomes are still unclear, the correlation between sperm DNA fragmentation, semen parameters and reproductive potential is emerging. DFI, big halo and SDI could contribute to the diagnosis of male infertility especially in categories of patients with poor prognosis of pregnancy.
Trial registration number: Not applicable

P-041 Reproductive concerns and sexual health in men with newly diagnosed testicular cancer prior to orchiectomy: preliminary results from an on-going study

N.F. Hoejris[1], Y. Frederiksen[2], S.H. Nielsen[3], S.L. Brand[4], M. Holt[4], A. Amidi[4], U.B. Knudsen[5]

[1]Aarhus University, Institute of Clinical Medicine, Aarhus, Denmark ; [2]Aarhus University and Aarhus University Hospital- Psychiatry, Department of Clinical Medicine and the Sexology Unit, Aarhus, Denmark ; [3]Regional Hospital of Horsens, Fertility Clinic, Horsens, Denmark ; [4]Aarhus University, Department of Psychology & Behavioural Sciences, Aarhus, Denmark ; [5]Institute of Clinical Medicine- Aarhus University, Gynecology & Obstetrics, Aarhus, Denmark

Study question: What is the prevalence of reproductive concerns among patients with newly diagnosed testicular cancer (TC), and how do they rate their sexual health (SH).
Summary answer: Of 20 patients, 75% (n = 15) were moderate to highly concerned about decreased reproductive functioning. Twenty-four percent exhibited overall low SH.

What is known already: Currently, only little is known about reproductive concerns among TC patients. Furthermore, these concerns have not been investigated in a TC population prior to orchiectomy. One study among post-surgery TC patients two years after diagnosis, reported that 28 % had high degree of reproductive concern. The literature indicates that TC patients' sexual health is negatively affected due to altered body image and sexual dysfunction. However, studies regarding sexual health have primarily been performed on long term survivors of TC. Thus, little is known about SH in this population prior to treatment.
Study design, size, duration: The present cross-sectional study included patients from the fertility clinic in Horsens, Denmark. Patients were approached at their pre-scheduled appointment for cryopreservation of semen prior to orchiectomy. Enrolment started March, 2019 and is still on-going. Preliminary data is included from 21 enrolled patients.
Participants/materials, setting, methods: Patients newly diagnosed with TC, who were referred to the fertility clinic for semen cryopreservation prior to orchiectomy and other treatment modalities were invited. The patients responded to a questionnaire package of which reproductive concerns were assessed with seven questions with Likert scale response options ranging from 0 (not concerned) to 5 (highly concerned). SH was assessed with the validated 22-item questionnaire European Organization for Research and Treatment of Cancer Sexual health questionnaire (EORTC-SHQ).
Main results and the role of chance: A total of 37 patients met the inclusion criteria and of these 21 were enrolled in the study. Due to technical issues, only 20 out of 21 patients completed the full questionnaire package. Patients were asked about concerns regarding the ability to father children. Nine patients (45%) were moderately concerned, and six patients (30%) were highly concerned. When asked about their concerns of not being able to father children without fertility treatment, the answers were mostly unaffected with eight patients (40%) being moderately concerned, and seven patients (35%) highly concerned.

Four patients (20%) were highly concerned that decreased semen quality would affect future or present relationships. Patients were also asked if they felt sufficiently informed regarding the chance of fathering children without help from a fertility clinic following cancer treatment. Three patients (15%) reported that they were insufficiently informed, while four patients (20%) responded only to a little extend. Five patients (23,8%) scored ≤ 50 on the EORTC SHQ indicating that they had low SH. Eleven patients (52,3 %) felt less masculine due to their disease. Furthermore, one patient (4,8 %) scored ≤ 50 on the symptomatic scale, indicating that he had symptomatic sexual problems as fatigue and sexual pain.
Limitations, reasons for caution: The relatively low participant number is a limitation, making the results less generalizable. Furthermore, there is a risk of selection bias due to the moderate inclusion rate. Also, the questionnaire examining fertility related concerns were non validated, and focused mainly on the fertility-related aspects of reproductive concerns.
Wider implications of the findings: A considerable number of patients with newly diagnosed TC show substantial reproductive concerns as well as lowered sexual health. These worries could possibly be alleviated by more sufficient information from the health professionals already in the beginning of the treatment phase, reducing further emotional distress during the remaining treatment period.
Trial registration number: ClinicalTrials.gov ID:NCT03880994

P-042 Impact of semen parameters, sperm DNA fragmentation and sperm aneuploidy in male infertility

Study question: Should sperm aneuploidies and sperm DNA fragmentation (sDNAfrag) be included as valid tests in the routine investigation of male infertility?
Summary answer: Sperm DNA fragmentation was associated with male age, oligozoospermia (OZ), oligoteratozoospermia (OT), astenoteratozoospermia (AT) and oligoastenoteratozoospermia (OAT). Sperm aneuploidies were associated with OT and OAT.
What is known already: Semen parameters assist male infertility diagnosis and treatment, but sDNAfrag and aneuploidy analysis could add useful information, as abnormal values compromise fertility. To include these tests in the routine diagnosis it should be determined if behave as informative parameter and add information regarding the fertility status. For that, further studies comparing these tests to semen parameters are needed, since previous results are not consensual. Additionally, standardization of a sDNAfrag cut-off is needed, as different sample sizes and techniques originate distinct results. Also, until a standardization of the protocol is missing, a cut-off value should be defined for each laboratory.
Study design, size, duration: A retrospective and prospective investigation was performed, within a 12 years period (April 2007-December 2019). A total of 835 infertile males with a normal karyotype (46,XY) were included. Karyotyping and evaluation of sDNAfrag and sperm aneuploidies were made at a public Genetic unit. All normozoospermic (NZ) patients with a born child and patients whose infertility treatments were done due to female factors were selected from our database and used as controls (60 individuals).
Participants/materials, setting, methods: Semen analysis followed WHO-2010 guidelines. sDNAfrag was evaluated using the TUNEL assay. Sperm aneuploidies were detected using FISH (chromosomes 13, 18, 21, X, Y). Several tests were applied: correlations for linear associations between numerical variables, ANOVA for comparisons between means, Dunn-test for post-hoc comparisons. To determine the sDNAfrag cut-off value, the area under the ROC curve, sensitivity and specificity, were calculated, with the Youden-Index used to find a threshold that maximizes both sensitivity and specificity.
Main results and the role of chance: Regarding male age, it was observed a positive correlation with sperm concentration, a negative correlation with sperm vitality (VT) and hypoosmolality, and a positive correlation with sDNAfrag. Regarding sDNAfrag, it was observed negative correlation with sperm concentration, total progressive motility (TPM), morphology, VT and hypoosmolality. Regarding sperm aneuploidies, both total sperm aneuploidy and total sperm disomy exhibited a negative association with sperm concentration, TPM and morphology. It was also investigated whose groups of individuals could be indicated for sDNAfrag or sperm aneuploidy testing. The NZ group evidenced significant lower sDNAfrag, total sperm aneuploidy and total sperm disomy in relation to the non-NZ group. In the NZ group, sDNAfrag was significantly lower in relation to the OZ, OT, AT and OAT groups. The NZ group presented significant lower percentages of sperm aneuploidy in relation to the OT and OAT groups, and significant lower percentages of sperm disomy in relation to the OAT group. Additionally, sDNAfrag was positively correlated with total sperm aneuploidy and total sperm disomy. From the present large population, ROC curve analysis allowed estimating a cut-off value of 18.8% for the TUNEL-assay (sDNAfrag), with 0.658 of area under the curve, 53.9% sensitivity and 76.7% specificity.
Limitations, reasons for caution: Although presenting a high number of cases and strict controls, the present study was unable to include as controls healthy men with proven fertility. Additionally, the present study did not take into account life-style factors and male associated pathologies besides infertility

Wider implications of the findings: Semen parameters were shown to be negatively correlated with sDNAfrag and sperm aneuploidies. As sDNAfrag testing and sperm aneuploidy testing were associated with semen abnormalities and male age, it is suggested their inclusion in the routine evaluation of infertile men, thus adding important complementary information about the fertility status.
Trial registration number: Not Appliable

P-043 Six years' retrospective statistical study (2013 – 2018) investigating the impact of Sperm DNA fragmentation on sperm analysis parameters

H. Bahri[1], W. Zidi[2], M. Benkhalifa[2]

[1]HB laboratory, Andrology / Reproductive Biology, Tunis, Tunisia ; [2]La Rabta Hospital- Faculty of Medicine of Tunis- University of Tunis El Manar- Tunis- Tunisia., Research laboratory LR99ES11 Department of Biochemistry, Tunis, Tunisia

Study question: What is the relationship between Sperm DNA fragmentation (SDF) levels and sperm analysis (*Spermocytogramme*) parameters results?
Summary answer: SDF level of patients with pathological *spermocytogramme* presents negative correlations to total spermatozoa mobility, vitality and concentration, and positive correlation to sperm morphology defects.
What is known already: The relationship between SDF and Sperm analysis parameters and especially sperm morphology needs to be more studied since few studies over the last years were focused on this relationship. However, abnormalities in these two parameters are considered as the most important biological indicators of male infertility. The pathogenesis of Teratozoospermia (<4% morphologically normal sperm cells according to WHO 2010) is continuously increasing over the last decade according to several studies. In addition, SDF is also increasing over the years because of several factors such as pollution, stress and lifestyle changing.
Study design, size, duration: Retrospective study including 331 infertile patients undergoing SDF-index testing with *Spermocytogramme* from January 2013 – December 2018. Patients divided into two groups: 143 patients with normal-*Spermocytogramme* and 188 patients with pathological-*Spermocytogramme*. Each group includes patients with abnormal SDF levels (>30%). Statistical analyzes were performed using SPSS22.0 for Windows-software. Kolmogorov–Smirnov-test for normality analysis and comparisons by Student-t-test or Mann–Whitney U-test, as appropriate. Pearson/Spearman' tests for correlations were used as appropriate, *P-value*<0.05 was considered as significant.
Participants/materials, setting, methods: 143 patients with normal *Spermocytogramme* (2.8% abnormal-SDF) vs 188 patients with pathological *Spermocytogramme* (10.6% abnormal-SDF). WHO-2010 instructions for sperm-analysis were used through Makler®-counting-chamber (Sefi-Medical Instrument Ltd) for sperm-concentration and motility-determination using Sperm-class-analyzer-software (CASA-system (Microptic®)) to detect sperm abnormalities. Normozoospermia was determined when sperm progressive-motility is ≥32%, sperm-concentration ≥15x10^6/mL, and sperm-morphology ≥4%. "Diff-Quick" staining-method for the coloration of the fixed-sperm-slides was used for Sperm-morphology analysis. GoldCyto Sperm®Kit (Goldcyto Biotech corp.) was used to analyze SDF.
Main results and the role of chance: SDF is significantly higher in pathological *spermocytogramme*' patients than in normal *spermocytogramme*' patients (17.02 ± 11.88 vs 12.16 ± 9.58 respectively). In patients with pathological *spermocytogramme*, SDF is negatively correlated to Progressive sperm motility (r= -0.137; p=0.042), Total sperm motility (r=-0.153; p=0.036), vitality (r=-0.140; p=0.048) and concentration (r=-0.195; p=0.007). In the other hand, SDF presented positive correlation with teratozoospermia and especially with sperm midpiece defects (r=0.171; p=0.02). However, SDF did not present any correlation with age, testosterone levels and total ejaculated sperm volume. However the latter was positively correlated to spermatozoa midpiece and head defects (r=0.156; p=0.034; r=0.203; p=0.006, respectively). These results are in accordance with García-Ferreyra *et al.* (2014) who found that men with abnormal spermatozoa morphology showed high levels of DNA fragmentation, Sá *et al.* (2015) who confirmed that semen with lower concentration, motility and morphology have higher levels of SDF and showed that sperm head staining patterns are correlated with the degree of SDF. In addition, recently the study of Jakubik-Uljaszstudy *et al.* (2020) could confirms our results when it concluded that detailed sperm structural defects coexist with abnormal nuclear sperm DNA dispersion and that men with teratozoospermia may have a higher risk for sperm DNA damage.
Limitations, reasons for caution: Our study is a retrospective statistical investigation that included patients attending to the laboratory for fertility diagnosis after a period of infertility. Meta-analyzes studies in addition to more prospective-randomized-controlled-trials with couples undergoing assisted-reproductive-treatments and in comparison with fertile men are needed to confirm the relationship between SDF and *spermocytogramme* defects.
Wider implications of the findings: These results should interest andrologists, reproductive science fundamentalists and embryologists who want to improve the investigations on the origin of infertility especially when it comes from male side.
Trial registration number: not applicable

P-044 A non-classical splice site variant in ANOS1 gene leading to Kallmann syndrome

H. Guo[1], Y. Xia[1], C. Cui[1]

[1]Henan Provincial People's Hospital- China, The Reproductive Medicine Center, Zhengzhou, China

Study question: Genetic risk of the non-classical splice site variant in *ANOS1* gene
Summary answer: A non-classical *ANOS1* splice site variant, c.1062+4T>C, causes Kallmann syndrome.
What is known already: Genetic abnormalities play a key role in the development of Kallmann syndrome. Although an overwhelming majority of missense and nonsense mutations occur in the exons of a gene, intron mutations can also be pathogenic.
Study design, size, duration: The research object is a family. Eight patients of the family were recruited in this study, three of them were diagnosed with Kallmann syndrome.
Participants/materials, setting, methods: Genomic DNA was extracted from peripheral blood and whole-exome sequencing (WES) was performed to identify the genetic abnormalities. PCR was performed to verify the WES results. The functional splicing reporter mini gene assay was performed to assess the impact of sequence variants on splicing.
Main results and the role of chance: The proband and other two patients exhibited the typical clinical features of KS. A non-classical splice site variant, c.1062+4T>C in *ANOS1* gene was identified, whereas the other unaffected family members did not have this mutation. This mutation caused the disappearance of the splicing site of intron 7 and the splicing position became the 156th base of exon 7, which caused a frame-shift mutation, leading to a premature termination of translation.
Limitations, reasons for caution: Since the ANOS1 gene is almost not expressed in the blood, in order to uncover the effect of this splice site variant of ANOS1, we carried out a functional splicing reporter mini gene assay in the mini gene vector pEGFP-N1.
Wider implications of the findings: This study shows that mutations in non-classical splicing regions are also pathogenic. Therefore, it is recommended that the detection and analysis of this gene should pay attention to the non-classical splice site variant.
Trial registration number: not applicable

P-045 A retrospective study on Hyaluronic acid binding sperm selection in ICSI cycles

J.Y. Lo[1], S.T. Tee[1]

[1]TMC Fertility Centre, IVF Lab, Selangor, Malaysia

Study question: Does Hyaluronic acid(HA) binding sperm selection prior ICSI produce better outcome compare to PVP?
Summary answer: No significant difference in fertilization rate, blastocyst utilization rate, pregnancy rate and miscarriage rate in HA vs PVP group.
What is known already: HA is natural, non-sulphated glycosaminoglycan secretion that abundantly found in the cervical mucus and the cumulus oophorus complex (COC). In in-vivo, HA binding sites on the sperm plasma membrane indicate sperm maturity, mature sperm reaching HA-coated COC can bind and

digest HA and subsequent hyperactivation further facilitate fertilization. In IVF, the use of HA tries to mimic in-vivo to select mature sperm with high DNA integrity prior to ICSI. In HA, movement of mature sperm is 'slowed' thus allow the selection of sperm to be used in ICSI. Sperm immaturity is known to associated with aneuploidy incidence in the embryos.

Study design, size, duration: ICSI cycle using HA (N=83) was adapted from January to December 2020 while ICSI cycle using PVP (N=133) was adapted from January 2018 to December 2019. Mean age of patient were 35.64±4.33 vs 34.15±4.75 for HA vs PVP group respectively. Fertilization rate, blastocyst utilization rate, pregnancy rate and miscarriage rate were recorded. This study included all ICSI cycle and both frozen and fresh embryo transfer data. Surgical retrieved sperm was excluded from this study.

Participants/materials, setting, methods: A 1.5ul of treated spermatozoa suspension was connected with a pipette tip to a 5ul droplet of fresh holding medium (Cook Gamete Buffer). Simultaneously, a 5ul droplet of HA medium (Origio SpermSlow) was connected to the 5ulL droplet of holding medium in a ICSI dish (Sparmed Oosafe) covered with oil (Vitrolife Ovoil). Sperm which were 'slowed' in the Sperm slow droplets with normal morphology according to WHO 2010 guideline were selected for ICSI at 400X.

Main results and the role of chance: The fertilization rate of the HA vs PVP- binding sperm are 68.6% vs 66.2%. As for the blastocyst utilisation rate is 61.6% vs 73.22% for HA vs PVP- binding sperm group. Pregnancy and miscarriage rate for HA vs PVP are 42.3 % vs 51.5 % and 19.4% vs 26.2% respectively.

There was no significant difference in the fertilization rates, blastocysts utilisation rate, pregnancy rate and miscarriage rate between the HA vs PVP- binding sperm groups (P<0.05). However, a trend of higher pregnancy (51.5% vs 42.3%; P=0.279) and miscarriage rate were observed in the PVP group (26 % vs 19 %; P = 0.545) as compared to the HA group, but the difference was not statistically significant. The reason behind this might be the HA assist to select the mature sperm with higher DNA integrity and low frequency of chromosomal aneuploidies which contribute to the lower miscarriage rate in the study.

Limitations, reasons for caution: This is a retrospective study on HA binding sperm selection vs PVP prior to ICSI.

Further research which includes a large number of RCT sample size should be warranted.

Wider implications of the findings: The HA- sperm binding selection ICSI might only be beneficial to certain group of patients (high- DNA fragmentation sperm). A larger RCT study may be necessary to establish a relationship between HA-sperm binding selection vs aneuploidy rate via PGT analysis.

Trial registration number: NOT APPLICABLE

P-046 Application of hyperspectroscopy as a new sperm diagnostic and selection technique for ICSI based on hyperspectral signature of single spermatozoa – a proof of concept

E. VILLANUEVA[1], M. Gi. Julia[2], J.M. D. lo. Santos[3], I. Hervas[2], A. Navarro-GomezLechon[2], R. Rivera-Egea[4], N. Garrido[2]

[1]AINIA, Automation Department, Paterna, Spain ;
[2]IVI Foundation, Andrology and Male Infertility, Valencia, Spain ;
[3]IVIRMA Valencia, IVF Laboratory, Valencia, Spain ;
[4]IVIRMA Valencia, Andrology Laboratory, Valencia, Spain

Study question: Is hyperspectral imaging of individual sperm cells an appropriate candidate technique with potential to identify molecular characteristics of single spermatozoa prior to microinjection?

Summary answer: Preliminary tests have allowed us to obtain the images, set up the methodology and the correct segmentation of each sperm into its signature spectra.

What is known already: Although image techniques such as fluorescence microscopy and Raman spectroscopy have been used to identify biomarkers on sperm cells, their translation to the fertility clinic is highly complex and unfeasible. Hyperspectroscopy has not yet been introduced in the reproductive field, but it has been successfully used in other medical disciplines to differentiate cell types or pathological versus healthy tissue. It relies on the combination of information from optical images and electromagnetic spectra produced by cells at different wavelengths. Therefore, it is an interesting candidate for objective non-destructive sperm selection before ICSI according to the presence of specific biomarkers.

Study design, size, duration: Pilot, prospective, observational study in the IVIRMA Valencia fertility clinic, designed as a proof of concept. Discarded semen samples were used for the technical setup and the preliminary tests of image acquisition. Hyperspectral images were obtained of 12 spermatozoa: two sperm cells were imaged 10 times each, while the other 10 sperm were imaged one time each.

Participants/materials, setting, methods: Samples were prepared on glass-bottom ICSI plates in PVP droplets according to routine clinical practice. Images were obtained using the camera HinaLea 4200M coupled to the Olympus IX73 inverted microscope. Hypercubes were extracted using MATLAB 2016a, and the most informative wavelength was chosen. Matrox Copilot software was used to process images and select the regions of interest (ROI) equivalent to one sperm. MATLAB was used to obtain the information for the pixels within each ROI.

Main results and the role of chance: Hypercube size for each image was 608x968x299 pixels. Each hypercube obtained provided information for 299 different wavelengths, from 402.8 to 998.3 nm. Once the hypercubes were obtained from each image, the spectra at 520 nm wavelength was selected as the one at which the pixel provided the most information. The background of each uploaded image was successfully removed by creating a mask, which was then used to extract and characterize all the spectra from each pixel of each sperm image. The result of this proof of concept, though measure qualitatively, is that the information obtained from hyperspectral imaging of individual sperm is highly reproducible and successful in showing overlapping spectra resulting from 10 different images of the same specimen. Spectra resulting from images of different sperm cells showed tangible differences on their composition demonstrating unique biochemical features of each. The next step will be to quantitatively measure the reproducibility and sensitivity of the technique in a larger sample, to then study the potential of single sperm hyperspectral imaging as a sperm selection tool for ICSI.

Limitations, reasons for caution: These are preliminary results obtained from the development of an appropriate methodology to adapt the acquisition of hyperspectral images in the clinic's IVF laboratory. Thus, the group will continue to evaluate the reproducibility, sensitivity, and informative capability of the technique before contemplating its use on samples destined to perform cycles.

Wider implications of the findings: Having developed a laboratory and image processing methodology that allows us to successfully segment each obtained image according to the hyperspectral information of every pixel of each individual sperm, we could move forward in testing the potential of these hyperspectral signatures to identify sperm markers related to successful reproductive outcomes.

Trial registration number: NOT APPLICABLE

P-047 Knowledge, professional attitudes and training of health professionals on male contraceptive methods

J. Perrin[1], J. Tcherdukian[2], A. Netter[3], E. Lechevalier[4], F. Bretelle[5], R. Mieusset[6]

[1]Ap-hm, CECOS Centre clinicobiologique d'AMP CHU La Conception, Marseille Cedex 5, France ;
[2]Aix Marseille University, University Department of General Medicine, Marseille, France ;
[3]AP-HM, Department of Gynaecology and Obstetrics- Gynépole- AP-HM La Conception University Hospital, Marseille, France ;
[4]AP-HM, Urology Department- La Conception University Hospital, Marseille, France ;
[5]AP-HM, Department of Gynaecology and Obstetrics- Gynépole- La Conception University Hospital, Marseille, France ;
[6]University Toulouse III-Paul Sabatier, Human Fertility Research Group- Andrology-Reproductive Medicine- Paule de Viguier Hospital- CHU de Toulouse, Toulouse, France

Study question: Among health professionals involved in contraceptive prescribing, what are the knowledge, professional attitudes and training on male contraceptive methods?

Summary answer: The health professionals involved in prescribing contraception are not sufficiently trained in male contraception and almost all of them want more.

What is known already: The most recent large-scale studies show that 70% of couple contraception is provided by women and that the majority of men and women would be willing to adopt male contraception as couple contraception. The medicalization of contraception places the medical

profession at the forefront of the acceptability of and information regarding a contraceptive method. However, only one study have evaluated health professionals' knowledge of the various methods of male contraception (MC), including male hormonal contraception (MHC) and male thermal contraception (MTC).

Study design, size, duration: Between April 2020 and June 2020, we carried out a descriptive prospective multicentre study in a medical population of 2243 prescribers of couple contraception in France.

Participants/materials, setting, methods: The participants were obstetrician-gynaecologists, medical gynaecologists, general practitioners or midwives. They completed a three-part numerical questionnaire, including i) sociodemographic characteristics and personal experiences with contraception, ii) knowledge and professional attitudes about male contraception and iii) training on male contraception.

Main results and the role of chance: The overall participation rate was 19% (340/2243). Condoms and withdrawal were known by 98% and 89% of the population, respectively. Vasectomy was known by 75% of the population and significantly better known by obstetrician-gynaecologists than by medical gynaecologists and general practitioners (p=0.026). Male hormonal contraception (MHC) and male thermal contraception (MTC) were known by 10% and 23% of the population, respectively, and were significantly better known by medical gynaecologists and general practitioners than by other specialties (p<0.001). More than half (55%) of the population never or infrequently offered MC during a couple's contraceptive request consultation. Female practitioners offered MC significantly more often than male practitioners (48% vs. 26%; p=0.033). Only 14% of the population had ever participated in training on MC, 96% wished to be better trained on MC, and 86% expressed a willingness to participate in such a training.

Limitations, reasons for caution: The population was mainly representative of medical health practitioners of southeastern France. There was an over-representation of women in all medical specialties, except for midwives.

Wider implications of the findings: Our study shows that health professionals involved in contraception have limited knowledge about MC and are eager to have more information about it. To advance the acceptability and dissemination of such contraceptive methods, it seems imperative to provide health professionals with an adapted training program on male contraception.

Trial registration number: 2020-01-23-03

P-048 Effects of bisphenol S and bisphenol F on human spermatozoa: an in vitro study

C. Castellini[1], N. D. Giammarco[1], S. D'Andrea[1], A. Parisi[1], M. Totaro[1], S. Francavilla[1], F. Francavilla[1], A. Barbonetti[1]

[1]Andrology Unit- San Salvatore Hospital- L'Aquila- Italy, Department of Life- Health and Environmental Sciences- University of L'Aquila- L'Aquila- Italy, L'Aquila, Italy

Study question: Are plasticizers bisphenol S (BPS) and bisphenol F (BPF) safer alternatives to bisphenol A (BPA) for human sperm function?

Summary answer: Unlike BPA, the analogues BPS and BPF do not significantly affect human sperm mitochondrial functions, motility and viability

What is known already: The widespread distribution of BPA, along with its reputation to be an endocrine disruptor has generated concerns about possible adverse effects for human health, thus prompting the European Food Safety Authority and the Food and Drug Administration to ban the use of this chemical in many plastic products. Following such restrictions, several substitutes have been developed, with BPS and BPF representing the main replacements to BPA. While it has been demonstrated that BPA promotes oxidative damages in spermatozoa from different species, including human, the possible effects exerted by BPS and BPF on human sperm, have not yet been investigated.

Study design, size, duration: We explored the effect of 4 h *in vitro* exposure to scalar concentrations of BPS and BPF (from 10 to 400 μM), and to 400 μM BPA on sperm motility, viability, mitochondrial membrane potential (ΔΨm) and mitochondrial generation of reactive oxygen species (ROS). In a set of experiments, the effect of a combination of both BPF (400 μM) and BPS (400 μM) on Δ m and mitochondrial ROS generation was also assessed.

Participants/materials, setting, methods: Sperm ΔΨm was analyzed by flow cytometry with the fluorescent lipophilic cationic dye JC-1. Flow cytometric assessment of mitochondrial generation of ROS was carried out using the lipid soluble cation MitoSOX red (MSR). Sperm motility and viability were evaluated by Computer-Aided Semen Analysis (CASA) and eosin assay, respectively.

Main results and the role of chance: The exposure to scalar concentration of BPS did not significantly affect sperm motility and viability with respect to untreated controls. A lower, albeit not significant, sperm motility was registered in samples exposed to the highest concentrations of BPF (300 μM and 400 μM). As expected, 400 μM BPA produced a complete sperm immobilization along with a dramatically loss in sperm viability. No significant differences were observed in sperm ΔΨm and ROS generation after exposure to scalar concentration of BPS compared to untreated controls and the trend towards lower ΔΨm and higher mitochondrial ROS generation at the highest concentrations of BPF did not reach statistical significance. On the contrary, after 4 h exposure to 400 μM BPA a significant lower ΔΨm and higher mitochondrial ROS generation were observed. Finally, the exposure to a combination of BPF and BPS at high concentrations (400 μM) did not significantly affect sperm ΔΨm, or mitochondrial ROS generation, when compared to 400 μM BPA, used as positive control. Limitations, reasons for caution: The present study only evaluated BPS and BPF effects, but in daily-life people are exposed to several plasticizers containing different bisphenols at different concentrations. Therefore, adverse effects of synergic exposure to BPA analogues other than BPS and BPF, alone or in combination with BPA, cannot be ruled out.

Wider implications of the findings: The analogues BPS and BPF, alone or in combination, appeared to be safer alternatives to BPA on sperm biology as they exert a neutral effect on sperm motility, viability, and mitochondrial functions even at high concentrations. These results could be useful to identify more secure plasticizer components.

Trial registration number: Not applicable

P-049 The presence of double heads is associated with increased frequency of the other sperm abnormalities

M. Handzhiyska[1], D. Parvanov[1], R. Ganeva[1], D. Aleksandrova[2], E. Tascudi[3], D. Velicova[2], P. Tsonev[2], I. Dzhagarov[2], V. Georgieva[2], S. Gogeva[2], L. Jelezarsky[2], G. Stamenov[4]

[1]Nadezhda Women's Health Hospital, Research, Sofia, Bulgaria ;
[2]Nadezhda Women's Health Hospital, Andrology, Sofia, Bulgaria ;
[3]Nadezhda Women's Health Hospital, Andrlogy, Sofia, Bulgaria ;
[4]Nadezhda Women's Health Hospital, Obstetrics and gynaecology, Sofia, Bulgaria

Study question: Is there an association between the presence of spermatozoa with double heads and the other sperm abnormalities in human semen?

Summary answer: Patients with double-headed spermatozoa had a significantly increased percentage of morphological abnormalities (head, midpiece and tail defects).

What is known already: The morphological evaluation of spermatozoa has a prognostic value for successful IVF procedure. It has been proven that certain morphological defects have a negative impact on fertilization, embryo quality, and pregnancy outcome in in-vitro fertilization cycles. Sperm abnormalities, such as double head, double tail and thin midpiece are rarely observed. However, their effect on the other sperm defects has not been well studied yet. The aim of this study was to examine the effect of the presence of double-headed spermatozoa on the frequency of occurrence of the other sperm defects.

Study design, size, duration: This retrospective study includes 2140 men aged between 18 and 73 years, with a mean of 36 years. It was conducted at Nadezhda Women's Health Hospital, Bulgaria between October 2015 and August 2020. A comparative analysis was performed between semen samples with and without double-headed spermatozoa and the other sperm abnormalities, as well as the percentage of morphologically normal forms.

Participants/materials, setting, methods: Morphological analysis was performed according to the Kruger's strict criteria. Totally 23 types of abnormalities were determined: head defects (small, large, amorphous, elongated, round, pear-shaped, double, acephalic, detached head, small and large acrosomal areas and spermatozoa without acrosome), midpiece defects (thick, bent, asymmetric, thin midpiece and cytoplasmic droplets), tail defects (stumped, coiled and double tail), acrosomal vacuoles, nuclear vacuoles and multiple defects. Statistics: Mann-Whitney U-test and T-test; $P \leq 0.05$.

Main results and the role of chance: Presence of double-headed spermatozoa was observed in 12.62% (270/2140) of the studied samples. In these

patients the frequency of occurrence of double-headed spermatozoa ranged between 1% and 29% with a mean of 0.41%±1.71%. Men with double-headed spermatozoa had significantly higher percentage of spermatozoa with small heads (24.51%±22.65%, P=0.04), round heads (11.69%±10.13%, P<0.01), nuclear vacuoles (10.64%±5.25%, P<0.01), sperm without acrosome (9.76%±8.61%, P=0.05), asymmetric midpiece (4.73%±3.96%, P<0.05), bent midpiece (8.9%±7.22%, P<0.01), thin midpiece (2.13%±4.44%, P<0.01), double tail (1.78%±0.8%, P<0.01), detached head (1.98%±1.42%, P<0.01), stumped tail (6.03%±5.19%, P=0.02), and cytoplasmic droplets (8.86%±5.02%, P<0.01) compared to the patients without double-headed spermatozoa. Moreover, the percentage of sperm with multiple defects in the double-headed group was significantly higher (35.53%±29.91%, P<0.01), while the percentage of normal forms was significantly lower (2.93%±3.64%, P<0.01) compared to the patients without double heads.

Limitations, reasons for caution: In this study unequal sample sized groups were compared. We also need to investigate whether the obtained results will be confirmed in patients with certain pathological states, such as oligozoospermia, teratozoospermia, and asthenozoospermia.

Wider implications of the findings: The present study revealed that the presence of double-headed spermatozoa in the ejaculate is related to an increased frequency of the other semen abnormalities. The double-headed spermatozoa could be used as an indicator for the total morphological quality of human spermatozoa

Trial registration number: not applicable

P-050 The effectiveness of the platelet-rich plasma treatment of men with severe oligoasthenoteratozoospermia

O. Somova[1], H. Ivanova[1], N. Sotnyk[2], K. Kovalenko[2], I. Feskova[1]

[1]Centre of Human Reproduction Sana-Med Clinic of Professor Feskov O., IVF Deparrtment, Kharkiv, Ukraine ;
[2]Centre of Human Reproduction Sana-Med Clinic of Professor Feskov O., Biothechnology Department, Kharkiv, Ukraine

Study question: To evaluate the effect of platelet-rich plasma (PRP) testicular injections on spermogram parameters of men with severe oligoasthenoteratozoospermia (OAT).

Summary answer: The PRP testicular injections have beneficial effects on spermatogenesis and enhance sperm concentration and motility in infertile men with OAT.

What is known already: The use of PRP therapy in assisted reproductive technologies is debatable. Despite the recent evidence of its positive effects in promoting endometrial and follicular growth, data from clinical studies are limited. There are only a few papers on the effectiveness of PRP therapy in the treatment of male infertility and sexual dysfunction. In more detail, the influence of PRP on spermatogenesis was carried out only on experimental animals. Although the mechanisms of its action have not yet been clarified, it is assumed that PRP, containing many biologically active molecules, realizes its effect through the tissue regeneration and cell proliferation.

Study design, size, duration: This prospective study included 68 men (34.6±5.2) years old with severe OAT (≤4 million/ml, motility ≤30%, normal sperm morphology ≤1%) receiving hormonal and antioxidant (AO) therapy during 6 months before in vitro fertilization cycles. 33 of them were injected once with autologous PRP (0.5 ml in each testicle). Spermogram and testosterone level were analyzed before the treatment and in 3, 4 and 6 months after it. Participants/materials, setting, methods: Sperm concentration, motility and morphology in ejaculate of 33 men of PRP group were compared with those in the group of 35 men without PRP within 6 months of starting the treatment. Total and free testosterone level were measured in blood serum. PRP was prepared by centrifuging the patient's own blood in the anticoagulant-containing tubes. The final concentration of platelets in the obtained sample was 950.000 – 1.250 000 cells in 1 ml.

Main results and the role of chance: 4 months after the PRP injection, sperm concentration and motility increased in 18 of 33 men of the PRP group compared with the baseline (before the treatment) – 4.2 (1.0; 6.9) vs 1.4 (0.1; 3.4) mln/ml (p<0.05) and 36.7 (30.6; 45.8) vs 17.7 (6.7; 28.2) % respectively (p<0.05).The maximum increase in sperm motility (but not in sperm concentration!) was observed in 24 men in 6 months – 49.6 (39.6; 56.4) % (p<0.05). Percent of morphologically normal spermatozoa in ejaculate slightly increased only in 12 men in that time period from 0-1 % to 1-2%. The total testosterone level was 2.4 times higher than the baseline (31.6±7.2 vs 13.2±4.3 nmol/l, p<0.05), the free testosterone level was 1.8 times higher (14.5±3.5 vs 7.9±3.0 pgl/ml, p<0.05).

Unlike the PRP group, in the group of men without PRP treatment, the sperm parameters did not changed compared with the baseline in 4 months after the starting hormonal and AO treatment. A significant increase of sperin concentration was observed only in 17 of 35 patients in 6 months. Sperm motility and percent of morphologically normal spermatozoa after the treatment did not differ from the baseline. Changes in the testosterone levels were similar to changes in PRP group.

Limitations, reasons for caution: Only young and middle-aged men were considered in the study. Large randomized controlled studies are required to confirm the PRP therapy efficacy and safety of f various fertility disorders. There are also no standardized protocols for PRP preparation.

Wider implications of the findings: PRP therapy may have great potential for the treatment of male infertility and improving spermatogenesis. Optimization of methods of PRP preparation and dosage of testicular injections can enhance reproductive outcomes in assisted reproductive technologies.

Trial registration number: not applicable

P-051 Differential resilience of sperm from different mammals to DNA decondensation

J. Ribas-Maynou[1], E. Garcia-Bonavila[1], M. Llavanera[1], J. Miró[2], S. Bonet[1], M. Yeste[1]

[1]University of Girona, Cell Biology, Girona, Spain ;
[2]Autonomous University of Barcelona, Animal Medicine and Surgery, Bellaterra Cerdanyola del Vallès, Spain

Study question: Does sperm from different species with different protamine 1/protamine 2 ratios have different resilience to sperm decondensation?

Summary answer: Sperm cells from species whose DNA is condensed with both protamine 1 and protamine 2 require less time in deprotamination steps.

What is known already: Sperm cells present a highly particular DNA condensation that is acquired during sperm differentiation, where most part of histones are replaced by protamines. Protamines are key elements for DNA condensation and, while protamine 1 is more conserved among species, protamine 2 has evolved differentially, existing only a few species that retain the mature protein in their sperm DNA. Changes in protamine expression rates have been described to be associated to head sperm size and shape. In addition, reduced amounts of protamine 2 are related to male infertility in species in which this protein is present.

Study design, size, duration: Cryopreserved sperm samples were treated with lysis solutions to induce DNA decondensation and formation of sperm haloes. In these treatments, the effect of different incubation times with proteinase K added to the lysis solution upon DNA decondensation was tested by analyzing core diameter, halo diameter and the Halo/core ratio in at least 50 sperm per sample.

Participants/materials, setting, methods: Species included in the study were Human, Equine, Donkey, Porcine and Bovine. Sperm samples from five different individuals for each species were included in the study. DNA decondensation included three lysis steps: first, a SDS + DTT incubation for 30 minutes; second, a DTT + NaCl treatment for 30 minutes; and third, a DTT + NaCl + Proteinase K treatment with a variable time of 0, 30 or 180 minutes.

Main results and the role of chance: The halo/core diameter, used as a representation of the degree of DNA decondensation, for 0 minutes, 30 minutes and 180 minutes of proteinase K incubation were: 4.68±0.51, 4.32±0.51 and 4.77±0.64, respectively for human sperm; 4.15±0.41, 4.57±0.53 and 4.68±0.63, respectively for Equine sperm; 4.40±0.64, 4.00±0.37 and 4.17±0.19, respectively for donkey sperm; 1.77±0.2, 3.05±0.14 and 4.13±0.39, respectively for porcine sperm; and 2.40±0.40, 3.36±0.22 and 4.19±0.38, respectively for bovine sperm. Differences of halo/core ratio in different times were only observed in porcine and bovine sperm, where increasing degrees of DNA decondensation were found (p<0.05). Therefore, these results show that while longer incubations in lysis solutions with proteinase K lead to higher DNA decondensation in porcine and bovine, they do not induce higher decondensation in human, equine and donkey. This evidence, coupled to the fact that porcine and bovine sperm present

null or very low protamine 2 content, suggests that its presence might confer higher DNA decondensation susceptibility.
Limitations, reasons for caution: Only sperm cells with normal sperm haloes were analyzed in the present study. As multiple studies show, haloes exhibited by sperm cells with DNA damage display higher diameter, that is why they were strictly excluded in this study with the aim to elucidate the average DNA decondensation.
Wider implications of the findings: Sperm DNA might have different degrees of DNA condensation, which can be associated to a higher difficulty of DNA decondensation, thus having implications in the sensitivity tests that assess sperm DNA integrity.
Trial registration number: Not applicable.

P-052 Structural and functional changes in the prostate gland of men following orchitis

A. Spaska[1], N. Dolynko[2]

[1]Ajman University, College of Medicine, Ajman, United Arab Emirates ;
[2]Precarpathian National University, Anatomy and Physiology, Ivano-Frankivsk, Ukraine

Study question: The aim of the study was to establish echometric parameters, hemodynamic and cytohistological changes in the prostate gland in men of reproductive age after orchitis.
Summary answer: After orchitis, volume and mass of the prostate increased compared to the control group, blood flow was reduced, histologically and electron microscopy changes were observed.
What is known already: According to the literature, prostate diseases in men of reproductive age are an important issue in urology and andrology. The most common among them are infectious lesions of the genitourinary system, which constitute about 45%. These include, orchitis, as a part of the infectious process of the entire reproductive system. Half of the cases of orchitis are sexually transmitted infections or associated with infections that come from urogenital tract. In the majority of patients orchitis leads to infertility. But the state of the prostate, under these conditions, remains poorly understood.
Study design, size, duration: We used ultrasound diagnostics and colour ultrasound angiography of the prostate gland of 10 men aged 36-42 years, who suffered from orchitis. The data of 7 healthy men of the same age served as control. For histological and electron microscopy served tissues of prostate gland obtained from the 5 men of the same age group during minor invasive surgery. Statistical processing of the results was carried out using the program Statistica 10. Participants/materials, setting, methods: The length, width, height, volume and mass of the prostate were determined in the grey scale mode. The vascular pattern was determined by colour Doppler mapping (the course of the blood vessels, their diameter, the number in the symmetric sections of prostate). Qualitative hemodynamic indicators: peak systolic blood flow velocity (Vps) cm/s, diastolic blood flow velocity (Vd) cm/s, time average velocity (TAV) cm/s, pulsatility index (PI), volumetric flow rate (V) L/min. Histological methods and TEM.
Main results and the role of chance: After orchitis, the volume of prostate gland increased to (26.0 ± 1.4) cm3 vs (21.2±1.3) cm3 in control and its mass increased to (27.4±1.2) g vs (22.1±1.6) g in control group. The blood flow in the prostate was reduced: peak arterial blood flow velocity in the peripheral zone decreased up to (6.8±0.46) cm/s vs (18.8±3.0) cm/s in control and diastolic blood flow velocity decreased up to (2.75 ± 0.26) cm/s vs (5.7±0.1) cm/s in the control group. The final sections of the glands were cystically enlarged, the squamous epithelium was flattened, the nuclei were pyknotic and the cell borders were indistinguishable. Epithelial folds and shape were preserved, prostatic bodies and acidophilus secretion in the gaps were preserved. The relative volume of the glandular epithelium decreased up to 56.5% and the volume of the fibrous-muscular-elastic component around the lobules increased up to 43.5%. In the capillaries of the prostate, the nuclei of the endothelial cells were deformed, the cytoplasm was vacuolated, the crysts in the mitochondria were reduced, the basement membrane was expanded and uneven. In the nuclei of the prostatic epithelium the perinuclear condensation of chromatin observed, cytoplasm was vacuolated and accumulated drops of fat, the mitochondrial cristae were homogenized.
Limitations, reasons for caution: The results of the investigation approved by the Commission on Biomedical Ethics of the Precarpathian National University as appropriate and those do not violate moral and ethical norms in conducting research (Protocol 3 dated 16.10.2019).
Wider implications of the findings: The results of research indicated changes in the prostate, which require further investigation of hormonal balance in men under these conditions.
Trial registration number: *

P-053 Concentration of bisphenol S in human seminal plasma negatively correlates with decreasing sperm concentration in ejaculate

K. Franzová[1], M. Ješeta[2], J. Navrátilová[3], S. Fialková[3], J. Kalina[3], J. Žáková[2], P. Ventruba[2]

[1]University Hospital Brno, Center of Assisted Reproduction- Gynecology and Obstetrics, Brno, Czech Republic ;
[2]Faculty of Medicine- Masaryk University Brno and University Hospital Brno- Czech Republic, Center of Assisted Reproduction- Department of Gynecology and Obstetrics, Brno, Czech Republic ;
[3]RECETOX Centre, Faculty of Science- Masaryk University- Brno- Czech Republic Charles University in Prague- Czech Republic, Brno, Czech Republic

Study question: Is there a relationship between concentration of bisphenol S in seminal fluid and spermiogram parameters?
Summary answer: Bisphenol S was detected in 81% of seminal plasma samples. Negative correlation was found between BPS concentration and total sperm count in normozoospermic men.
What is known already: Human spermatogenesis can be influenced by a range of chemicals present in our environment. Bisphenol S (BPS) is a very frequent compound commonly used as a softener in production of plastics, where it has replaced bisphenol A. It is an endocrine disruptor frequently associated with negative effects on reproduction. It has been observed that BPS can affect testicular development in rodent males. In addition, it has cytotoxic, reprotoxic and neurotoxic effects and induces the oxidative stress bringing negative effects on spermatogenesis. BPS has been detected in food, drinks or cosmetics. Its direct effect on spermatozoa or spermatogenesis is still unclear.
Study design, size, duration: A total of 38 patients (25 normozoospermic) aged 24 to 42 years, non-smokers, with BMI between 19,9-32,9 were included in this prospective study from 2018 to 2020. None of them had varicocele, urogenital infections or other urological problems. Their seminal plasma was separated by centrifugation. BPS was extracted using solvent extraction followed by preconcentration step. The samples were analysed on Agilent 6495 Triple Quadrupole. Two MS/MS transitions were used for quantitative LC-MS/MS analyses.
Participants/materials, setting, methods: All the men included in this study signed an informed consent and agreed with analyses of their samples. These analyses were approved by Ethical committee of University Hospital Brno. We evaluated the relationship between concentration of BPS in seminal plasma, sperm concentration, total sperm count, total motility, progressive motility, morphology and fragmentation of DNA in spermatozoa. Statistical evaluation was performed by one individual one-dimensional regression model (p-value lower than 0.05 were considered as statistically significant).
Main results and the role of chance: The examination revealed the presence of BPS in 31 samples of seminal plasma (81% of all the samples). In 6 samples, the concentration was under level of detection and in one sample under level of quantification. In 7 samples, a very high concentration was detected (>0.1 ng/ml). These values were then compared to spermiogram parameters and sperm DNA integrity. There were no significant differences between the concentration of BPS and morphology of spermatozoa, progressive motility and total motility. In case of the DNA integrity, the opposite trend was observed, lower proportions of spermatozoa with fragmented DNA were found in samples with higher concentrations of BPS. Evaluation of sperm concentration and BPS concentration showed relationship of increasing BPS concentration with significantly lower sperm concentration, the differences were most obvious when only the normozoospermic men were compared. Evaluation of BPS concentration and total sperm count revealed the same trend with statistically significant difference in the category of normozoospermic men. Due to the small number of samples, a negative effect of extreme values on the statistical evaluation cannot be excluded. Currently, more analyses focused on detection of BPS in seminal plasma are carried out in order to obtain sufficiently larger data set.

Limitations, reasons for caution: A limitation is the number of samples included and analysed in this study, which slightly reduced the power of statistical analysis.
Wider implications of the findings: These results document that BPS was present in 81% of analysed samples. Knowing the concentration of BPS in seminal fluid is important for understandig of impact of BPS on male fertility. Our future work will be focused on detection of other bisphenols in seminal plasma.
Trial registration number: MH CZ – DRO (FNBr, 65269705), AZV NV18-01-00544, Czech Ministry of Education, Youth and Sports (CZ.02.2.69/0.0/0.0/19_074/0012727)

P-054 Apoptosis related-microRNAs in Oligoasthenoteratozoospermia and Azoospermia men may reveal novel study of freezing damage

M. Ezzati[1], M. Pashaiasl[1]

[1]Faculty of Anatomical Sciences- Faculty of medicine- Tabriz University of medical sciences- Tabriz- Iran., Department of Anatomical sciences- Faculty of medicine- Tabriz University of medical sciences- Tabriz- Iran., Tabriz, Iran

Study question: Could choosing of non-apoptotic spermatozoa by biological biomarkers such as microRNAs promote post-thaw fertilization ability?
Summary answer: Biological alterations in correlation with apoptosis and oxidative stress markers such as microRNAs may preserve the function and fertility of spermatozoa during cryopreservation.
What is known already: Biological changes of cryopreserved spermatozoa such as microRNAs against cryo-injury were investigated. It was presented that several sperm parameters such as motility and abstinence period can impact the percentage of post-thaw sperm survival. Recent study, reported that microRNAs related to process of motility, sperm structure and apoptosis were associated with different expression after cryopreservation. More comprehensive study needed to fully mention the effect of microRNAs and their correlations with other biomarkers in cryopreservation.
Study design, size, duration: Our study was performed on 58 men who were 24-40 years old. Their ejaculated samples were classified as sever (concentrations less than 5 million sperm/mL) Oligoasthenoteratozoospermia (SOAT), mild (concentrations 5 million – 10 million sperm/ mL) Oligoasthenot eratozoospermia (MOAT), obstructive azoospermai (OA), Non obstructive azoospermai (NOA) (absence of spermatozoa in the semen) and normal group (concentrations more than 15 million sperm/ mL). Then each sample was grouped into fresh and cryopreserved one.
Participants/materials, setting, methods: Density Gradient centrifugation (DGC) was performed to obtain high quality sperm without round cells after freeze-thawing. Biopsy of testicular tissue was prepared after Testicular Sperm Extraction (TESE) surgery. Then biological biomarkers were examined before and after cryopreservation including microRNA-122 (miR-122), miR-383, miR-15b, miR-184, miR-34c and target genes such as P53, Caspase9 and CYCLIN D1, using Quantitative real-time polymerase chain reaction (RT-PCR). Glutathione peroxidase (GPx), Superoxide dismutase (SOD) and malondialdehyde (MDA) using imaging multi-mode reader.
Main results and the role of chance: There was a significant reduction in sperm total motility and morphology in Cryopreserved-infertile groups (MOAT and SOAT) compared with the Fresh-infertile groups. Decreased level of GPx activity was associated with increased concentration of MDA during freeze-thawing procedure in oligoasthenoteratozoospermia. Also increasing levels of SOD, and DNA fragmentation were showed. Our data demonstrated that reduction of CYCLIN D1 in MOAT-Cryopreserved (P=0.0174) and NOA-Cryopreserved (P=0.0001) groups were considerable compared with their fresh ones. We observed high level of Capase9 and in cryopreserved groups (P=0.01).The expression of miR-34c was increased significantly in NOA-Cryo (P=0.0064), and OA-Cryo (P=0.0441) in comparison with their fresh groups. The expression of miR-184 (P=0.0275) was enhanced in NOA-Cryo as compared to NOA-Fresh. Quantitative RT-PCR demonstrated meaningful decrease level of miR-383 expression in SOAT-Cryopreserved as compared with SOAT-Fresh (P=0.0223). On the other hand, expression level of miR-383 was increased in NOA group significantly (P= 0.0437) and in OA group non-significantly during freezing. There was non-significant decrease of miR-122 and miR-15b in MOAT and SOAT-Cryopreserved groups in comparison to their Fresh groups. We observed reduced expression of miR-122 (P=0.0109) and miR-15b (P=0.0322) in OA group after freezing. Also, there was meaningful increased level of miR-15b (P=0.0234) in NOA-Cryo compared with Fresh.
Limitations, reasons for caution: Because of the ethical principle, we can not obtain testicular samples from normal groups. So, we analyzed NO and OA groups with each other.
Wider implications of the findings: Our study documented that total motility can be interfered by microRNAs. This phenomenon effects on the total motility of post-thaw spermatozoa. Also the increase level of MDA may disturb microRNAs regulation in the infertile cases. These non-coding RNAs may be known as fertility biomarker to development of freeze-thawing strategies.
Trial registration number: 60961

P-055 Methylation dynamics of the sperm epigenome after chemotherapy: a case study

A.S. Neyroud[1], A. Rolland[2], B. Evrard[2], N. Alary[2], N. Dejucq-Rainsford[2], B. Jégou[2], L. Bujan[3], C. Ravel[1], F. Chalmel[2]

[1]CHU de Rennes, Biology of reproduction, rennes, France ; [2]Univ Rennes- Inserm- EHESP- Irset Institut de recherche en santé- environnement et travail - UMR_S 1085- F-35000 Rennes- France., Inserm, Rennes, France ; [3]CHU de Toulouse, Biology of reproduction, Toulouse, France

Study question: What is the evolution of the sperm epigenome after chemotherapy in a patient with testicular cancer (TC)?
Summary answer: These new data on epigenetic recovery profil after TC are useful tools for counseling and reassuring these patients.
What is known already: An important issue for young men affected TC is how TC and its treatment will affect, transiently or permanently, their future reproductive health. The consequences of cancer treatment on the sperm epigenome during the recovery periods are topical issues of ascendant significance as epigenetic modifications to the paternal genome may have deleterious effects on the offspring.
Study design, size, duration: Here we report the epigenomic profiling of frozen sperm from a TC patient before and after the treatment at different time points (6, 9, 12 and 24 months) by using RRBS analysis (Reduced representation bisulfite sequencing method).
Participants/materials, setting, methods: A testicular tumor (testicular germ cell tumor) was diagnosed in a 30 years old patient. A cryopreservation of spermatozoa was proposed before treatment.Semen samples were obtained 2 times before treatment and 4 times after treatment (6, 9, 12 and 24 months following the initiation of treatment).
Main results and the role of chance: Upon collection, sampling after chemotherapy ranged from 0,6 to 4,2 million per sperm straw between 6 and 24 months after the treatment, always increasing.

In order to capture the direct effect of the treatment on the methylation changes, the DMR detection has been operated between pre-chemotherapy samples (pair-wise) and the time point of 6 months. Among the 179 hqDMRs, 74 are differentially methylated between the PreCT and PostCT6m samples (16 hyper- and 68 hypo-methylated) associated with 49 DMGs (15 hyper- and 34 hypo-methylated).

We further sub-clustered the 74 hqDMRs between PreCT and PostCT6m into 6 patterns, 3 hyper- and 3 hypo-methylated. Briefly, patterns P1 and P4 include hqDMRs that quickly get back to their pre-treatment methylation status just after 9th months onwards. Patterns P2 and P5 include hqDMRs that slowly get back to their pre-treatment methylation status between 12 and 24 months after treatment. Patterns P3 and P6 include hqDMRs that remain hyper- or hypo-methylated even after 24 months.

We have intersected the genes (DMGs) associated with the detected hqDMRs with those known to be important or expressed during embryogenesis. We thus detected that 7 hyper-methylated and 6 hypomethylated DMGs were involved (or expressed) during embryonic / fetal development.
Limitations, reasons for caution: This study involves a single patient. As the patient made no major changes in his personal way of life, we hypothesized that sperm parameter variations may be attributable to the BEP treatment.
Wider implications of the findings: The altered methylated status of those DMGs important for early development might modify their expression pattern and thus affect their function during key stages of embryogenesis leading to

potential developmental disorders. It is important to notice that among the 110 DMGs none of them correspond to known imprinted genes.
Trial registration number: not applicable

P-056 To graft or not to graft? Intratesticular grafting of testicular tissue from Klinefelter boys to the mouse testis as possible novel in vivo model

M. Willems[1], P. Sesenhausen[1], I. Gies[2], V. Vloeberghs[3], J. D. Schepper[2], H. Tournaye[3], E. Goosens[1], D. Va. Saen[1]

[1]Vrije Universiteit Brussel, Biology of the testis, Brussels, Belgium ; [2]Universitair ziekenhuis Brussel, Department of Pediatrics- Division of Pediatric Endocrinology, Brussels, Belgium ; [3]Universitair ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium

Study question: Can intratesticular transplanted testis tissue from Klinefelter boys to the mouse testis be used to study the mechanisms behind testicular fibrosis?
Summary answer: Grafting of testicular tissue from Klinefelter boys to the mouse testis is not a valuable new *in vivo* model to study Klinefelter-related testicular fibrosis.
What is known already: Klinefelter syndrome (KS; 47, XXY) affects 1-2 in 1000 males. Most KS men suffer from azoospermia due to a loss of spermatogonial stem cells. Additionally, testicular fibrosis is detected from puberty onwards. However, mechanisms responsible for fibrosis and germ cell loss remain unknown. An optimal *in vivo* model to study the KS testicular fibrotic process is not available.

This study aimed to evaluate a possible *in vivo* model to study KS-related testicular fibrosis. In addition, the effect of the mast cell blocker ketotifen, which showed positive effects on fertility in infertile non-KS patients, was evaluated in this graft model.
Study design, size, duration: First, the survival time of the KS graft was established, since it was the first time KS tissue was transplanted to the mouse testis. Testes were collected after two, four, six and eight weeks after which histological and immunohistochemical evaluations were performed. Next, the effect of daily ketotifen injections on the fibrotic appearance of intratesticular grafted testicular tissue from KS and controls was evaluated.
Participants/materials, setting, methods: Testicular biopsy samples from pre- and peripubertal KS (n=22) and age-matched control samples (n=22) were transplanted to the testes of six weeks old Swiss Nu/Nu mice (n=22). Prior to grafting, testicular tissue pieces were cultured in vascular endothelial growth factor (VEGF) for five days. Next, tissues were transplanted to the mouse testes. Testicular transplants were analysed by immunohistochemistry. In the second experiment, mice were given daily subcutaneous injections of ketotifen or saline.
Main results and the role of chance: Four weeks after transplantation, all KS grafts could still be retrieved. At a later timepoint, degeneration of the tissue could be detected. In the grafts, recovered four weeks after transplantation, about 30% of the tubules in peripubertal grafts showed a good integrity, while in the prepubertal tissue, 83% of the tubules were intact. A fibrotic score was assigned to each graft. No significant changes in fibrotic score was observed between testicular biopsies before or after transplantation. However, an increased ($p<0.01$) fibrotic score was observed after in-vitro treatment with VEGF both in control and KS tissue. Based on recovery and tubule integrity grafts were recovered after four weeks in the second experiment. Treatment with ketotifen did not result in significant histological differences compared to non-treated grafts (KS and control tissue).

The survival potential of grafts from KS testicular biopsies of pre- and peripubertal boys was patient- and age-dependent. After four weeks, most KS tissue starts to degenerate. In prepubertal tissue, seminiferous tubules were mostly intact, while tissue from adolescent boys was impaired. Interestingly, no loss of germ cells was observed after transplantation of the testicular tissue.
Limitations, reasons for caution: The availability of tissue from young KS patients is very scarce, leading to a low number of included patients (n=8). Testicular tissue pieces from the same patient were included to evaluate the differences before and after transplantation. However, histological variability between testicular tissue biopsy pieces is well-known in KS patients.
Wider implications of the findings: Since testicular tissue from KS boys, transplanted to the mouse testes, already starts to degenerate after four weeks and the integrity is not optimal, we conclude that this is not a valuable model for future studies. *In vitro* models to study the KS-testicular fibrosis should be investigated.
Trial registration number: NA

P-057 Preliminary evaluation of laser confocal Raman spectroscopy as a noninvasive method for detecting sperm chromosome aneuploidy

M. Li[1], L. Hu[1], Y. Ji[1]

[1]Central South University, Institute of Reproductive and Stem Cell Engineering-School of Basic Medical Science, changsha, China

Study question: To evaluate the efficiency and accuracy of Raman microspectra in detecting sperm chromosome balance state by DNA content difference.
Summary answer: Raman spectroscopy can identify the difference of X and Y sperm DNA content, but the accuracy still needed to be improved for clinical application.
What is known already: Aneuploid sperm fertilization affects embryo quality and leads to the waste of oocytes in Assisted Reproductive Technology (ART). Raman spectroscopy can identify substances and observe molecular changes through specific spectral patterns with high specificity and has become a new hot spot in ART. Previous research has used this technology to detect embryo culture medium to evaluate the aneuploidy of embryos. The DNA content of X and Y in sperm was different, which may serve as a marker for sperm aneuploidy detection by Raman spectroscopy.
Study design, size, duration: The significant difference in the morphology of the sex chromosomes of X and Y spermatozoa leads to a substantial difference in the DNA content. We perform Raman spectroscopy to identify the spectral differences of the sperms, especially the differences in sperm DNA content. We further verified the accuracy with fluorescence in situ hybridization (FISH).
Participants/materials, setting, methods: Spermatozoa were provided by healthy donors with normal aneuploidy, and analysis parameters met the current World Health Organization (WHO, 2010) standards. Sperm heads were detected by laser confocal Raman spectroscopy and obtained the corresponding spectra. The sperm chromosome information was classified by Standard principal component analysis (PCA) and identified by fluorescence in situ hybridization (FISH). Student's t-test and Receiver operating characteristic (ROC) curve analysis was performed for further analysis.
Main results and the role of chance: Standard principal component analysis (PCA) after unqualified quality control divided spermatozoa into two groups according to the calculation and calibration results, 22 cases in group A and 31 cases in group B. Then, we conducted frequency distribution histogram statistics on the above data, and the results showed that there were differences in frequency distribution at I785 = 23,750 and Area714 -1162 = 3,250,000. The FISH analysis identified sex chromosomes of 59 spermatozoa, which was not exactly one-to-one correspondence with the results of PCA analysis. Then we further analyzed the sperm of 59 cases by statistical analysis. The results showed that there were significant differences between X sperm (n = 39) and Y sperm (n = 20) at 714-1162 cm-1 and 785 ($P<0.05$). ROC curve analysis was used to evaluate the sensitivity of correlation between sperm DNA content and Raman spectra. The results showed that the corresponding thresholds of I785 = 24,986.5 and Area714-1162 cm^{-1} = 3,748,990 were the best for distinguishing the two kinds of sperm. When the sperm's peak value of 785 or 714-1162cm^{-1} exceeds the above thresholds, X-sperm's possibility greatly increased. The AUC of the ROC curve in both cases was 0.662 and 0.696, respectively.
Limitations, reasons for caution: Current Raman spectroscopy requires spermatozoa elution and fixation, which damage the sperms. Furthermore, current Raman spectral data are not obtained from the whole sperm head, limiting the accuracy of this technique.
Wider implications of the findings: Our results indicated that Raman spectroscopy had potential application value for sperm aneuploidy detection and could be used as a noninvasive selector for normal haploid sperms in the ART.
Trial registration number: LL-SC-2018-038

P-058 The effect of sperm DNA fragmentation on intracytoplasmic sperm injection (ICSI) outcome

M. Arafa[1], H. Elbardisi[1], S. AlSaid[1], H. Burjaq[2], T. AlMazooqi[3], A. Majzoub[1]

[1]Hamad Medical Corporation, Urology/Surgery, Doha, Qatar ;
[2]Hamad Medical Corporation, Assisted conception unit, Doha, Qatar ;
[3]Hamad Medical Corporation, Obstetrics and Gynecology, Doha, Qatar

Study question: Does the sperm DNA fragmentation (SDF) level impact the clinical outcome of couples undergoing intracytoplasmic sperm injection (ICSI)?
Summary answer: No significant effect was observed for SDF on the reproductive outcome of couples undergoing ICSI.
What is known already: Sperm DNA Fragmentation (SDF) has emerged as an important biomarker in the assessment of male fertility potential. It is currently being used as one of the advanced sperm function tests along with other conventional methods in male fertility evaluation. The impact of SDF on the reproductive outcomes of ICSI remains to be controversial. Evidence extracted from three meta-analyses have indicated that higher SDF is not associated with a negative impact on ICSI outcomes. On the contrary, another meta-analysis revealed that SDF can have a significant impact on the pregnancy rate of ICSI with an OR of 1.31.
Study design, size, duration: This is a retrospective cohort study carried out in the assisted conception unit of a tertiary medical center. The study duration was over a 5-year period from August 1st, 2014 to August 1st, 2019. The charts of 1922 patients who underwent ICSI were screened for inclusion in the study. Inclusion criteria were patients who underwent ICSI using ejaculate spermatozoa and had a recorded SDF test done within a week before ICSI (n=390).
Participants/materials, setting, methods: Sperm chromatin dispersion was used to evaluate SDF utilizing the Halosperm G2 test kit (Halotech, Madrid, Spain). All patients performed the ICSI trial using ejaculated spermatozoa. Patients were divided according to the SDF level into 3 groups; SDF <20% (n=148), SDF 20-30% (n=133), and SDF >30% (n=109). Female partner fertility status was recorded and couples were grouped into 2 groups based on age and AMH levels; (1) favorable female and (2) unfavorable female status.
Main results and the role of chance: Overall, clinical pregnancy occurred in 45% of cases, live birth rate was 33.60%, and 1.30% of patients had miscarriage. A significant negative correlation between SDF and sperm count (r-0.232), motility (r-0.469), progressive motility (r-0.312) and normal morphology (r-0.297) was detected (p<0.001 for all). Fertilization rate, clinical pregnancy and live birth rate were greater in patients with lower SDF than those with higher SDF in both favorable and unfavorable groups, however the difference was not statistically significant (Table 1).
Limitations, reasons for caution: The main limitation of our study was the retrospective nature of the study where some data may be missing or incomplete. The data was also retrieved from one ART center, therefore our data lacked diversity within methodologies for IVF and SDF testing.
Wider implications of the findings: SDF was found to be significantly correlated with conventional semen parameters highlighting its significance as a robust diagnostic test during male fertility evaluation. In this study, while patients with higher SDF values had worse reproductive outcomes with ICSI, the results did not reach statistical significance.
Trial registration number: NA

P-059 Association between seminal levels of Fe and semen quality

R. Rodrigue. Díaz[1], L. Alcaide-Ruggiero[1], R. Blane. Zamora[1], J. Gome. Rodríguez[1], S. Paz[2], A. Hardisso. d. l. Torre[2], A. Gutierrez[2], C. Rubio[2], S. Hess-Medler[3]

[1]Hospital Universitario de Canarias. Facultad de Medicina. Universidad de La Laguna, Obstetrics and Gynecology, La Laguna. Tenerife, Spain ;
[2]Facultad de Medicina. Universidad de La Laguna, Toxicology, La Laguna. Tenerife, Spain ;
[3]Facultad de Medicina. Universidad de La Laguna, Clinical Psychology-Psychobiology and Methodology, La Laguna. Tenerife, Spain

Study question: The detection of metals in semen offers a new field in the study of male infertility.
Summary answer: Normozoospermia is associated with higher amounts of Fe. In males with pathological spermiogram, the percentage of men with Fe in semen was lower than expected.
What is known already: Increased levels of Fe in human semen appear to have a significant correlation with male fertility, suggesting that Fe in human seminal plasma has an important factor in male reproductive function. Fe acts as an antioxidant being a co-factor of catalasa, which protects sperm. On the other hand, elevated Fe levels are associated with sperm damage and continues to increase the lipid peroxidation that will affect the plasma membrane and the sperm motility. Most authors associate Fe with sperm motility and higher estimated fertility potential, based on standard semen parameters in fertile men, which are associated with lower levels of Fe.
Study design, size, duration: A prospective study was carried out in 102 men in a Reproduction unit in Tenerife, from February to April 2018 as a part on an epidemiologic study of environmental contaminants and male reproduction. The participant were categorized into two groups, according to the results of semen analysis following the World Health Organization guidelines: the pathological and the normal semen group that constituted the control group. The metal was determined in semen samples.
Participants/materials, setting, methods: Semen quality and levels of Fe were measured in seminal plasma on a total of 102 men attended successively, for the initial infertility evaluation, The collected samples were used for both semen analysis following the World Health Organization (WHO) guidelines and metal detection and carried out using a Makler® counting chamber (Irvine Scientific, CA) and for metals, were determined by ICP-OES (Inductively Coupled Plasma-Optical Emission Spectrometry) in semen samples.
Main results and the role of chance: The percentage of males with the presence of Fe was 97.1% and the average level were 0.6283 mg/Kg. When analyzing the relationship between the spermiogram parameters with the levels of Fe in the semen, significant differences were found. All men with a normal sperm analysis presented Fe in semen, but among men diagnosed with altered spermiogram, the percentage of men with Fe in semen (92.7%) was lower than expected (97%) (2 128 1 =4.59; *p* =0.032). As for the concentration of Fe in spermiogram in the first quartile (25% lower), measuring 0.33 mg/Kg, more pathological samples were found than expected (χ2 133 2 =6.921; *p*=0.031) having a higher probability of being more pathological (52% vs 31.4%). On the other hand, men with pathological sperm concentration, have higher levels of Fe, in the fourth quartile (0.61 mg/kg), with more frequency than expected (90.6% vs 97%) (χ2 136 1 =6.48; *p*=0.011). The association between BMI and the presence of Fe was statistically significant. In obese males (BMI ≥30.0 kg/m2),

	Favorable group			Unfavorable group		
SDF	**<20**	**20-30**	**>30**	**<20**	**20-30**	**>30**
Fertilization rate	75%	77.8%	73.03%	71.4%	75%	80%
Clinical pregnancy	52.2%	51.2%	48.5%	34%	39.2%	31.7%
Miscarriage	1%	1.2%	2.9%	0%	0%	2.4%
Live birth rate	50%	42.9%	41.9%	26.1%	33.3%	16.7%

p value >0.05 in all.

the percentage of men with Fe in semen (80%) was lower than expected (97%) ($\chi 2\ 42\ 2 = 11.302$; $p = 0.001$).
Limitations, reasons for caution: The limitation of this study was the volume of semen that could be obtained for metal detection, only 0.8 mL. because the collected samples were used for both semen analysis and metal detection.
Wider implications of the findings: The determination of metals in semen opens a new field in the study of male infertility and many cases of unknown infertility could be due to metal presence or absence in semen, with the option of performing treatments.
Trial registration number: not applicable

P-060 Dose- dependent mitigation of lead acetate toxicity in males on embryo development in female mice

P. Dolati[1], M.J. Zamiri[1], A. Akhlaghi[1], Z. Jahromi[2]

[1]Shiraz University, Department of Animal Science- College of Agriculture, Shiraz, Iran ;
[2]Shiraz University of Medical Science, Stem Cells Technology Research Center, Shiraz, Iran

Study question: Does quercetin (75 or 100 mg/kg BW/day) co-administration with lead acetate to male mice affects embryonic development in female mice?
Summary answer: The low-dose quercetin (75 mg/kg BW/day) ameliorated the adverse effects of lead acetate on mouse embryogenesis.
What is known already: Lead causes male infertility by impacting on endocrine system and spermatogenesis, and may exert undesirable effects on the offspring. The currently approved treatment for lead poisoning is the use of chelating agents, which form an insoluble complex with lead and shield it from biological targets; thus, reducing its toxicity. One of the main mechanisms of lead-induced toxicity is oxidative stress, and it has been reported that natural antioxidants can reduce the heavy metals toxicity. The aim of the present study was to examine the protective effects of quercetin on the toxicity induced by lead acetate on the embryogenesis in mice.
Study design, size, duration: Sexually mature (eight-week-old) NMRI male mice (n= 24) were randomly divided into four groups (n= 6 per group) receiving (i) distilled water (control group); (ii) lead acetate (150 mg/kg BW/day) dissolved in deionized water (LA); (iii) lead acetate (150 mg/kg BW/day) + quercetin (75 mg/kg BW/day) (LQ75); (IV) lead acetate (150 mg/kg BW/day) + quercetin (100 mg/kg BW/day) (LQ100). Treatments were applied daily as oral gavages for one cycle of the seminiferous epithelium (35 days).
Participants/materials, setting, methods: At the end of treatment administration, the males were joined with super-ovulated females, and the retrieved zygotes were cultured for evaluation of the embryo development (at 2-cell, 4-cell, 8-cell, and blastocyst stages), and blastocyst cell number using differential staining (propidium iodide and bisbenzimide). After incubation of capacitated sperm with oocytes, an ultraviolet light microscope was used following 3 min incubation with 25 μg⁄mL bisbenzamide solution for fertilization assessment.
Main results and the role of chance: Lead acetate (LA) treatment of male mice decreased the 2-cell stage compared with the control group ($P > 0.05$). There was no difference between control and LQ75, and between LA and LQ100. The other stages of embryonic development were not significantly affected by the treatment. Overall, early embryonic development in the control and LQ75 mice were better than LQ100 and LA mice.

The number of cells in the trophectoderm and inner-cell mass were not affected by treatments. However, the total blastocyst cell number in the control was higher than in the other groups; there was no significant difference between LQ100, LQ75 and LA groups. Fertilization rate was not affected by the treatments ($P < 0.05$).

Quercetin acts as a potent antioxidant at low doses, but at high doses exerts a pro-oxidant action. According to previous reports, higher concentrations of quercetin increased apoptosis and necrosis while decreasing the activities of the antioxidant enzymes. Also, it has been suggested that quercetin might disrupt the endocrine system and interfere with Sertoli cell function and sperm motility.
Limitations, reasons for caution: A limitation of this study is narrow dose selection; more studies are needed to determine the effective dose of quercetin in ameliorating the lead toxicity. There are also side effects of lead-quercetin chelates such as metal redistribution, essential metal loss, accumulation and persistency in intracellular sites, and peroxidation.
Wider implications of the findings: Lead administration adversely impacted on the embryogenesis; on the other hand, paternal quercetin co-administration somewhat ameliorated the adverse effects of lead on mice embryogenesis.
Trial registration number: Not applicable

P-061 Protective effect of melatonin against bleomycin, etoposide, and cisplatin (BEP) chemotherapy-induced testicular toxicity in Wistar rats: A biochemical, immunohistochemical and apoptotic genes based evidence

M. Moradi[1,2], A. Faramarzi[3,4], N. Goodarzi[2], A.H. Hashemian[5,6], H. Cheraghi[1], C. Jalili[4]

[1]Faculty of Veterinary Medicine- Razi University, Department of Clinical Sciences, Kermanshah, Iran ;
[2]Faculty of Veterinary Medicine- Razi Universtiy, Department of Basic and Pathobiological Sciences, Kermanshah, Iran ;
[3]Health Technology Institute, Fertility and Infertility Research Center, Kermanshah, Iran ;
[4]Medical School- Kermanshah University of Medical Sciences-, Department of Anatomical Sciences, Kermanshah, Iran ;
[5]School of Health- Kermanshah University of Medical Sciences, Department of Biostatistics, Kermanshah, Iran ;
[6]Health Institute- Kermanshah University of Medical Sciences-, Research Center for Environmental Determinants of Health RCEDH, Kermanshah, Iran

Study question: Does exogenous melatonin (MLT) attenuate BEP-induced damage in testicular cells and spermatogenesis in a dose-dependent manner?
Summary answer: Melatonin protected the testes against BEP-induced testis damage through ameliorating nitro-oxidative stress, apoptosis, and inflammation. However, there was no significant difference between melatonin-treated groups.
What is known already: Recently, the prevalence of testicular cancer (TC), accounting for the most common cancer among young people of reproductive age (15–40 years), has risen internationally. BEP chemotherapy has increased the 5-year survival rate of TC patients at all stages of testicular germ cell tumors to 90-95%. However, BEP creates a high incidence of male infertility and even long-term genotoxic effects, which emerges as a critical health issue. Melatonin is a well-known potent antioxidant with widespread clinical applications that recently has been giving increasing attention to its role in male sub/infertility.
Study design, size, duration: 60 Adult male Wistar rats were randomly assigned to six groups (n=10/group). Group 1, 3, and 4 were injected with vehicle, 10 and 20 mg/kg of melatonin, respectively. Other groups received one cycle of bleomycin, etoposide, and cisplatin for a total of 3 weeks with or without melatonin. Melatonin administration started daily one week before BEP initiation continued on days 2, 9, and 16; and one week after the completion of the BEP cycle.
Participants/materials, setting, methods: Bodyweight, testes weight, Sperm parameters (count, motility, viability, and morphology), testosterone hormone level, testicular histopathology, stereological parameters, testicular level of malondialdehyde (MDA), nitric oxide (NO), and total antioxidant capacity (TAC), the expression of Bcl-2, Bax, Caspase-3, p53, and TNF- (Real-time PCR and immunohistochemistry) were evaluated at the end of the study (day 35).
Main results and the role of chance: Our findings showed that melatonin restores the BEP-induced reduction in the body and testes weight (P<.05). the evaluation of quantitative analysis of the testes stereological procedures, QRT-PCR examination and immunohistochemical (IHC) staining revealed that melatonin reverses the BEP-induced impaired spermatogenesis (P<.05). Furthermore, melatonin rectifies BEP-induced disturbance on sperm count, motility, viability, and morphology. The testosterone level in the BEP-treated group was decreased significantly by comparison with the control group (P<.01). By contrast, co-administration of 10 and 20 mg/kg of melatonin could enhance the serum testosterone level significantly (P<.05). Moreover, melatonin enhanced the antioxidant status of the testis by elevating TAC and ameliorating MDA and NO levels. More notably, QRT-PCR examination indicated that melatonin therapy suppressed BEP-induced apoptosis by modulating apoptosis-associated genes such as Bcl-2, Bax, Caspase-3, p53 in the testis (P<.01). Besides, Co-administration of 10 and 20 mg/kg of melatonin with BEP regimen decreased significantly the population of p53 (54.21 ±6.18 % and 51.83±8.45, respectively) and TNF- positive cells (42.91±9.92 % and 33.57±2.97, respectively) by comparison to the BEP group.

Also, melatonin with low and high doses could enhance the expression of Bcl-2 protein in spermatogenic cells line (59.19±10.18 %, 63.08±5.23, respectively) compared to the BEP-treated group.
Limitations, reasons for caution: Owing to limited laboratory facilities we were not able to perform further studies to verify the mechanism of melatonin in the specific targets by using transfection technique and transgenic.
Wider implications of the findings: These findings can draw attention to the clinical application of melatonin and also suggest that melatonin may be an attractive agent for attenuating chemotherapy-associated male sub/infertility. This indolamine also may shorten the fertility recovery period in patients undergoing chemotherapy with the BEP regimen.
Trial registration number: N/A

P-062 Annexin-V MACS method could be a good choice for sperm selection with high PLCZ1 expression and high blastocyst rate in high DFI male factor

M. Saleh. Novin[1], Z. Zandie[1], M. Bakhtiari[1], R. Aflatoonian[1]

[1]iran university of medical science, medial, Tehran, Iran

Study question: What effect does Annexin-V MACS method have on sperm selection by pLCZ1 expression and blastocyst rate in male DNA fragmentation?
Summary answer: AnnexinV-MACS method could be a good choice for sperm selection with high pLCZ1 expression and high blastocyst rate in high DNA fragmentation male factor.
What is known already: Sperm selection based on morphology and motility in ART techniques, is not enough for choosing the best sperm especially in male factor patients. In Annexin-V magnetic activated cell sorting (MACS) technique, apoptotic sperm are separated from non-apoptotic one by negative selection. So, this method can improved quality of compaction rate in embryo. PLC is oocyte activating factors that it starts oscillations of calcium ca2+ in oocyte and it has a significant effect on fertilization and implantation.
Study design, size, duration: Semen samples from 30 male factor infertile couples with high DFI (DFI>30%) were selected and divided into two group (control and experimental) in each patient.
Participants/materials, setting, methods: Control was washed with DGC and experimental one was selected by MACS-DGC. Retrieved eggs in each patient, were divided in 2. Both group were injected by DGC and MACS respectively. Semen parameters and DFI (SCD test) were analyzed before and after processing. After ICSI, rate of fertilization, embryo development and blastocyst formation were evaluated. Real time PCR evaluate expression of PLC . Comparison between results of two groups was assessed by SPSS analysis.
Main results and the role of chance: Results showed that, sperm motility and morphology after MACS method (45%, 1.7%) was significantly higher than DGC method (40%, 1.1%) and before washing (35%, 0.9%). Percent of DFI in MACS group (36%) was significantly decreased compared to DGC (45%) and primitive group (55%). The number of oocytes were injected in DGC group was 93 and in MACS group was 111. Fertilization rate in both groups was almost the same (72.07% in MACS vs 73.11 in DGC). Rate of day 3 embryo with good grade in MACS group (72. 5%) was significantly higher than DGC (51.47%) (P<0.05). The blastocyst rate in MACS-DGC group (69.69%) was significantly increased compared to DGC group (48%). PLCζ gene expression in MACS-DGC was significantly higher than DGC group (p-value=0.046).
Limitations, reasons for caution: This experiment was performed invivo.
Wider implications of the findings: Sperm selection by MACS-DGC method can improve sperm motility, morphology and reduce sperm DFI. No significant difference was observed in fertilization rate, but percent of high-quality embryo on days 3 and 5 was significantly higher by this method,also it can be suggested as a good choice for patients with highDF.
Trial registration number: not applicable

P-063 The influence of lifestyle factors on sperm quality by motile sperm organelle morphology examination (MSOME)

A. Sebastianelli[1], F. Battaglia[2], L. Caponecchia[1], C. Fiori[1], I. Marcucci[2], P. Lazzari[2], P. Salacone[1]

[1]Pathophysiology of Reproduction and PMA - S.M Goretti Hospital - Latina- Italy, Department of Maternal Infant, Latina, Italy ;
[2]Unit of Obstetrics and Gynecology -S.M.Goretti Hospital- Latina- Italy., Department of Maternal Infant, Latina, Italy

Study question: This study aimed to investigate the influence of lifestyle factors on sperm quality according to Motile Sperm Organelle Morphology Examination (MSOME) criteria.
Summary answer: The introduction of MSOME permits the examination of subcellular defect like nuclear vacuoles at hight magnification (6000x) in real time on vital sperm.
What is known already: It is increased accepted that lifestyle factors have an impact on sperm quality. Recent evidence shows that the selection of spermatozoa based on the analysis of morphology under high magnification may have a positive impact on embryo development in cases with severe male factor infertility and/or previous implantation failures. Therefore, MSOME has been considered as representing an improvement in the evaluation of semen quality. Although numerous studies have shown the influences of nutrition, lifestyle, age on semen quality, only very few study, have considered the influence of these factors on the vacuolization rate in semen analysis (MSOME criteria)
Study design, size, duration: The objective of this prospective study was to compare the semen parameters of 87 male patients undergoing evaluation or treatment of infertility at Unit of Pathophysiology of Reproduction ad PMA-Santa Maria Goretti Hospital -Latina according to MSOME and WHO (World Health Organization) criteria between January and September 2019.Written informed consent was obtained from all partecipant of this study.
Participants/materials, setting, methods: The subjects were divided into three groups according to age: Group I ≤ 35 years, group II ,36-40 years; and Group III ≥ to 41 years .All patients filled a questionnaire answering questions regarding age, BMI, caffeine and alcohol consumptions, smoking and nutrition behavior. Were excluded from the study patients with chromosomal alteration. For multifactorial lifestyle influence patients were evaluated with a point base system with a cut-off >2 and cut off<3 for unhealthy style.
Main results and the role of chance: There was no difference between the groups with regard all semen parameters such as volume, concentration, number of leukocytes, morphology and vitality (%).The percentage of spermatozoa with LNV (Large Nuclear vacuoles) was significantly higher in the older group than in the younger (I and II) (39,14±13,74 vs 31,8±12 and 31,7 ±13,4 rispectively (p<0,05)which does not correspond to a worsening of semen morphology. Regression analysis demonstrated a correlation between the percentage of spermatozoa with LNV and male age (r = -0,1) (p<0,001). There was no correlation between lifestyle parameters ad enviroments factors . Comparing the semen parameters of healthy and unhealthy population we found no difference except a significantly higher number of spermatozoa with vacuoles in the unhealthy population (p <0.001)
Limitations, reasons for caution: Although the sample examined in this study is limited in size and other studies are needed to confirm this evidence, the data available to us support the routine use of MSOME for ICSI and as a criterion for semen analysis with potential clinical repercussions.
Wider implications of the findings: To date, there are few works in the literature that analyze the relationship between the morphology assessed with the MSOME and the age of the patients and the results are conflicting. To our knowledge many works agree with our results.
Trial registration number: not applicable

P-064 Application of an artificial intelligence model for morphologic prediction of fertilization-competent human spermatozoa

T.Y. Leung[1], C.L. Lee[1], P.C.N. Chiu[1]

[1]The University of Hong Kong, Department of Obstetrics and Gynecology, Hong Kong, Hong Kong

Study question: What is the role of artificial intelligence in selecting fertilization-competent human spermatozoa according to their morphological characteristics? Summary answer: The established AI model in this study can be potentially used to select semen samples with superior fertilization potential in clinical settings.
What is known already: Defective spermatozoa-zona pellucida (ZP) interaction causes subfertility and is a major cause of low IVF fertilization rates. While ICSI benefits patients with defective spermatozoa-ZP binding, a standard method

to identify such patients prior to conventional IVF is lacking. The application of artificial intelligence to sperm morphology analysis has become a topic of growing interest owing to the fact that the conventional assessment is highly subjective and time-consuming. Deep-learning, a core element of artificial intelligence (AI), incorporates the convolutional neural networks (CNN) to process all the data composing a digital image through successive layers to identify the underlying pattern.
Study design, size, duration: The fertilization-competent spermatozoa were isolated according to their binding ability to the ZP. The ZP-bound and -unbound spermatozoa were collected for functional assays and to establish an AI model for morphologic prediction of sperm fertilization potential. Human spermatozoa (n=289) were isolated from normozoospermic samples. Human oocytes (n=562) were collected from an assisted reproduction program in Hong Kong. Sample collection has been ongoing and will continue until the end of this study in November 2021.
Participants/materials, setting, methods: Sperm-ZP binding assay was employed to collect ZP-bound and -unbound spermatozoa. The fertilization potential and genetic quality of the collected spermatozoa were evaluated by our established protocols. Diff-Quik- stained images of ZP-bound and -unbound spermatozoa were collected respectively for the establishment of an AI model. A novel algorithm for sperm image transformation and segmentation was developed to pre-process the images. CNN architecture was then applied on these pre-processed images for feature extraction and model training.
Main results and the role of chance: Our result showed that the sperm-ZP binding assay had no detrimental effect on sperm viability when compared with the raw samples and unbound-sperm subpopulations. ZP-bound spermatozoa were found with statistically higher acrosome reaction rates, improved DNA integrity, better morphology, lower protamine deficiency and higher methylation level when compared with the unbound spermatozoa. A deep-learning model was trained and validated by analyzing a total of 1,334 and 885 of ZP-bound/ unbound spermatozoa to evaluate the predictive power of sperm morphology for ZP binding ability. Our newly trained AI-based model showed initial success in classifying the ZP-bound/ unbound spermatozoa according to their morphological characteristics with high accuracy of 85% and low computational complexity.
Limitations, reasons for caution: This sperm selection method requires micromanipulation and relatively long processing time to recover ZP-bound spermatozoa. In addition to limited availability, the use of human materials may result in interassay variations affecting the reproducibility of this method among laboratories.
Wider implications of the findings: In light of current findings, AI-based sperm selection method may provide high predictive values of sperm fertilization potential for clinical purposes. This method is particularly applicable to patients who had poor fertilization outcomes after conventional IVF treatments or those with high degree of defective sperm-ZP binding ability.
Trial registration number: not applicable

P-065 Advanced paternal age does affect egg donation program outcomes?

M. Miguens[1], A.M. Quinteir. Retamar[2], D. Acosta[1], G. Veg. Balbuena[1], E. Carreras[1], A. Coscia[1], S. Papier[1]

[1]cegyr, fertility, buenos aires, Argentina ;
[2]cegyr, egg donation, buenos aires, Argentina

Study question: Does increasing paternal age has a negative impact in fertilization (FR), blastulation (BR), clinical pregnancy (CPR) and miscarriage (MR) rates in an egg donation program?
Summary answer: The increase paternal age in an egg donation program has not a negative impact in fertilization rate, blastulation rate, clinical pregnancy rates and miscarriage rates.
What is known already: It is well documented that semen quality is affected with increasing paternal age but there is no evidence-based definition of what is advanced paternal age. There is controversial information about if the increasing paternal age affects in vitro fertilization results, and when this negative impact could begin.
Study design, size, duration: This was a single center retrospective cohort study, involving 485 first single embryo transfer of an egg donation program, from January 2017 to December 2019.
Participants/materials, setting, methods: All first embryo transfer of egg donation cycles performed at CEGyR, Buenos Aires, Argentina were included. Elevated sperm DNA fragmentation (TUNEL >20), sperm bank, and testicular biopsy cycles were excluded. Patients were divided according to male partner age: (1) <41, (2) 41-44, (3) 45-50 and (4) >50 years old. Group (1) was considered the control group. Statistical analyses were performed for FR and BR with ANOVA and CPR and MR with chi-squared tests.
Main results and the role of chance: The number of patients in group (1) was 200, in (2) 130, in (3) 117 and in (4) 38. Male average age was 36,8 in group (1), 42,2 in (2) 47,1 in (3) and 54,2 in group (4). The FR in group (1) was 72,60%, in group (2) was 73%, in (3) was 75% and 73% in (4). ANOVA results for FR: F=0,65 (p: 0,58). The BR, defined as the relation between the total number of blastocysts over the number of fertilized oocytes in a cycle, was in group (1) 46,35%, in group (2) was 45%, in group (3) 46%, and in group (4) 42%. ANOVA results for BR F=0,36 (p:0,78). The CPR in group (1) was 42,19%. Comparing with the other groups: group (2) was 37,09% (chi-square statistic=0,64 p:0,43); group (3) 34,58% (2,32 p:0,13); and group (4) was 32,43% (1,48 p:0,22). The MR in group (1) was 12,49%. Comparing with the other groups: group (2) was 18,55% (chi-square statistic=2,31 p:0,12); group (3) 14,94% (1,01 p:0,32); and group (4) was 15,85% (0,91 p:0,33). For all results analyzed there were not a statistically difference between groups.
Limitations, reasons for caution: The main limitation of this study was its retrospective design based on data from a single center which may be subject of bias.
Wider implications of the findings: Further large prospective studies are required to make meaningful comparisons. Our findings give no support for a general recommendation.
Trial registration number: not applicable

P-066 Does microfluidic sperm sorting (MSS) affect embryo euploidy rates in couples with high sperm DNA fragmentation (SDF)?

M. Keskin[1], E.G. Pabuçcu[1], A. Tufan[1], D.Ö. Demirkıran[2], R. Pabuçcu[1]

[1]Ufuk university, Obstetrics and gynecology, Ankara, Turkey ;
[2]Centrum IVF clinic, Embriyology, Ankara, Turkey

Study question: Does MSS (microfluid chip-sorted spermatozoa selection) provide improvement on embryo quality and euploidy rates in couples with high SDF (sperm DNA fragmentation) and previous failed in vitro fertilization/ intracystoplasmic sperm injection (IVF/ICSI) cycles?
Summary answer: Use of MSS technique provides higher number of top quality blastocysts compared to density gradient centrifugation (DGC), however euploidy and live birth rates weren't improved.
What is known already: Previously it has been reported that sperm DNA damage leads to poor embryo development and there is a significant association between SDF and high embryo aneuploidy rates. Recently this fact raised attention to sperm selection techniques such as MSS to enhance embryo quality, miscarriage rates and embryonic euploidy rates.
Study design, size, duration: This was a retrospective electronic medical record (EMR) analysis of a tertiary assisted reproduction center between 2016 and 2020. All EMR were reviewed to select eligible cases as; couples undergoing a new IVF/ICSI cycle with PGT-A (preimplantation genetic testing for aneuploidies). In total, data from 243 patients were obtained for the analysis that accounts for 688 embryos.
Participants/materials, setting, methods: Patients had at least 2 previous failed IVF cycles and males had at least 20% SDF. In their new cycles, MSS was offered, preceding ICSI and PGT-A. Couples who accepted the technique were assigned to MSS group (92 cycles with 310 embryos) and the rest were managed with DGC and assigned as controls (151 cycles with 378 embryos). Azoospermia cases and women with age>43, uterine abnormalities, trombophilia were excluded. Biopsies were performed at blastocyst stage.
Main results and the role of chance: Two groups were comparable in terms of demographic data including women and men age, SDF, sperm parameters and cycle characteristics. There was no difference between groups in terms of fertilization rates (MSS 85% vs DGC 79% p=0.9), euploidy rates (MSS 53.2% vs DGC 50.7% p=0.3), mean no of euploid embryo per patient (MSS 1.09 vs DGC 0.95 p=0.3), positive pregnancy test (MSS 50% vs DGC 38.4% p=0.06), clinical miscarriage (MSS 7.6% vs DGC 6.6% p=0.7) and live birth rates (LBR)(MSS 42.4% vs DGC 31.7% p=0.09). Total no of blastocysts and top quality blastocysts

were significantly higher in MSS group than in DGC (3.9 vs 2.5 p<0.01 and 1.6 vs 0.8 p<0.001 respectively).
Limitations, reasons for caution: Retrospective design, small sample size, lack of proper randomization and power analysis are the main limitations.
Wider implications of the findings: Offering PGT-A to couples with unexplained repeated IVF failures and high SDF seems feasible. MSS for such cases improves embryonic division process as improved blastulation rates were documented. However, euploidy rates were not improved in MSS group revealing that other factors influence comprehensive chromosomal status of an embryo.
Trial registration number: not applicable

P-067 Utility of evaluating semen samples from adolescents with Klinefelter Syndrome for cryopreservation: A multi-institution evaluation

K. Chu[1], N. Punjani[2], D. Nassau[1], J. Kashanian[2], R. Ramasamy[1]

[1]University of Miami Miller School of Medicine, Department of Urology, Miami- FL, U.S.A. ;
[2]Weill Cornell Medicine, Department of Urology, New York- NY, U.S.A.

Study question: Should physicians continue to evaluate semen analysis from adolescents with Klinefelter Syndrome for fertility preservation?
Summary answer: In the largest multi-institutional retrospective database to-date for this patient population, no sperm was found in ejaculate for cryopreservation amongst adolescent males with Klinefelter Syndrome.
What is known already: Klinefelter Syndrome is the most common genetic condition leading to male infertility and non-obstructive azoospermia. The condition causes decreased testicular growth, leading to lower production of testosterone and resulting deficiencies in secondary sexual characteristics. While testosterone therapy may be required for hypogonadism, there may be impact on future fertility potential. Current practice is to have KS adolescent patients provide semen analyses to identify potential sperm for cryopreservation. While the incidence is low, current epidemiological studies have been with limited sample size.
Study design, size, duration: This was a retrospective study of all adolescent Klinefelter Syndrome patients seen at the male infertility clinics of two large academic institutions between the years of 2015 to 2020. Adolescence was defined as the ages of 10 – 19 years old, as per the World Health Organization.
Participants/materials, setting, methods: A total of 116 patients were identified for the retrospective study database. Demographic information including weight, height, comorbidities, concurrent medications were collected. Hormone levels such as FSH, LH, testosterone, and estrogen were included for 77 patients. Additionally, semen analyses were available for 49 patients. Main results and the role of chance: Of the 49 patients with semen analyses, only 3 patients had rare sperm in ejaculate not sufficient for cryopreservation while the remaining had azoospermia. The average ejaculate volume of the provided semen samples was 0.9 cc. The average serum total testosterone level of adolescent Klinefelter Syndrome patients was 236 ng/dL. As expected, gonadotropin levels were found to be elevated (mean: 18.47 IU/L for FSH and 9.12 IU/L for LH).
Limitations, reasons for caution: The main limitation for this study was the sample size.
Wider implications of the findings: The findings from the largest retrospective study of this patient population imply a need to revisit counseling regarding the need for semen analyses in adolescent Klinefelter Syndrome patients.
Trial registration number: not applicable

P-068 CatSper4 cation channel expression is low in male infertility and is affected by cryopreservation

N. Kilic[1], T. İrez[2], N. Dayioğlu[3]

[1]kilic.nergis, clinical embriyology, Tekirdag, Turkey ;
[2]Health Science Institute, clinical embriyology, Tekirdag, Turkey ;
[3]Heatlh Sciences İnstitute, Biostatistics, Istanbul, Turkey

Study question: Is CatSper4 expression in sperm related to functional parameters and does cryopreservation affect CatSper4 expression?
Summary answer: In this study, it was aimed to investigate whether CatSper4 has a relationship with sperm parameters and is CatSper 4 affected by cryopreservation.
What is known already: CatSper membrane channels, known as cation channels, are thought to play an important role in the insufficiency of sperm physiology, acrosome reaction, and chemotaxis movement. There is no study on cation channel distribution in an infertile male patient. In addition, studies conducted in recent years have shown that cryopreservation techniques have negative effects on sperm DNA, but there is no analysis in the literature regarding the effects of cryopreservation on CatSper4 ion channel proteins.
Study design, size, duration: Samples of the patients who applied to the Andrology laboratory in the Medical Park Hospital IVF unit between March 1 and June 1 in 2020 were included in the study. Also, patients with no family history of no genetic anomalies , no varicocele and azoospermia were included.The study were divided into 4 groups in accordance with the male infertility guideline of the European Association of Urology as normozoospermic (control group), the asthenoteratozoospermia, teratozoospermia, and oligoastenotheratozoospermia.
Participants/materials, setting, methods: In this prospective study, semen analysis, DNA fragmentation, and CatSper 4 by IHC of control group patients with normospermia (n=40) and oligospermia(n=50), asthenospermia(n=40), and teratozoospermia(n=38) patients were compared and differences resulting from cryopreservation were evaluated by Wilcoxon signed Ranks Test.
Main results and the role of chance: It was observed that CatSper4 protein positivity was localized in the middle part of the sperm and it was statistically higher in the normozoospermic patient group compared to the other groups (p=0,01). When the positivity values of CatSper4 protein before and after freezing were compared in the groups, it was seen that the values decreased (p=0,001,p=0,01). Sperm DNA fragmentation was found to be lowest in normospermia and statistically significantly higher in other groups. Cryopreservation application increased DNA fragmentation in all groups (p<0,001 , p<0,01).
Limitations, reasons for caution: Unfortunately, embryo screening in patients with low CatSper4 expression is not available in the present study. Soon we plan to screen a broader clinical pregnancy series and present the IVF results associated with CatSper4.
Wider implications of the findings: Our study indicated that, CatSper4 expression is quite high in normospermia when compared with the other groups, particularly oligoasthenoteratozoospermia and asthenoteratozoospermia. There are almost no studies on this subject in the literature, and we think that it should be studied in larger patient groups and in unexplained infertile cases.
Trial registration number: not applicable

P-069 microfluidic sperm sorting vs density gradient to yield sperm with reduced DFI for patients undergoing IVF-ICSI

D.P. Makwana[1], S. Makwana[1], T. Sen[1]

[1]Vasundhara Hospital Limited- Jodhpur- Rajasthan- India, Department of A.R.T., Jodhpur, India

Study question: To compare the effect of sperm preparation methods on the DFI of semen sample for patients undergoing ICSI.
Summary answer: On comparing the results, microfluidic sperm sorting yielded sperms with significantly less DFI as compared to density gradient method of sperm preparation.
What is known already: The DNA integrity of the sperm plays an important role to ensure formation of good quality embryos with increased potential of fertilization, growth and ultimately implantation.. Centrifugation has shown to add stress to the sperm and leading to DNA damage, therefore there is a need to develop techniques of sperm preparation which help in retrieving as many sperms with intact DNA from the unprocessed sample as possible. Microfludic is fluid dynamic based technique of sperm preparation. in this study, we evaluated if microfluidic sperm sorter can recover motile sperm with better DNA integrity compared to density gradient preparation method.
Study design, size, duration: Prospective randomized study conducted in 80 patients undergoing IVF-ICSI with normal semen parameters (based WHO criteria 2010). DFI was done using Sperm Chromatin Dispersion (SCD) test in split semen samples prepared by microfluidic sperm sorter and density gradient method. Sperm morphology and motility were also recorded and evaluated based on the WHO 2010 criteria.
Participants/materials, setting, methods: Semen parameters of the sample were assessed by microscopic examination. DFI of each unprocessed sample was carried out using SCD test, following that the sample was split and sperm preparation was done using microfluidic sperm sorter and density gradient. the recovered sperm were tested for DFI and the results were compared.

Main results and the role of chance: Mean DFI in unprocessed semen samples was 23%. the analysis of split semen samples post preparation showed that the DFI was significantly reduced with the use of microfluidic sperm sorter (mean DFI 0.6%) as compared to density gradient (mean DFI 9%).
Limitations, reasons for caution: A major limitation of the microfluidic sperm sorter is the use sperm concentration and motility of the semen sample. In oligospermic and asthenospermic samples, density gradient is the preferred method of preparation. Lack of data showing improvement in clinical outcomes with reduced DFI is also a major limitation.
Wider implications of the findings: Microfluidics has shown to significantly reduce the DFI of the semen sample, it requires no extra equipment and cost and is relatively easy to pick up. Density gradient method of sperm preparation continues to be the preferred method due to its versatility and recovery of good quality sperm.
Trial registration number: not applicable

P-070 Evaluation of SARS-CoV-2 in human semen and effect on total sperm number: A prospective observational study

J. Best[1], **M. Kuchakulla**[1], **K. Khodamoradi**[1], **T. Lima**[1], **F. Frech**[1], **J. Achua**[1], **O. Rosete**[1], **B. Mora**[1], **H. Arora**[1], **E. Ibrahim**[1], **R. Ramasamy**[1]

[1]*University of MIami, Urology, MIAMI, U.S.A.*

Study question: Is the SARS-CoV-2 virus present in human semen and what is the impact on semen parameters following an infection?
Summary answer: SARS-CoV-2 infection, though not detected in semen of recovered men, can affect TSN in ejaculate in the acute setting.
What is known already: Early epidemiological data has suggested that the primary mode of transmission is through respiratory droplets, but the presence of SARS-CoV-2 has been identified in other bodily fluids such as feces, urine, and semen.
Study design, size, duration: We prospectively recruited thirty men diagnosed with acute SARS-CoV-2 infection using real-time reverse transcriptase-polymerase chain reaction (RT-PCR) of pharyngeal swab specimens. Thirty semen samples from recovered men were obtained 11-64 days after testing positive for SAR-CoV-2 infection. The median duration between positive SAR-CoV-2 test and semen collection was 37 days (IQR=23).
Participants/materials, setting, methods: Semen samples were collected from each individual using mailed kits. Follow-up semen samples were done with mailed kits or in-person in office setting. Semen analysis and PCR was performed after samples were received.
Main results and the role of chance: The median total sperm number (TSN) in ejaculate was 12.5 million (IQR=53.1). When compared with age-matched SARS-CoV-2(-) men, TSN was lower among SARS-CoV-2(+) men (p=0.0024). Five men completed a follow-up sperm analysis (median 3 months) and had a median TSN of 18 million (IQR=21.6). No RNA was detected by means of RT-PCR in the semen in 16 samples tested.
Limitations, reasons for caution: First, most of the semen samples came from non-severe men of whom were in the recovery stage and lacked symptoms. Additionally, our sample size was relatively small and overnight mail-in semen analysis kits were used during the acute phase of infection to minimize contact with positive subjects.
Wider implications of the findings: Our findings suggest extremely low risk of viral transmission during sexual contact and assisted reproductive techniques, although further data need to be obtained. The impact on TSC in recovered men from SARS-CoV-2 infection is concerning, nevertheless long-term follow-up of these men is critical to determine the nadir of TSC.
Trial registration number: 20200401

P-071 Human Papillomavirus Infection and impact on men fertility

N. Madzunkov[1], **K. Madjunkova**[1]

[1]*Gyn Department, Ob/Gyn, Skopje, Macedonia*

Study question: Is there any correlation between men infertility and HPV infection and its impairment on sperm quality?
Summary answer: There is a significantly higher prevalence of high-risk HPV in infertile men than fertile men. HPV infection does not impair sperm quality.
What is known already: Many factors may cause the infertility in males and females. Human papillomavirus are the most frequently sexually transmitted DNA viruses and etiological agents of cervical cancers. There is association between HPV infection in females and adverse pregnancy outcomes such as spontaneous abortion and spontaneous preterm delivery. Previous studies have reported the detection of HPV DNA in semen and in different sites of the male reproductive tract, such as glans penis and scrotum. Recent reports suggested that HPV may affect sperm parameters and lead to male infertility. The impact of HPV infection upon male fertility abnormality has received far less attention.
Study design, size, duration: In this study case control study we examined 38 fertile and 36 men from infertle couples.
Participants/materials, setting, methods: we examined the swabs of the entire penile surface and semen samples for HPV detection and genotyping from 38 fertile men and 36 from men from infertile couples.HPV were detected with PCR method. Sperm was also examined for its motility, sperm quantity and morphology .
Main results and the role of chance: Among 36 confirmed infertile males, only 8 (22.22 %) cases were tested positive for HPV of semen samples and 2 among fertile men were HPV-positive (5.26%) of semen samples. Among infertile males 14 (38.88%) had HPV positive penile swabs, and only 1 (2,63%) had positive HPV swab among fertile men. The most prevalent HPV types in the male external genitalia were HPV-16. The most prevalent HPV types in semen were HPV-53. This data revealed a significant association between high-risk HPV and male infertility (P=0.03). Sperm quality (morphology and motility) did not differ significantly between men with seminal HPV infection and uninfected men.
Limitations, reasons for caution: There were some limitations in the study such as differences in age. sample sizes and the number of HPV genotypes detected.
Wider implications of the findings: We need larger studies and more further investigations to confirm the impact of HPV on male infertility.
Trial registration number: 2

P-072 Pregnancy rate in male factor infertility with oligoastheneteratozoospermia - evaluation of Letrozole and Coenzyme Q10 supplementation on sperm parameter

D. Se. Sharma[1]

[1]*CLINIC, O&G, ALIPURDUAR, India*

Study question: Male infertility due to idiopathic oligoasthenoteratozoospermia- Does combining Letrozole as antiestrogenic with Coenzyme Q10 as antioxidant give better pregnancy rate ?
Summary answer: Combination of Co enzyme Q10 with Letrozole can significantly improve semen parameters and outcome of clinical pregnancy rate in idiopathic oligoasthenoteratozoospermic patients.
What is known already: Elevated levels of reactive oxygen species(ROS) are a major cause of idiopathic male factor infertility which results in sperm membrane lipid peroxidation, DNA damage and apoptosis leading to decrease sperm viability and motility. Antioxidant like Coenzyme Q10 have been used empiricallyin the treatment of oligoasthenozoospermia based on its ability to reverse oxidative stress and sperm dysfunction. Aromatase inhibitor like Letrozolehave been used in idiopathic male infertility by reducing estrogenic effect on spermatogenesis and reducing feedback inhibition of hypothalamopituatarygonadal axis. Thus a therapeutic strategy would need to use supplements to increase sperm energy metabilism, minimise free radical damage.
Study design, size, duration:
Study design: prospective comperative clinical study
Primary purpose: treatmenr
Size: 60 infertile male attending OPD of SHRISTI HEALTHCARE diagnosed as idiopathic oligoasthenoteratozoospermia
Duration: from March2018 to February 2020
Primary outcome: improvement in sperm count, motility and morphology after treatment
Secondary outcome: clinical pregnancy rate and live birth rate.
Participants/materials, setting, methods: Exclusion criteria: Smoker, drug and alcohol abuse, medical treatment with gonadotropin and steroids, varicocele.60 patients were randomisedinto 3 groups. Gr A(N=20) received Letrozole 2.5mg/day + Co enzyme Q10 300mg/day for 3 months, Gr B(N=20) received Letrozole 2.5mg/day for 3 months, and Gr C(N=20) received Coenzyme Q10

300mg/day for 3 months. History taking, general examination, semen analysis, sr.FSH,LH, Testesteron, E2 and scrotal duplex were done for all patients.
Main results and the role of chance: After treatment, Gr A as compared to Gr B and C showed significant imprivement in all 3 parameters of semen eg sperm count(3.15±3.38 - 20.9±2.11, p<0.001), sperm motility(5.25±3.25 - 42.85±3.30, p<0.001), sperm morphology(2.26±7.81 - 25.89±7.05, p<0.001). Improvement in sperm count and morphology was seen in Gr B(Letrozole gr) but not in sperm motility whereas Gr C (Co enzyme Q10 gr)showed significant improvement in sperm motility and morphology but not in sperm count. 10 pregnancies occured during follow up period of 1 yr. Clinical pregnancy rate was 30%in Gr A(6/20), 5% in Gr B(1/20), AND 15% in Gr C(3/20). Live birth rate was 83% in Gr A(5/6), 33.3% inGr C(1/3) whereas sponteneous abortion occured in Gr B pregnancy.
Limitations, reasons for caution: Limitation of my study was the small sample sizewhich could have some bias in outcome. I did not evaluate DNA fragmentation and level of ROS. Latest evidences report that evaluating ROS can be a diagnostic tool in predictingthe best responder to supplementation.
Wider implications of the findings: Majority of studies had investigated the effect of antioxidant and aromatase inhibitor on semen parameter but few concluded their effect on live birth rate. Assisted reproductive techniques are expensive and not universally available, so any pharmacological agent with satisfactory effectiveness should be considered as 1st line treatment of oligoasthenoteratozoospermia.
Trial registration number: NOT APPLICABLE

P-073 High-intensity interval training modulates the effects of hypertension on inflammatory mediators in testis in adult spontaneously hypertensive rats

I. Giometti[1], A. Veras[2], F. Pacagnelli[1], L. Schaffer[1], M. Oliveira[1], R. Nespolo[1], A. Santos[1], F. Souza[1], C. Castilho[1], A.P. Favareto[1], L. Mendes[1], G. Teixeira[2]

[1]Universidade do Oeste Paulista - UNOESTE, Programa de Pós-graduação em Ciência Animal, Presidente Prudente - SP, Brazil ;
[2]Universidade Estadual Paulista - UNESP, Departamento de Educação Física, Presidente Prudente - SP, Brazil

Study question: Is the high-intensity interval training (HIIT) able to prevent the increase of the inflammatory proteins in the testis of spontaneously hypertensive rats (SHR)?
Summary answer: HIIT for 8 weeks inhibits the increase of the tumor necrosis factor alpha (TNFα) and the interleukin 6 (IL6) in the testis of SHR.
What is known already: Hypertension increases the inflammatory cytokines of the cardiovascular system, causing damage in the microcirculation and in the testes. Hypertension is a cause of low fertility in men and exercises are indicated to decrease blood pressure and improve overall health. HIIT is characterized by short periods of exercise, with an intensity equal to or greater than the anaerobic threshold, separated by recovery periods. HIIT can be indicated for cardiac patients, as this type of training improves the cardiac autonomic nervous system and lipemic control in both hypertensive and normotensive individuals.
Study design, size, duration: Male Wistar-Kyoto rats without hypertension and SHRs were divided into 3 groups (n=4): WKY (Wistar-Kyoto); SHR; and SHR-HIIT (SHRs that performed HIIT). The HIIT was realized in treadmill for 5 days/week for 8 weeks. HIIT started with 5 times of 4 minutes of 100% of the maximum exhaust speed, with active rest intervals of 3 minutes at 60%. There was an increase of once every week until reaching 7 times each session.
Participants/materials, setting, methods: Samples from testicles were used for immunostainig IL6 and TNFα. After the blocking, the sections were subjected to reaction of specific antibodies IL6 (1:50, E-4, sc-28343) and TNFα (1:50, 52B83, sc-257) at 4°C overnight, and with secondary antibodies m-IgGK (1:200, IgG-HRP, sc-516) at room temperature for 2 hours. Diaminobenzidine (1:50) was used against Harris stained with Hematoxylin and evaluated in the photomicroscope. Data were analyzed by One-Way ANOVA followed by Tukey post test (P<0.05).
Main results and the role of chance: The immunostainig of IL6 was higher in SHR (10.23 ± 0.47) than in SHR-HIIT (8.69 ± .44) group (P=0,0237). From the same perspective, immunoexpression of TNFα was higher in SHR (10.10 ± 0.42) than WKY (8.24 ± 0.24) and SHR-HIIT (7.82 ± 0.39) groups (P=0.0018).
Limitations, reasons for caution: As a limitation of the study, we have no measurement of fertility parameters to affirm that the HIIT improve the fertility because of the reduction of inflammatory mediators.
Wider implications of the findings: The hypertension drugs have a negative effect on fertility. HIIT can be suggested as a treatment for hypertension as an alternative to medication, since HIIT can inhibit the increase of the inflammatory mediators in testis and its consequences to the reproduction. Financial support by São Paulo Research foundation, FAPESP (2018/22682-0).
Trial registration number: 2018/22682-0

P-074 Chromatin Maturity Index (CMI) in unfixed and live spermatozoa and Aniline Blue (AB) stained as an additional evaluation parameter in idiopathic male infertility

T. Notari[1], M. Piscopo[2], L. Bosco[3], S. Pecoraro[4], N. Serra[5], D. Ricciardi[6], G. Capra[7], L. Montano[8]

Study question: To investigate whether idiopathic male infertility may be due to the presence of histones in motile spermatozoa using a modified AB staining protocol.
Summary answer: No correlation between CMI in live motile spermatozoa, DNA Fragmentation Index (DFI) and other conventional seminal parameters were found in male infertile patients.
What is known already: The AB stain discriminates between lysine-rich histones and arginine/cysteine-rich protamines. Transition from histones to protamines during spermatogenesis remodels chromatin packaging and abnormalities in the substitution of those proteins maybe interfere with seminal parameters and affect male infertility. The correlation between CMI and seminal parameters is known, but little is knowledge about live and motile spermatozoa associated to CMI because literature report only spermatozoa fixation before staining. Sperm chromatin carries half of the genomic material to offspring. Spermatozoa nuclear status is crucial for balanced transmission to future generations, and histones modifications are directly involved in epigenetic mutations.
Study design, size, duration: Retrospective observational study of 77 men underwent to standard semen analysis, including the evaluation of CMI and DFI, enrolled from January to December 2020. Mean age of the men was 36.63±8.26 years old, sperm concentration 46.69±37.23 mill/mL, linear progressive motility 39.35±15.31%, normal morphology 6.42±3.40%, DFI 25.91±10.29%. 200 spermatozoa for evaluation of CMI and 300 for DFI were analyzed respectively.
Participants/materials, setting, methods: Semen samples of 77 patients were collected and analyzed according to 5th edition of WHO guidelines (2010) for examination of human semen. For the evaluation of CMI we performed a new modified protocol for AB stain directly in live spermatozoa. Dilution 1:1 fresh semen and Aniline Blue colorant were mixed and placed on a slide and examined in bright field microscopy x1000 magnification. DFI was evaluated using Sperm Chromatin Dispersion (SCD) test.
Main results and the role of chance: Of all spermatozoa analyzed, 82.58±29.98% were white, 17.17±17.21% were pale blue, and 28.53±21.09% were dark blue. By our modified protocol, directly in live spermatozoa, we correlated AB staining with motility and , surprisingly, all motile spermatozoa

observed were not stained (white), while pale or dark blue spermatozoa resulted always immotile. For this reason, we have considered pale blue spermatozoa as AB positive, in disagreement with some authors. So, maybe, we should reconsider pale blue stained spermatozoa as abnormal. We also observed AB negative spermatozoa with morphological head, neck and tail defects, underlining the independence of these two parameters: nuclear status and morphology. We have observed no statistically significant differences between conventional semen parameters, DFI and CMI, so nuclear analysis seems to be independent parameters. The statistical analysis was performed by Matlab statistical toolbox version 2008 (MathWorks, Natick, MA, USA) for Windows at 32 bit; finally all tests with *p-value (p)* < 0.05 were considered significant. Attention should be paid to the evaluation of CMI not only in astenozoospermic patients, where a lower CMI is known, but also in normozoospermic infertile patients.

Limitations, reasons for caution: This is a preliminary observational study on a small number of normozoospermic or mild asthenozoospermic patients. The study should be considered as a pilot study. Future studies with higher number of samples are necessary in order to confirm the results obtained.

Wider implications of the findings: This is the first study that reports AB staining on unfixed live spermatozoa with a modified protocol. Our study underlines the necessity of classify pale blue spermatozoa as AB positive. Further investigations are necessary. This is a starting point for future analysis to be carried out under the project EcoFoodFertility.

Trial registration number: not applicable

P-075 HAART exacerbates anti-Koch-induced reproductive toxicity via suppression of androgen and down-regulation of cGMP signaling

M. Hamed[1], R. Akhigbe[2]

[1]*Buntai Medical and Diagnostic Laboratories- Osogbo- Nigeria, Laboratory Services, Osogbo, Nigeria ;*
[2]*Ladoke Akintola University of Technology- Ogbomoso- Oyo State-, Physiology, Ogbomoso, Nigeria*

Study question: Will highly active antiretroviral drugs (HAART) and antikochs impair reproductive function when used singly and concurrently?

Summary answer: HAART exacerbates antikoch-induced reproductive toxicity by stimulating testicular and penile oxido-inflammatory response. This was associated with suppression of androgen and down-regulation of cGMP signaling.

What is known already: Although the advent of HAART and antikochs has significantly improved the clinical status, life expectancy and quality of life of patients with HIV/tuberculosis, these drugs are with shortcomings. Studies have reported that HAART induces testicular toxicity and impairs sperm quality. Similarly, antikochs has been shown to trigger oxidative testicular and sperm damage. Available data have implicated HAART and antikoch in the pathogenesis of male infertility via oxidative stress-mediated mechanism. However, no study has reported the impact of the concurrent administration of both HAART and antikochs as seen in patients with TB/HIV co-infection on testicular function, sexual behaviour and fertility outcome.

Study design, size, duration: This is a prospective experimental study using animal model. Forty sexually mature inbred male Wistar rats of comparable age were used for the study. The study lasted 8 weeks.

Participants/materials, setting, methods: Animals were acclimatized for two weeks after which they were randomly allotted into four groups (n=10). The control rats 0.5mL of distilled water as vehicle, anti-Koch-treated rats received a cocktail of anti-tuberculosis drugs (Rifampicin, Isoniazid, Pyrazinamide, and Ethambutol), HAART-treated animals received a cock-tail of antiretroviral drugs (Efavirenz, Lamivudine, and Tenofovir), while the HAART+antikochs-treated rats received treatment as HAART-treated as well as antikoch-treated. The doses of drugs used were the Human Equivalent doses for rats.

Main results and the role of chance: HAART exaggerated antikoch-induced increase in testicular lactate dehydrogenase activity, concentrations of lactate and uric acid, and reduced testicular sorbitol dehydrogenase activity. Furthermore, HAART worsens antikoch-induced decline in the activities of testicular and penile superoxide dismutase, catalase, glutathione peroxidase, and glutathione-S-transferase, as well as glutathione concentration, but increased malondialdehyde levels in testicular and penile tissues, as well as penile and testicular DNA fragmentation. Similarly, HAART aggravates antikoch-driven reduction in penile cGMP, circulatory and testicular testosterone, serum prolactin, LH and FSH, impaired sperm quality, sexual behaviour, and fertility outcome.

Limitations, reasons for caution: This is a prospective study using animal model; hence findings should be extrapolated to human with care. Human studies are thus recommended.

Wider implications of the findings: This study demonstrates for the first time the impact of HAART and antikoch, when used singly or in combination, on sexual behaviour, sperm quality and penile and testicular integrity. The findings add to the available literature by providing the molecular mechanism through which HAART and/or antikoch possibly impair reproductive function.

Trial registration number: N/A

P-076 Probability of sperm retrieval in azoospermic patients and mRNA expression profile of JMJD1A, TNP2 and PRM2 : in a subset of karachi population

S. Amjad[1], S. Mushtaq[2], R. Rehman[3], N. Zahid[4], A. Munir[5], P.Q.R. Siddiqui[1]

[1]*Ziauddin University, Physiology, Karachi, Pakistan ;*
[2]*Ziauddin University, Biochemistry, Karachi, Pakistan ;*
[3]*Aga Khan University, Department of Biological & Biomedical Sciences-, Karachi-, Pakistan ;*
[4]*Aga Khan University, Surgery, Karachi, Pakistan ;*
[5]*Australian Concept Infertility Medical Center, Andrology-, Karachi, Pakistan*

Study question: To access successfulness of sperm retrieval by evaluating the mRNA expression profile of JMJD1A, TNP1, TNP2, PRM1 and PRM2 in patients undergoing surgical sperm retrieval procedure.

Summary answer: Probability of sperm retrieval in azoospermia is decreased when mRNA expression profile of JMJD1A TNP2 and PRM2 in testicular tissue is decreased.

What is known already: Studies have been done on expression of JMJD1A in non-obstructive azoospermic patients in other part of the world with smaller sample size but this is the first study in Pakistan with larger number of patients. Study design, size, duration: Crossectional study, 100 azoospermic patients coming for purpose of sperm retrieval by TESE or micro-TESE in Australian Concept Infertility Medical Center, Karachi,from March, 2018 to December, 2019

Participants/materials, setting, methods: All recruited azoospermic patients were evaluated by history, physical examination, and hormonal assessment. RNA was extracted by pureLink RNA Micro kit and mRNA expression of the JMJD1A, TNP1, TNP2, PRM1 and PRM2 genes was determined using innu-SCRIPT One Step RT_qPCR SyGreen kit. For quantitative variables independent t test and for categorical variables chi-square/ Fisher Exact test was used. Unadjusted and adjusted prevalence ratio were reported by using cox regression algorithm. Main results and the role of chance: The patients were categorized into (i) Group-I: Patients with successful sperm retrieval n= 42, (ii) Group-II: Patients with unsuccessful sperm retrieval n= 58. The patients were categorized into (i) Group-I: Patients with successful sperm retrieval n= 42, (ii) Group-II: Patients with unsuccessful sperm retrieval n= 58. Azoospermic men in the successful sperm retrieval group had significantly decreased expression of JMJD1A (P<0.001), TNP2(P<0.001), and PRM2 (P 0.008). In addition to this regarding hormonal parameters: FSH (P 0.004), LH(P<0.001), TSH(P<.011) were significantly different in azoospermic men with successful and unsuccessful sperm retrieval. In multivariate analysis, after adjusting for the other covariates, a significant association was found between JMJD1A, TNP2, PRM2 and successful sperm retrieval (p-value <0.05).

Limitations, reasons for caution: It is unicentric and outcomes for fertilization were not assessed. Azoospermic patients from multi-centeres were difficult because of lack of facility of sperm retrieval procedures at these centers and it was difficult to follow the fertrilization outcome.

Wider implications of the findings: This will be useful for making the decision in azoospermic men to proceed for ICSI or not. In addition to this, the repetition of unnecessary surgical procedures can be avoided, as the azoospermic men often undergo number of rounds of ICSI, with the hope of becoming biological father.

Trial registration number: non-clinical trials

P-077 Performance of the postwash total motile sperm count as a predictor of pregnancy at the time of intrauterine insemination

A. Kasturiraj[1], S. Reddy[1], M. Daniel[1], S. Namboor. Srinivasan[1], N. Raja[1], E. Reddy[1]

[1]Sri Ramachandra institute of higher education and research, reproductive medicine and surgery, Chennai, India

Study question: Is the performance of the postwash total motile sperm count a predictor of pregnancy at the time of intrauterine insemination?
Summary answer: The number of motile spermatozoa inseminated (NMSI) in IUI can be used to define clear range of pre /postwash sperm parameters.
What is known already: There is no consensus about the optimal number of motile spermatozoa inseminated (NMSI) required for a reasonable chance of pregnancy after IUI. A meta-analysis of 16 studies assessing NMSI and IUI outcomes, concluded that at cut-off levels between 0.8 and 5 million, defined as the ability to predict failure to become pregnant. The purpose of this study is to determine the range of NMSI as a predictor of success in IUI.
Study design, size, duration: This prospective study includes 60 patients who underwent semen analysis at an academic infertility centre (SRIHER) during the month of December 2020 and January 2021.
Participants/materials, setting, methods: A total of 60 infertile couples who underwent IUI at our academic centre were enrolled in our study. A detailed history and infertility work up was done before proceeding for IUI, as per the department protocol. The semen was prepared by discontinuous 2 layered density gradient method. The results were analyzed by patient factors including age, BMI, semen parameters, NMSI. The NMSI were divided into 4 groups: A (<1), B (1-4), C (5-9), D (>10).
Main results and the role of chance: The mean age of the infertile couples who underwent IUI was (28.2 ± 3.8) in females and (31.8 ± 3.8) in males respectively. The sperm parameters such as concentration (21.8 ± 14.8), motility (53.15 ± 13.22), morphology (2.43 ± 1.33) respectively. When the NMSI was group C (5-9 x 10^6) the pregnancy rate was 38.5 % whereas the pregnancy rate was 37.5% in group D (>10 x 10^6). In the other sub groups such as group A(<1 x 10^6) and group C (1-4 x 10^6) the pregnancy rate was 14.2% and 12.5 % respectively.
Limitations, reasons for caution: Infertile men with Azoospermia, Men with Retrograde ejaculation, Testicular samples, Epididymal samples, Infected samples. All of the above samples were avoided. It cannot be used for counselling during the initial infertility workup, but only during/after the IUI procedure.
Wider implications of the findings: The results suggest that NMSI can be a predictor of success in IUI in patients who are < 30 years of age & ≥35 years, NMSI does not appear to be a useful. The effect of NMSI on pregnancy rate needs to evaluated on a larger scale .
Trial registration number: not applicable

P-078 Prognostic factors for male fertility recovery after microsurgical varicocelectomy

A. Shomarufov[1], V. Bozhedomov[1], F. Akilov[2], S. Mukhtarov[3], S. Giyasov[2], S. Abbosov[1], A. Kamalov[4]

[1]Faculty of Fundamental Medicine of Lomonosov Moscow State University, Urology and Andrology, Moscow, Russia C.I.S. ;
[2]Tashkent Medical Academy, Urology, Tashkent, Uzbekistan ;
[3]Republican Specialized Scientific-Practical Medical Center of Urology, Director, Tashkent, Uzbekistan ;
[4]Medical Research and Educational Center Lomonosov University Clinic, Director, Moscow, Russia C.I.S.

Study question: What clinical and laboratory parameters are reliable predictors of spontaneous pregnancy (SP) after microsurgical varicocelectomy in men from infertile couples?
Summary answer: Predictors of SP after microsurgical varicocele repair are the male age, baseline total sperm motility, and postoperative increase level of TPMSC.
What is known already: Varicocele is the most common correctable cause of male subfertility. According to the recent meta-analyses and studies, microsurgical varicocelectomy is the "golden standard" method for varicocele repair. However, it is still unclear why at least one-third of subfertile men do not experience improvement in semen parameters and more than half of them do not report fertility recovery after varicocelectomy. There is no consensus so far on the factors affecting the efficacy of varicocele repair in men from infertile couples.
Study design, size, duration: This retrospective study comprises 93 men from infertile couples, with palpable varicocele, astheno-/oligozoospermia, and who underwent microsurgical subinguinal or inguinal varicocelectomy from September 2015 to May 2019.
Participants/materials, setting, methods: The changes in semen analysis were assessed (in 3-6 months after surgery) according to WHO-2010, spontaneous pregnancy (SP) rates after surgery also were considered. A stepwise discriminant analysis was performed to identify predictors of SP after varicocelectomy. An increase in TPMSC by at least 12.5 million was defined as a significant effect (SE) of varicocelectomy (reference values for the total number and progressive sperm motility according to WHO-2010: 39 million x 0.32 (32%) progressively motile).
Main results and the role of chance: Almost all semen parameters (except for semen volume) changed positively after surgery. Sperm concentration increased from 62 mln/ml (17-107) to 85 mln/ml (39-134) p<0.001, TPMSC increased by an average of 27 mln (2.8 times; p<0.001). SE was observed in 52% of cases (n = 48), a slight favorable effect in 21% (n = 20), and no effect in 27% (n = 25). 29 patients (31%) reported SP within a year after varicocele repair. 83% of patients (24 from 29) who reported pregnancy after varicocelectomy showed SE. According to the stepwise discriminant analysis, significant predictors of pregnancy after varicocelectomy were the male age (coefficient of the canonical discriminant function = -0.16), the initial total sperm motility (0.02), and the postoperative increase of TPMSC (0.01). Wilks' lambda was 0.67 and canonical correlation 0.57. The predictive ability of the prognostic model (discriminant function) with these three predictors was 84%, specificity 87%, and sensitivity 76%. The function real predictive accuracy for SP was 70% (21 correct out of 30 predicted).
Limitations, reasons for caution: The small sample size and the inability to obtain accurate data on the health condition of female partners were the main limitations of the study. Nevertheless, the findings are statistically significant, which suggests that they can be extrapolated to the general sample of subfertile men with clinical varicocele.
Wider implications of the findings: The proposed algorithm (function) for the prediction of SP showed satisfied predictive accuracy, and after its external validation can be recommended in 3-6 months after varicocele repair to decide whether it is advisable to expect an SP within a year or to include an infertile couple in ART programs immediately.
Trial registration number: Not applicable

P-079 A spontaneous LH peak before triggering for intrauterine insemination with donor sperm (IUI-D) is associated to lower live birth rates

A. Blazquez[1], D. Garcia[2], P. Calvillo[1], R. Vassena[2], A. Rodriguez[3]

[1]Clinica Eugin, Medical Department, Barcelona, Spain ;
[2]Clinica Eugin, Scientific Department, Barcelona, Spain ;
[3]Clinica Eugin, Corporate Medical Department, Barcelona, Spain

Study question: Are live birth rates after IUI with donor sperm (IUI-D) and controlled ovarian stimulation comparable between women with a spontaneous LH peak vs those without?
Summary answer: Biochemical, clinical, ongoing pregnancy rates and live birth rates were higher among women without an LH peak.
What is known already: It is common clinical practice to trigger ovulation in IUI cycles once specific criteria are met; if a natural LH surge appears, adjusting the IUI timing may become necessary. Pregnancy rates seem to be slightly better when IUI is scheduled in relation to the presence or absence of an LH peak in non-stimulated cycles. In IUI with stimulated cycles, however, there is no consensus in the medical literature regarding the best moment to program the IUI, due to different inclusion criteria, different IUI timing and definition of LH peak among studies.
Study design, size, duration: Retrospective cohort study of 9,657 IUI-D cycles performed between 2012 and 2019 in one fertility center. IUI-D without LH peak (n=6,679) versus IUI-D with LH peak (n=2,978) were compared. Differences in pregnancy outcomes between study groups were evaluated using a Pearson's Chi2 test. A p<0.05 was considered statistically significant.
Participants/materials, setting, methods: The definition used to define an LH peak is > 10UI/L in the last follicular control. In cases without an LH peak,

when at least one dominant follicle reached 17mm, ovulation was triggered with human chorionic gonadotropin in the following 24h, and IUI-D was performed 38h after triggering. In cases with an LH peak, ovulation was triggered the 6h following the detection, and IUI-D was also performed 38h later.
Main results and the role of chance: The women BMI and age were comparable between groups, with a mean±SD of 35.2±4.8 years old, and 24.3±4.7 for BMI. Other characteristics such as number of previous inseminations, type of stimulation drug, initial dose, total dose, stimulation length and number of follicles > 16mm in the last follicular control were also comparable. As expected, the LH level at the last follicular control was different between groups, with a mean of 5.1UI/L in the no-LH peak and 21.4IU/L in the LH peak group. The group without an LH peak had higher biochemical, clinical, ongoing and live birth rates compared to the group with LH peak: 27.7% vs. 20.7%; 19.5% vs. 15.5%; 17.7% vs. 13.7%; 16.3% vs. 12.6%, respectively (p-value<0.001).
Limitations, reasons for caution: The main limitation of the study is its retrospective nature. Also, a definition of LH peak based in absolute values was used; a definition based in relative values may lead to different results.
Wider implications of the findings: A definition of LH peak based on absolute numbers is imprecise, and the cut-off of 10UI/L does not allow a good scheduling for IUI. A LH peak based on relative values could improve the detection of patients starting ovulation and the accuracy in programming IUI.
Trial registration number: not applicable

P-080 Higher sperm DNA fragmentation reduces the proportion of good quality embryos at day 5 on IVF and ICSI cycles from unselected males

I. Hervá. Herrero[1], A. Pacheco[2], R. Rivera-Egea[3], M. Gi. Julia[1], A. Navarro-Gomezlechon[1], N. Garrido[1]

[1]IVI Foundation- Health Research Institute La Fe- Av. Fernando Abril Martorell- nº106- Torre A- Planta 1ª- 46026- Valencia- Spain, Andrology and Male infertility research group, Valencia, Spain ;
[2]IVIRMA Madrid- Av. del Talgo 68-70- 28023- Madrid- Spain., Andrology Laboratory and Sperm Bank, Madrid, Spain ;
[3]IVIRMA Valencia- Plaza de la Policia Local 3- 46015- Valencia- Spain., Andrology Laboratory and Sperm Bank, Valencia, Spain

Study question: Does sperm DNA fragmentation (SDF) reduce the ratio of good-quality embryos in day 3 (D3) and day 5 (D5) of embryonic development?
Summary answer: High sperm DNA fragmentation (SDF >15%) is associated with poor embryo quality at blastocyst-stage per cycle in unselected patients undergoing IVF and ICSI.
What is known already: It has been shown that the proportion of spermatozoa with DNA fragmentation is higher in infertile men than in semen from fertile men. However, the controversy regarding the impact that sperm genome damage can have on IVF or ICSI treatments is evident in the published literature. The effects of SDF would become evident after activation of the embryonic genome at 8-cell stage, compromising not only the quality of the embryos obtained, but also the reproductive outcomes, as reduced implantation rates, higher miscarriages rates and thus, a decreased chance of pregnancy.
Study design, size, duration: This multicentric observational retrospective study included 1339 couples who underwent 2759 IVF-ICSI cycles using autologous oocytes from January 2000 to March 2019. All men have an SDF test in their ejaculated spermatozoa by TUNEL assay (Terminal deoxynucleotidyl transferase dUTP nick end labeling). The subjects were divided into two groups according to their sperm DNA integrity: low (≤15%) (n=2287 cycles) or high (>15%) (n=472) SDF.
Participants/materials, setting, methods: Embryo quality was assessed complying morphological standards at cleavage-stage on D3 and at blastocyst-stage on D5 (inner cell mass (ICM) and trophectoderm (TE) grade (A, B, C or D)) in according to ASEBIR's embryo selection criteria, being embryos of good quality those categorized as A+B. The outcomes were calculated in relation to the total number of zygotes obtained. The results were compared by Student t test; p value <0.05 was considered significant.
Main results and the role of chance: The SDF average of the low group was 5.8% (95% CI 5.6-5.9) whereas in high group was 23.7% (95% CI 23.0-24.4). The female age was equal, 37.1 years (95%CI 37.0-37.2) and 37.1 years (95% CI 36.8-37.4) respectively. A total of 9796 embryos were evaluated. The optimal cleavage-stage embryo rate per cycle was 25.0% (95% CI 21.7-28.3) (8.0 average cells number, 1.5 embryo fragmentation average, symmetry 1, mononucleated cells) versus 26.7% (95 %CI 19.1-34.2) (7.9 average cells number, 1.8 embryo fragmentation average, symmetry 1, mononucleated cells) when comparing between groups (p<0.001). Blastocyst-stage arrival rate (number of embryos at D5) per cycle was 55.8% (95% CI 54.3-57.2) in ≤15% SDF group (embryo quality score was ICM A:12.1%, B:69.5%, C:8.8%, D:4.5%; TE A: 7.5%, B:42.2%, C:42.2%, D:8.1%) and 55.9% (95% CI 52.8-59.1) in the >15% SDF group (ICM A:12.0%, B:68.7%, C:10.6%, D: 5.2%; TE A:9.1%, B:44.8%, C:37.8%, D:8.3%) (p<0.001). The good quality blastocyst rate per cycle was significantly higher in the group with SDF ≤15%, 27.7% (95%CI 26.5-29.0) versus SDF >15% (27.4% (95%CI 24.6-30.2)). Of the total number of blastocysts, the proportion of A+B blastocyst was 60.5% (95% CI 58.3-62.7) and 64.2% (95% CI 59.2-69.2) (p<0.001), respectively.
Limitations, reasons for caution: The retrospective and multicenter nature of this study leads to uncontrolled biases derived from the clinical practice. Although the results were not adjusted for female's age, it was not statistically different between groups. Embryo morphology evaluation was performed by senior embryologists, it still remains a subjective evaluation, though.
Wider implications of the findings: In this study, a higher amount of data was compiled so that a large number of embryos were analyzed. The DNA integrity of the sperm may be an important consideration when poor quality embryos were obtained in the previous cycle when deciding on the next clinical strategy to apply.
Trial registration number: NA

P-081 Microfluidic sorting does not improve clinical outcomes compared to magnetic activated cell sorting (MACS) in Assisted Reproduction

C. González-Ravina[1], A. Pachec. Castro[2], M. Cru. Palomino[3], A. Requen. Miranda[4]

[1]IVI-RMA Global/IVI-RMA Sevilla, IVI-RMA Global Headquarters/Andrology Laboratory-, Sevilla, Spain ;
[2]IVI-RMA Madrid, Andrology laboratory, Madrid, Spain ;
[3]IVI-RMA Global, IVI-RMA Global Headquarters, Madrid, Spain ;
[4]IVI-RMA Global/IVI-RMA Madrid, IVI-RMA Global Headquarters/IVI-RMA Madrid, Madrid, Spain

Study question: Does microfluidic sorting improve clinical outcomes over magnetic activated cell sorting (MACS) in ovum donation cycles?
Summary answer: Performing microfluidic sorting does not seem to improve clinical outcomes compared to MACS in ovum donation cycles.
What is known already: Novel sperm selection techniques, such as magnetic activated cell sorting (MACS), have been described as useful procedures to increase reproductive outcomes when male factor is present. Because of centrifugation steps associated to swim-up or density-gradient can induce sperm DNA fragmentation, microfluidic sperm sorters are being used to isolate motile human spermatozoa based on fluid dynamics and avoiding sample manipulation. This new technology has been shown to reduce the level of sperm DNA damage, especially double strand breaks, but an improvement of clinical outcome by using this technique remain unclear.
Study design, size, duration: Prospective and observational study to evaluate the efficacy of a sperm sorting technique based on microfluidic technology versus a technique based on the removal of apoptotic spermatozoa by MACS. The study was performed between May 2019 to January 2021 in IVI Madrid and IVI Sevilla. All men attending for an ovum donation cycle during the aforementioned study period were included. The exclusion criteria were sperm concentration <5 mill/mL and <15% of progressive motile spermatozoa.
Participants/materials, setting, methods: Seminal samples from couples participating in the study were divided into two aliquots; each of them was processed according to one of the study methods. Subsequently, each of the processed sperm samples was used to microinject half of the oocytes obtained during oocyte retrieval. In all case, a single-embryo transfer was performed. Variables were expressed as mean values and standard deviations. Statistical analysis was performed by ANOVA and Chi-squared where applicable; significance established under 0.05.
Main results and the role of chance: We included 48 couples in the study; of these, n=31 transferred an embryo derived from a MACS processed sperm

sample, while n=17 received an embryo from the microfluidic one. Groups were homogeneous in terms of number of transferred embryos and frozen embryos, usable blastocyst rate and fertilization rate; results were as follows for MACS and microfluidic processing respectively: number of transferred embryos (1.0±0.0 vs. 1.0±0.0, p=0.978); number of frozen embryos (1.6±0.5 vs. 1.4±0.7 p=0.168); usable blastocyst rate (40.7% vs. 43.1%, p=0.384); and fertilization rate (80.4% vs. 75.3%, p=0.075). However, according clinical outcomes, we observed significant differences in implantation rate (74.2% vs. 58.8%, p<0.001) and in clinical pregnancy rate (74.2% vs. 58.8%, p<0.001); finally, the miscarriage rate was similar between the two groups of study (6.4% vs. 5.8%, p=0.876).
Limitations, reasons for caution: This study has not considered the indication in male factor couples due to a high degree of double-strand DNA fragmentation. Therefore, more specific studies are required to determine in which patients, microfluidics sorter selection would significantly improve clinical outcomes.
Wider implications of the findings: In an unselected population**,** magnetic activated cell sorting significantly improves clinical outcomes compared to a microfluidic technique, so this latter method should not be recommended without a male factor indication associated with sperm DNA damage. The proposed microfluidic technology does not seem to offer a flow-free approach to select spermatozoa.
Trial registration number: NCT04061486

P-082 Effect of semen hyper viscosity (SHV) on blastocyst formation rate and implantation rate

A. Suthar[1], N. Sharma[2], V. Mishra[3], R. Aggarwal[3], H. Sheth[2], K. Patel[2]

[1]IKDRC -IVF UNIT, IKDRC HOSPITAL, ahmedabad, India ;
[2]IKDRC Hospital - IVF Unit, Embryology, ahmedabad, India ;
[3]IKDRC Hospital - IVF Unit, obs and gynae, ahmedabad, India

Study question: Does semen hyper viscosity effects blastocyst formation rate
Summary answer: Hyper viscosity of semen sample later results in poor blastocyst formation rate and lower implantation rate.
What is known already: Normal range of semen hyper viscosity ranges between 12-29%.Highly viscous semen samples impairs the physical and chemical characteristics of seminal fluid and due to which seminal oxidative damage increases which further increases the ROS and reduces the sperm motility there are some factors that can affect the seminal viscosity out of which one is Male accessory gland infection, Hypo function of prostate seminal vesicles and varicoceles. SHV create hindrance in semen preparation.
Study design, size, duration: Retrospective study was conducted from June 2019 to Oct 2020 at IVF unit IKDRC hospital.
Participants/materials, setting, methods: 142 patients were enrolled from June 2019 to Oct 2020 in IVF unit IKDRC hospital and divided into two groups. Group A (n=83) patients with hyper semen viscosity and Group B (n =69) patients with normal semen viscosity, inclusion and exclusion criteria's were same for both the groups, only patient with normozoospermia were taken. Semen analysis was done by using WHO manual 2010.
Main results and the role of chance: In group A with hyper semen viscosity fertilization rate was (49.2% vs. 70% p= <0.001) vs in group B with normal semen viscosity which is significantly higher in group B, Blastocyst formation rate (18.4% vs 35% p=<0.01) and implantation rate (9.4% vs 20% p=<0.005) both are significantly higher in group B . Which implies fertilization rate , blastocyst formation rate and implantation rate is significantly lower in patients with semen hyper viscosity.
Limitations, reasons for caution: Larger randomized control studies are needed to strengthen these results.
Wider implications of the findings: Our study demonstrates that patients having higher semen viscosity have poor blastocyst formation rate and implantation rate due to oxidative stress.
Trial registration number: not applicable

P-083 Analysis of chromosomal segregation and interchromosomal effects (ICE) in sperms from balanced translocation carriers using fluorescence in situ hybridization (FISH) after sperm selector separation

A. Machowetz[1], O. Shebl[2], M. Maurer[1], T. Ebner[2], H.C. Duba

[1]Kepler Universitätsklinikum Linz, MedCampus IV Zentrum Medizinische Genetik Linz, Linz, Austria ;
[2]Kepler Universitätsklinikum Linz, Kinderwunsch Zentrum Linz, Linz, Austria

Study question: Influence of sperm selector separation of sperms on their translocation load, segregation pattern, motility and occurrence of interchromosomal effects
Summary answer: Sperm selector separation led to reduction of the translocation load, shift in segregation pattern and lower rates of interchromosomal effects within sperm samples
What is known already: Balanced translocations in men are known to be one of the main causes of reproductive failure. The segregation pattern in sperms is determined by the distribution of the chromosomes during meiosis. Interchromosomal effects can also influence the distribution of chromosomes that are not involved in the translocation. The sperm selector used consists of two concentric chambers, which are overlaid by a U-ring and a cover glass. Motile sperms migrate from the native ejaculate in the medium filled inner chamber by using a capillary bridge created by the U-ring. This avoids potential harmful centrifugation and allows accumulation of motile sperms.
Study design, size, duration: Twenty-one carriers of balanced translocations participated in the study. In addition, 15 patients were involved as control. All participants signed an informed consent (F-8-15). Samples of three patients did not meet the internal quality criteria and had to be excluded from analysis. The study started in 2015 and is still ongoing.
Participants/materials, setting, methods: Liquefied native ejaculate was processed with a sperm selector. Native ejaculate, non-migrated sperms from the outer chamber and migrated sperms from the inner chamber were transferred onto glass slides, fixed and underwent a decondensation treatment. For segregation analysis FISH translocation specific FISH probe mixes were used and tested on patient's blood. Interchromosomal effects were analysed with FISH probes for the chromosomes X, Y, 18 and 13, 21. Evaluation was done manually using fluorescence microscopy.
Main results and the role of chance: Segregation analysis was done for more than 25,000 sperms from men carrying a balanced translocation (18 patients with reciprocal and 3 patients with Robertsonian translocation). Separation via sperm selector led to a reduction in translocation load (native to separated approach 49,1±11,5% to 34,8±9,4% (P=<0,01), the rate depending on the specific translocation. There was also a shift in the segregation pattern, which seemed to be influenced by the specific translocation and the resulting steric alignment of the corresponding quadrivalent / trivalent. Additionally, more than 90,000 sperms from patients with balanced translocations were analysed for interchromosomal effects. Separation led to reduced maldistribution rate (native to separated approach 7,1±3,5% to 5±3,1%, P=<0,01) whereas the steric alignment of the corresponding quadrivalent / trivalent seems to influence the interchromosomal effect as well. For control, sperms from control patients were analysed regarding the chromosomes X, Y, 18 and 13, 21. In about 90,000 control sperms separation led to reduced maldistribution rate (native to separated approach 5,4±1,5% to 3,8±1,1%; P=<0,01).
Limitations, reasons for caution: The number of accumulated strand-break-free sperms depended on the motility and sperm count of the native ejaculate. Examinations are not reproducible, as each sample delivery is influenced by external circumstances
Wider implications of the findings: Sperm selector separation can be used before ART to reduce the translocation load and rate of maldistribution in sperms from carriers of balanced translocations. This could have a considerable impact on PGT results after trophectoderm biops.
Trial registration number: not applicable

P-084 Microfluidic Sperm Sorting (MFSS) technique versus Physiological Intracytoplasmic Sperm Injection (PICSI) technique in high DNA fragmentation index sperm samples

G. Kant[1], K.D. Nayar[1], H. Sharma[1], S. Gupta[1], S. Mishra[1], K. Nayar[1]

[1]Akanksha IVF Centre, Reproductive Medicine, New Delhi, India

Study question: To evaluate the effectiveness of using Microfluidic Sperm Sorting (MFSS) technique and Physiological Intracytoplasmic Sperm Injection (PICSI) technique in patient with high DNA fragmentation index (DFI) sperm samples.

Summary answer: Sperm selected by microfluidic sorting are associated with significant increase in day 3 grade A embryo development rate, clinical pregnancy rate over PICSI.

What is known already: DNA damage is unrecognisable in living sperm prior to insemination and an increased sperm DNA fragmentation index has been associated with lower fertilization rates, impaired embryo development and reduced pregnancy rates. Standard semen processing techniques are associated with centrifugation, which may induce reactive oxygen species and DNA damage. In strategies to minimize sperm DNA fragmentation, Physiological ICSI can relatively reduce sperm DNA fragmentation by 67.9% (Parmegiani et al., 2010) while new technique Microfluidic sperm sorter technique also demonstrate sperm selection with significantly reduced DNA damage.

Study design, size, duration: A prospective randomised study was conducted from 1st August 2019 to 31st December 2020. Two hundred patients were randomised by computer generated list and divided into 2 groups. Group A (n=100) , in which sperm were processed by microfluidic sperm sorter (MFSS) while in group B (n=100), sperm were selected by Physiological Intracytoplasmic Sperm Injection (PICSI) technique and morphologically normal motile sperm were injected by Intracytoplasmic sperm injection (ICSI) technique in all mature oocytes.

Participants/materials, setting, methods: The study period included all normozoospermic patients with high DNA fragmentation index (>25%) while oligospermic, asthenozoospermic samples, patients with poor ovarian reserve and advanced age were excluded from the study. All A grade embryos were vitrified and transferred in frozen embryo replacement cycle. Both groups were compared on the basis of fertilisation rate, day 3 grade A embryo development rate , clinical pregnancy rate and miscarriage rate.

Main results and the role of chance: Cycle characteristics (female age, length of stimulation, gonadotrophin dose, number of oocytes and number of transferred embryos) were similar in both groups. Between the 2 groups, There was a significant increase observed in day 3 grade A embryo development rate (60% vs. 42%, p-0.016) and clinical pregnancy rate (62% vs. 46%, p-0.049), while no statistical significant difference observed in fertilisation rate (82% vs. 78%, p-0.80) and miscarriage rate (12% vs. 11%, p- 1). Limitations, reasons for caution: Larger randomised control studies are needed to strengthen these results.

Wider implications of the findings: We have demonstrated that sperm sorted by microfluidic helps in selection of sperm with better DNA integrity over Physiological ICSI. Using it in routine practice can help in reducing the negative effect of reactive oxygen species and thus improve pregnancy rate and live birth rate.

Trial registration number: MCDH/2019/31

P-085 Sperm retrieval after microdissection testicular sperm extraction (micro-TESE) and pregnancy outcomes of intracytoplasmic sperm injection (ICSI) in men with Klinefelter syndrome

V.H. Dinh[1], H. Nguye. T.H[1], H. Nguye. B.[1], T. Nguye. A.[1], C. Trin. K.[1], Q. H. D.[1], D. Nguye. M.[2], H. L. T.[3], H. Pha. M.[4]

[1]Andrology and Fertility Hospital of Hanoi, Andrology department, Hanoi, Vietnam ;
[2]Andrology and Fertility Hospital of Hanoi, IVF Laboratory, Hanoi, Vietnam ;
[3]Andrology and Fertility Hospital of Hanoi, ART department, Hanoi, Vietnam ;
[4]Andrology and Fertility Hospital of Hanoi, Research Department, Hanoi, Vietnam

Study question: What are the sperm retrieval rate and ICSI outcomes in azoospermic men with Klinefelter syndrome (KS)?

Summary answer: In men with KS, a sperm retrieval rate of 51.3% after the first attempt micro-TESE, and 4 live births after ICSI were observed. What is known already: Klinefelter syndrome (KS) is encountered in 10% of men with azoospermia. Micro-TESE is presently used to treat infertility for KS patients with nonobstructive azoospermia. The retrieved sperms can be used for ICSI. Study design, size, duration: From June 2019 to July 2020, 39 azoospermic patients with KS were examined for the presence of testicular spermatozoa. Participants/materials, setting, methods: Participants were recruited from couples attending the Andrology and Fertility Hospital of Hanoi Vietnam, for infertility treatment. Micro-TESE was performed to extract testicular tissue. After retrieval, ICSI was used with fresh sperm. Main results and the role of chance: The sperm retrieval rate of first attempt micro-TESE in KS men was 51.3% (20/39). Logistic regression analysis showed patient age did not affect the sperm retrieval rate of micro-TESE (OR 0.99, 95% CI 0.88 - 1.11). Similarly, no association was observed between serum FSH, LH, testosterone level, and testicular volume with the success of sperm retrieval. The fertilization rate after ISCI in patients with retrieved sperm was 60% (12/20). Clinical pregnancy and ongoing pregnancy rates were 50% (10/20) and 40% (8/20). There were 4 live births. No sufficient data were available to test the effect of clinical or biological parameters on ICSI outcomes.

Limitations, reasons for caution: Our data rely on a cohort of KS patients attending a single fertility clinic. The sample size did not allow regression analysis for any ICSI outcome.

Wider implications of the findings: Micro-TESE is helpful in retrieving sperm in azoospermia KS patients with sperm retrieval rate reaching 50%. ICSI following micro-TESE can lead to an ongoing pregnancy rate of 40% with some result in live births. The outcome of micro-TESE is independent of any clinical or biochemical parameters tested.

Trial registration number: Not applicable

P-086 High level of sperm DNA breaks in infertile men with varicocele: its association with sperm cells death, seminal oxidative stress, and spermatic parameters

O. Ammar[1], M. Mehdi[1]

[1]Laboratory of Histology Embryology and Cytogenetic LR 18 ES 40- Faculty of Medicine University of Monastir- Street Avicenne- Monastir 5019- Tunisia., Department of Histology Embryology and Cytogenetic, Monastir, Tunisia

Study question: Our objectives were to determine the extent of nuclear sperm injury in varicocele patients with and without altered spermatic parameters and to investigate its relationship with apoptosis and oxidative stress.

Summary answer: Oxidative stress (OS) in the varicocele patients may play a role in the etiology of nuclear sperm DNA damage associated with apoptosis.

What is known already: Varicocele is associated with high level of DNA Breaks.

Study design, size, duration: Ejaculated sperm samples from 51 patients diagnosed with varicocele and 29 fertile men were examined. According to the guidelines, the patient's sperm samples were classified into varicocele with normal semen parameters (n = 11) and varicocele with abnormal semen parameters (n = 40).

Participants/materials, setting, methods: Sperm DNA breaks was assessed using terminal deoxynucleotidyl transferase dUTP nick end labeling assay. The proportion of both viable and dead spermatozoa with externalized phosphatidylserine was detected by the bivariate annexin V cy3/6-CFDA staining method. Seminal malondialdehyde (MDA) amounts and antioxidant enzymes activities of superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx) were measured spectrophotometrically.

Main results and the role of chance: Sperm DNA Breaks, viable spermatozoa with externalized PS, and MDA levels were significantly higher in studied subgroups of patients with varicocele, either with normal or with abnormal semen parameters than controls. The seminal antioxidant enzymes activities were significantly reduced in both subgroups of patients with varicocele compared to the controls. The percentage of spermatozoa with fragmented DNA was positively correlated to the MDA level as well as the proportion of viable spermatozoa with externalized PS. However, the decreased seminal antioxidant status was negatively correlated with the increased proportion of sperm DNA fragmentation and apoptotic spermatozoa.

Limitations, reasons for caution: We suggest further comparative studies connecting the varicocele patients with and without altered spermatic parameters representing high level of DNA fragmentation with more apoptotic and oxidative stress markers.

Wider implications of the findings: This study reveals that impaired seminal antioxidant profile and increased seminal level of lipid peroxidation may be involved in the pathophysiological mechanisms of cell death-mediated DNA breaks in patients with varicocele.

Trial registration number: Not applicable

P-087 Paternal age clinical effect on cumulative live birth rates (CLBR) per inseminated oocyte, embryo transfer and embryo transferred in autologous IVF-ICSI cycles of infertile males

A. NAVARR. GOMEZ-LECHON[1], R. Rivera-Egea[2], I. Hervas[1], M. Gi. Julia[1], N. Garrido[1]

[1]IVI Foundation- Health Research Institute La Fe- Av. Fernando Abril Martorell-nº106- Torre A- Planta 1º- 46026- Valencia- Spain., Andrology, Valencia, Spain ; [2]IVIRMA Valencia- Plaza de la Policia Local 3- 46015- Valencia- Spain., Andrology Laboratory and Sperm Bank, Valencia, Spain

Study question: Is reproductive success measured as CLBR per inseminated oocyte, per embryo transfer and per embryo transferred affected by paternal age in autologous IVF-ICSI cycles?
Summary answer: The number of embryo transfers and embryos transferred until live birth, but not the number of inseminated oocytes, were significantly different among the age groups.
What is known already: In recent years, there has been an increase of the average paternal age at which the first child is conceived. Therefore, there is a growing interest on the study of the impact of male age on the reproductive outcomes in assisted reproduction cycles (ART). Several studies have shown negative effects of advanced paternal age on semen parameters, embryo aneuploidy, miscarriage, male infertility,.... However, other studies have found no association between them. Hence, the impact of paternal age on reproductive outcomes still remains uncertain, leading to a need of more research on this topic, which this study tries to address.
Study design, size, duration: This retrospective observational multicentric cohort study has included autologous IVF-ICSI treatments (n=6295) performed to couples with etiology of male infertility (non-normozoospermic) in Spain IVIRMA clinics between January 2008 and March 2020 using patients' own sperm sample. Paternal age ranged from 20 to 75 years. The study population was categorized in 5 groups following the criterion of homogenizing the number of observations between groups: 20-34 (A), 34-37 (B), 37-39 (C), 39-42 (D) and 42-75 (E) years.
Participants/materials, setting, methods: Considering that male age could be a factor affecting reproductive outcomes, we evaluated men with different age that performed an autologous IVF-ICSI treatment with their own semen, etiology of male infertility and known age. Data was exported in order to obtain the clinical database and Kaplan-Meier was used for data analysis. P<0.05 was considered statistically significant. We measured reproductive success by CLBR per embryo transfer, per embryo transferred and per inseminated oocytes until live birth.
Main results and the role of chance: This study considered approximately 2976 patients and 4385 embryo transfers. The CLBR per inseminated oocyte showed no significant difference between the study groups: A (6.43%, 48.24%, 81.38%), B (5.74%, 52.14%, 82.87%), C (6.14%, 49.83%, 83.69%), D (5.89%, 53.60%, 81.16%) and E (6.61%, 47, 52%, 77.85%) for 4, 13 and 21/22 inseminated oocytes, respectively. In terms of CLBR per embryo transfer, the results obtained for each of the age groups were: A (31.81%, 71.89%, 87.63%), B (28.89%, 67.87%, 82.63%), C (27.10%, 68.87%, 88.17%), D (23.45%, 64.63%, 100.00%) and E (22.88%, 55.48%, 63.31%) for 1, 4 and 7 embryo transfers, respectively. There were statistically significant differences in the CLBR per embryo transfer between the studied age groups (p<0.0001). CLBR per embryo transferred for each age group was as follows: A (10.85%, 60.53%, 80.88%), B (9.34%, 59.75%, 78.23%), C (11.89%, 57.63%, 74.97%), D (10.25%, 52.71%, 77.76%) and E (11.71%, 51.50%, 71.51%) for 1, 4 and 7 embryos transferred, respectively. As in the case before, there were statistically significant differences in the CLBR per embryo transferred between the age groups (p<0.05). The findings presented highlight that the increase in paternal age could be affecting the reproductive outcomes in IVF-ICSI cycles using autologous oocytes.
Limitations, reasons for caution: The retrospective nature of this study leads to biases derived from the clinical practice and to the presence of missing data (limiting sample size). Moreover, this study considered autologous cycles, therefore the results were not adjusted for female factors.
Wider implications of the findings: Our study showed that reproductive outcomes measured by CLBR per embryo transfer and embryo transferred until live birth were significantly different between the paternal age groups in autologous IVF-ICSI cycles of infertile males. Hence, paternal age could be affecting reproductive outcomes and it should be considered for improving infertility counselling.
Trial registration number: NA

P-088 Sexual functioning is impaired in cancer survivors after cancer therapy

E. Reiser[1], K. Vomstein[1], S. Hofer-Tollinger[1], G. Pinggera[2], E. Strassgschwandtner[1], A.L. Zippl[1], B. Böttcher[1], B. Toth[1]

[1]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine-, Innsbruck, Austria ; [2]Medical University Innsbruck, Department of Urology, Innsbruck, Austria

Study question: Is impaired sexual functioning correlated to sperm quality in cancer survivors?
Summary answer: Erectile dysfunction affects 25.0% of cancer survivors, independent of sperm quality. 22.9% of patients show symptoms consistent with a reduced testosterone level.
What is known already: Gonadotoxic treatment in male cancer patients can end up in reversible or permanent impaired spermatogenesis, testosterone insufficiency, and sexual dysfunction.
Study design, size, duration: In this prospective single-center study, sexual functioning was assessed in male cancer survivors, who underwent sperm cryopreservation at the Department of Gynecological Endocrinology and Reproductive Medicine, Medical University Innsbruck, Austria from 01/2010 to 12/2018. Sexual functioning was assessed between 03-12/2020 via two questionnaires: Aging Male Score (AMS) and International Index of Erectile Function (IEEF-EF).
Participants/materials, setting, methods: Thirty-five cancer survivors (testicular cancer: n=16 [45.7%], hematological malignancies: n=15 [42.9%], others: n=4 [n=11.4%]) filled in two questionnaires (AMS and IEEF-EF) during routine follow-up visit at the Department of Gynecological Endocrinology and Reproductive Medicine, Medical University Innsbruck and the Department of Urology, Medical University Innsbruck, Austria. Moreover, sperm quality was assessed and normozoospermia was defined in accordance with the 2010 WHO criteria (sperm concentration ≥15 million/mL, progressive motility ≥32%, and ≥4% normal morphology).
Main results and the role of chance: Mean age at sperm cryopreservation and follow-up visit was 25.1±4.2 and 31.9±6.3 years, respectively with a mean follow-up time of 81.4±12.5 months. Rate of erectile dysfunction was low (75.0% no dysfunction, 15.6% low dysfunction, 3.1% low-moderate dysfunction, 3.1% moderate, 3.1% severe dysfunction). Moreover, AMS score indicated no, low, moderate and severe symptoms consistent with a low testosterone level in 77.1%, 8.6%, 2.9%, and 2.9% of patients, respectively. Oligozoospermia was observed in up to 48% of the patients with TM and in only 23% patients with HM. Patients with TM showed significantly reduced sperm count (18.7 × 106/mL [5.3–43.0]) and total sperm count (42.4 × 106/ejaculate [13.3–108.5]) compared to HM (p=0.03). There was no difference in sexual functioning between patients with HM or TM. Sexual functioning did no correlate with sperm count, progressive motility or morphology.
Limitations, reasons for caution: Although the study may be limited by its small sample size, it is the first to assess a correlation of sperm quality and sexual dysfunction in cancer survivors.
Wider implications of the findings: As every fourth male cancer patient suffers from impaired sexual functioning after gonadotoxic treatment, this important topic should be addressed in clinical and scientific future. Future studies should focus on both, somatic and psychosomatic reasons for sexual dysfunction.
Trial registration number: none

P-089 Paternal age affects the performance of EAU guidelines for genetic testing in infertile men: implications for candidate selection

E. Ventimiglia[1], L. Boeri[1], E. Pozzi[1], F. Belladelli[1], G. Fallara[1], L. Candela[1], P. Capogrosso[2], N. Schifano[1], D. Cignoli[1], G. Colandrea[1], J. Cornelius[3], A. Mattei[3], C. Abbate[1], F. Montorsi[1], A. Salonia[1]

[1]IRCCS Ospedale San Raffaele, Division of Experimental Oncology/Unit of Urology- URI, Milan, Italy ; [2]ASST Sette Laghi – Circolo e Fondazione Macchi Hospital, Unit of Urology, Varese, Italy ;

[3]Luzerner Kantonsspital, Unit of Urology, Lucerne, Switzerland

Study question: We aimed at challenge EAU Guidelines for genetic testing performance in infertile men according to normal vs. advanced paternal age (APA).
Summary answer: EAU Guidelines perform better in karyotype analysis (KA) and Y-chromosome microdeletions (YCM) investigation in men above 35 years of age.
What is known already: EAU Guidelines for genetic testing in infertile men recommend specific threshold for candidate selection for both KA (<10 million spermatozoa/ml) and YCM (<5 million spermatozoa/ml). However, paternal age is not taken into account for candidate selection in this setting.
Study design, size, duration: Data from 2188 infertile men (according to WHO definition) consecutively evaluated at a single academic centre were analysed.
Participants/materials, setting, methods: Demographic, clinical and laboratory data were analysed. Semen analyses were based on 2010 WHO criteria. Advanced age was defined as above 35. All men underwent KA and YCM testing. EAU Guidelines were validated in our cohort and according to APA. Specificity, sensitivity, and AUC were estimated for all scenarios. A Wald-type test compared AUC according to APA for KA and YCM. Decision curve analysis (DCA) estimated the benefit of using EAU Guidelines according to APA.
Main results and the role of chance: Median (IQR) paternal age was 37 (34-41) years. Advanced paternal age was found in 1306 (60%) of included men. Prevalence of KA and YCM was 4% (48 men) and 1% (13 men), respectively. EAU Guidelines sensitivity, specificity and AUC in the overall population were 85%, 47% and 66% for KA, whereas they were 100%, 57% and 80% for YCM. When stratifying according to APA, EAU Guidelines performed better in men over 35 both in terms of KA and YCM detection. Specifically, AUC for KA detection in men with APA was 70% vs. 63% in younger men (p=0.04). AUC for YCM detection in men with APA was 82% vs. 79% in younger men (p=0.03). DCA confirmed higher net benefit in using EAU Guidelines in old vs. young men for the detection of both KA and YCM.
Limitations, reasons for caution: It is a retrospective analysis at a single, tertiary-referral academic centre, thus raising the possibility of selection biases.
Wider implications of the findings: EAU Guidelines for genetic testing in infertile men perform differentially according to APA. KA and YCM are better detected in older men, likely due to a wider pool of confounding etiological factors in young men. These results suggest the implementation of more accurate predictive models in younger men.
Trial registration number: Not Applicable

P-090 Cumulative live birth rates (CLBR) per embryo transfer, embryo transferred and inseminated oocyte are not affected by paternal age in infertile male donor egg cycles

L. Mossetti[1], A. Navarro-Gomezlechon[2], R. Rivera-Egea[3], I. Hervas[1], M. Gi. Julia[1], N. Garrido[1]

[1]IVI Foundation- Health Research Institute La Fe- Av. Fernando Abril Martorell-nº106- Torre A- Planta 1ª- 46026- Valencia- Spain, Andrology, Valencia, Spain ; [3]Andrology Laboratory and Sperm Bank- IVIRMA Valencia- Plaza de la Policia Local 3- 46015- Valencia- Spain., Andrology Laboratory and Sperm Bank, Valencia, Spain

Study question: Is reproductive success measured as CLBR per inseminated oocyte, per embryo transfer and per embryo transferred affected by paternal age in donor egg IVF-ICSI cycles?
Summary answer: Paternal age does not significantly affect reproductive outcomes measured by CLBR per inseminated oocyte, embryo transfer and embryo transferred in donor egg IVF-ICSI cyles.
What is known already: In recent years, the delay in the start of formation of a family has led to an increase of the average male age at which the first child is conceived. Therefore, there is a growing interest on the study of the impact of male age on the reproductive outcomes in assisted reproduction cycles (ART). Several studies have evaluated the effect of paternal age on reproductive outcomes using donor egg cycles to control for female factors. However, the results obtained on this topic are still controversial leading to a need of more research about it, which this study tries to address.
Study design, size, duration: This retrospective observational multicentric cohort study has included donor IVF-ICSI treatments (n=1539) performed to couples with etiology of male infertility (non-normozoospermic) in Spain IVIRMA clinics between January 2008 and March 2020 using patients' own sperm sample. Paternal age ranged from 28 to 74 years. The study population was categorized in 5 groups following the criterion of homogenizing the number of observations between groups 28-38 (A), 38-41 (B), 41-44 (C), 44-48 (D) y 48-74 (E) years.
Participants/materials, setting, methods: Considering that male age could be a factor affecting reproductive outcomes, we evaluated men with different age that performed a donor IVF-ICSI treatment with their own semen, etiology of male infertility and known age. Data was exported in order to obtain the clinical database and Kaplan-Meier was used for data analysis. P<0.05 was considered statistically significant. We measured reproductive success by CLBR per embryo transfer, per embryo transferred and per inseminated oocytes until live birth.
Main results and the role of chance: This study considered approximately 836 patients and 1411 embryo transfers. The CLBR per inseminated oocyte showed no significant difference between the study groups: A (3.09%, 42.61%, 71.96%), B (4.53%, 39.76%, 84.19%), C (5.89%, 47.04%, 78.61%), D (2.99%, 46.7%, 73.15%) and E (3.89%, 38.39%, 78.85%) for 7, 12 and 17 inseminated oocytes, respectively. In terms of CLBR per embryo transfer, the results obtained for each of the age groups were: A (51.55%, 70.69%, 92.18%), B (50.40%, 78.13%, 100.00%), C (53.68%, 71.69%, 100.00%), D (51.71%, 79.72%, 100.00%) and E (46.69%, 60.02%, 70.01%) for 3, 5 and 7 embryo transfers, respectively. No statistically significant differences were found among the studied age groups. CLBR per embryo transferred also did not show statistically significant differences between the age groups: A (8.43%, 53.34%, 72.13%), B (8.55%, 44,67%, 71.65%), C (10.40%, 53.94%, 72.49%), D (7.25%, 43.61%, 75.12%) and E (8.21%, 45.99%, 64.55%) for 1, 4 and 7 embryos transferred, respectively. Therefore, no significant differences were found in the number of inseminated oocytes, embryo transfers and embryos transferred needed to achieve a live birth between the age groups (p>0.05), suggesting that maybe paternal age has no relevant clinical effect on donor egg cycles with our categorization.
Limitations, reasons for caution: The retrospective nature of this study leads to biases derived from the clinical practice and to the presence of missing data (limiting sample size). Moreover, this study included donor egg cycles for controlling female factors, so this limits the generalization of our results to a population of young women.
Wider implications of the findings: Our study showed that the reproductive success measured as CLBR per embryo transfer, embryo transferred and inseminated oocytes was not statistically significant different among the studied age groups in donor egg cycles. Therefore, considering our study setting, paternal age does not affect reproductive success, however further studies should be done.
Trial registration number: NA

P-091 Magnetic Activated Cell Sorting (MACS) improves euploid blastocysts rate in pre-implantation genetic testing cycles with high levels of sperm DNA fragmentation and advanced paternal age.

F. Scarselli[1], E. Cursio[1], A. Colasante[1], V. Zazzaro[1], P. Andrea[1], S. Gatti[1], D. Paccagnini[1], D. Uva[1], C. Cerquetti[1], P. Greco[1], A. Greco[1], C. Mencacci[1], K. Litwicka[1], M.G. Minasi[1], E. Greco[1]

[1]Villa Mafalda, Reproductive Medicine, Rome, Italy

Study question: Can MACS increase euploid blastocyst rate in Pre-implantation Genetic Testing (PGT) cycles for AMA-APA (Advanced Maternal-Paternal Age) in patients with high sperm DNA fragmentation (SDF)?
Summary answer: A slight increase in euploid blastocyst rate was found using MACS in infertile patients with high SDF undergoing PGT cycles compared to the control group.
What is known already: Many authors have shown a close correlation between the presence of apoptotic markers on spermatozoa and the failure of assisted reproduction treatments. In normal physiological conditions, apoptotic spermatozoa with phosphatidylserine (PS) residues externalized on the plasma membrane, are eliminated along female genital tract, preventing oocyte fertilization. MACS eliminates apoptotic sperm whit PS residues using superparamagnetic microbeads conjugated with annexin V. This technique reduces the proportion of sperm with high rates of SDF and can be used to maximize ART

procedures results. MACS application improves sperm quality, fertilization, cleavage and pregnancy rates reducing miscarriage rate.
Study design, size, duration: From June to November 2020, 10 couples in which MACS was applied to select non-apoptotic spermatozoa, were randomly enrolled in our study (MACS group) and 8 couples without MACS were considered as controls (No-MACS Group). All couples in both groups underwent a PGT cycle and had high sperm DNA Fragmentation (> 20%). A higher rate of euploid and diploid-euploid mosaic blastocysts were obtained in the MACS group compared to the control group.
Participants/materials, setting, methods: Patients with severe oligoasteno teratozoospermia were excluded. MACS protocol was performed as follows: semen sample was analyzed (WHO 2010) and washed with buffered medium; pellet was removed and a swim-up was performed. Retrieved spermatozoa were washed with a binding buffer (Miltenyi Biotec), centrifuged (400 g x 4 minutes) and supernatant discarded. Pellet was covered with Annexin-V and re-suspended. After 15 minutes incubation at room temperature, the sample was eluted through the column and collected for ICSI.
Main results and the role of chance: In MACS group, female and male mean age ± SD were 41.6 ± 2.1 and 43.5 ± 7.3, respectively. Female and male mean age ± SD were 41.7 ± 2.8 and 44.6 ± 8.1 in the No-MACS group, respectively. In MACS and No-MACS groups, injected oocytes were 44 and 35, fertilized oocytes were 32 (72.3%) and 27 (77.1%) (NS), blastocyst formation rates were 71.8% (23/32) and 48.1% (13/27) (NS), respectively. In No-MACS group, only 1 euploid and 1 diploid-euploid mosaic blastocysts were obtained (1/13 = 8%) (NS). In MACS group, 4 euploid blastocysts were formed (4/23 = 17.4%) whereas mosaic diploid-euploid blastocysts were 3/23 (13.0%) (NS). Aneuploid blastocysts were 16/23 (69.6%) in MACS group and 11/13 (84.6%) in No-MACS group (NS).
Limitations, reasons for caution: AMA and APA of couples enrolled should be considered as a limit of the study. A larger number of patients and biopsied blastocysts are needed to analyze clinical results and perform a robust statistical analysis establishing if MACS is useful to improve transferable blastocyst rate in patients with high SDF.
Wider implications of the findings: MACS is useful to select non apoptotic sperms; although fertilization, cleavage and blastocyst rates are not improved, aneuploid blastocysts rate slightly decreases using MACS. It l possible that, selecting spermatozoa free from PS residues, MACS allows to choose spermatozoa with a better DNA packaging, thus affecting the embryo ploidy.
Trial registration number: non applicable

P-092 The more, the merrier: does ejaculatory frequency influence seminal parameters in oligospermic men?

C. Massarotti[1], E. Maccarini[2], L. Loberti[3], C. D. Leo[1], S. Stigliani[2], P. Scaruffi[2], P. Anserini[2]

[1]University of Genova, Academic Unit of Obstetrics and Gynecology- DINOGMI department, Genova, Italy ;
[2]IRCCS Ospedale Policlinico San Martino, Physiopathology of Human Reproduction, Genova, Italy ;
[3]University of Genova, School of Medicine, Genova, Italy

Study question: Does ejaculatory frequency during the three months preceding semen collection influence semen parameters in oligospermic men?
Summary answer: A frequency of 2-3 ejaculations/week during the three months preceding semen collection significantly optimizes sperm motility, without any reduction in sperm concentration.
What is known already: Male gametes undergo crucial physiological and biochemical changes during epididymal transit, but a longer storage is known to have negative effects on semen quality, especially on motility. Previous studies focused on abstinence prior to semen collection, while few data are available on the effect of ejaculation frequency. On one hand, a longer storage could increase exposure to reactive oxygen species and a pro-inflammatory environment, with a reduction in vitality and motility. On the other, an increased ejaculation frequency could cause a reduction in sperm volume and concentration. The effects of ejaculatory frequency are particularly understudied in men with oligospermia.
Study design, size, duration: This is a retrospective study performed at a tertiary level public infertility center. We included all semen samples, collected both for diagnostic purposes and ART cycles between September 2019 and September 2020, with a sperm concentration of 15 million/ml or less, and an abstinence of 3- 5 days. Exclusion criteria were surgically collected or collected for fertility preservation semen samples.
Participants/materials, setting, methods: Standard demographic and clinical data were recorded, as well as semen parameters. Ejaculation frequency was considered "optimal" (at least 2-3/week) or "reduced" (<1/week). The potential predictive role of ejaculation frequency, age, BMI, smoking habits, previous cryptorchidism, varicocele, days of abstinence on semen parameters was evaluated by univariate and then by multivariate analysis for all factors significant in the univariate models. P< 0.05 was considered statistically significant. Main results and the role of chance: Out of 738 men, 491 reported an optimal ejaculation frequency, 247 had <1 ejaculation/week, no one reported everyday ejaculations. Total sperm mobility (35.91±22.84% vs. 32.28±16.91%, p=0.02) and sperm rapid progressive motility (5.56±6.09% vs. 4.20±6.1%, p=0.006) were significantly higher in the group with optimal ejaculation frequency. Ejaculation frequency remained predictive of total mobility (p=0.04) and rapid progressive mobility (p=0.03) in a multivariate linear regression model with age and sperm concentration. Sperm volume (2.92±1.56 ml vs. 2.91±1.54 ml, p=NS) and concentration (5.74±5.05 mil/ml vs. 6.05±4.78 mil/ml, p=NS) did not significantly differ depending on the declared ejaculation frequency.
Limitations, reasons for caution: The study is retrospective and ejaculatory frequency was self-reported as an estimate of the mean of the number of ejaculations per week.
Wider implications of the findings: Optimizing ejaculatory frequency may improve ART outcomes as well as success of spontaneous conceptions. There is no reason to limit ejaculatory frequency in oligospermic men for a hypothesized benefic in sperm concentration.
Trial registration number: not applicable

P-093 The use of donor sperm improves post-ICSI live birth rates in advanced maternal age women

M.R. Mignin. Renzini[1], M. Da. Canto[1], M.C. Guglielmo[1], D. Garcia[2], E. D. Ponti[3], A. L. Marca[4], R. Vassena[2], J. Buratini[1]

[1]Biogenesi- Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy ;
[2]Clinica Eugin, Research, Barcelona, Spain ;
[3]ASST, Medical Physics, Monza, Italy ;
[4]Clinica Eugin, Clinics, Modena, Italy

Study question: Can the use of donor sperm improve post-ICSI live birth rate in advanced maternal age (AMA) patients?
Summary answer: The use of donor sperm increases post-ICSI live birth rate while substantially reducing abortion occurrence in AMA patients.
What is known already: Oocyte DNA repair capacity decreases with maternal age, when sperm DNA integrity is particularly important to avoid the transfer of gene truncations and *de novo* mutations to the zygote. Optimal DNA repair activity in the zygote requires paternal inheritance of 8-oxoguanine DNA glycosylase (OGG1), a rate-limiting enzyme in the base excision repair pathway. However, the involvement of paternal aging and sperm quality in the severe drop in fertility observed in AMA patients has not been addressed. While strategies to mitigate the impact of AMA on fertility have exclusively targeted oocyte quality, the sperm contribution in this scenario remains somehow neglected.
Study design, size, duration: Retrospective, multicentric, international study including 755 first ICSI cycles with patients' own oocytes achieving a fresh ET between 2015 and 2019, 337 of which using normozoospermic partner semen and 418 using donor sperm. The association of sperm origin (partner *vs.* donor) with live birth was assessed by univariate/multivariate analysis in non-AMA (<37 years, n=278) and AMA (≥37 years, n=477) patients. ICSI outcomes were compared between partner and donor sperm in non-AMA and AMA patients.
Participants/materials, setting, methods: The study was conducted in 3 fertility clinics including 755 Caucasian patients aged 24 to 42 years. Univariate/multivariate analyses were performed to test the association of sperm origin with live birth; infertility factor, maternal age, oocyte yield and number of embryos transferred were included in the model as confounding variables. In addition, ICSI outcomes were compared between donor and partner sperm groups with the Chi-square (percentages) or with the Wilcoxon sum rank (continuous variables) tests.

Main results and the role of chance: The multivariate analysis revealed that the use of donor sperm was positively and independently associated with live birth occurrence in AMA [1.82 OR (1.08-3.07) 95% IC; p=0.024], but not in non-AMA patients [1.53 (0.94-2.51); p=0.090]. Maternal age [0.75 (0.64-0.87); p<0.001], number of MII oocytes recovered [1.14 (1.05-1.23); p=0.001] and number of embryos transferred [1.90 (1.27-2.86); p=0.002] were also independently associated with live birth in AMA patients. Live birth and delivery rates were 70-75% higher, while miscarriage rate was less than half in donor sperm compared to partner sperm AMA cycles (LBR: 25.4% *vs.* 14.5%, p=0.003; DR: 22.5% *vs.* 13.5%, p=0.008; MR: 18.0% *vs.* 39.5%; p=0.009). Implantation (17.4% *vs.* 13.5%; p=0.075) and clinical pregnancy rates (27.5% *vs.* 22.3%; p=0.121) did not significantly differ between sperm donation and partner sperm AMA cycles. Male age was substantially lower (23.6 ± 5.2 *vs.* 41.4 ± 5.0; p<0.0001) and oocyte yield was higher (5.1 ± 3.1 *vs.* 4.3 ± 2.6; p<0.0001) in sperm donation compared to partner sperm AMA cycles, while maternal age did not vary (39.8 ± 1.6 *vs.* 39.6 ± 1.7; p=0.348).

Limitations, reasons for caution: This study is limited by its retrospective nature and by differences in patients' profiles between sperm donation and homologous cycles, although this variation has been controlled for in the statistical analysis.

Wider implications of the findings: The findings suggest that donor sperm can improve live birth rates by drastically reducing miscarriage occurrence in AMA patients. Therefore, the present results may influence AMA treatment decisions and, above all, contribute for AMA patients to achieve a healthy birth.

Trial registration number: not applicable

P-094 Kidney function impairment in primary infertile men

G. Fallara[1], L. Boeri[1], L. Candela[1], E. Pozzi[1], F. Belladelli[1], P. Capogrosso[2], W. Cazzaniga[1], E. Ventimiglia[1], N. Schifano[1], A. Costa[1], D. Cignoli[1], J. Cornelius[3], A. Mattei[3], F. Montorsi[1], A. Salonia[1]

[1]San Raffaele Hospital, Division of Experimental Oncology/Unit of Urology, Milan, Italy ;
[2]ASST Sette Laghi – Circolo e Fondazione Macchi Hospital, Unit of Urology, Milan, Italy ;
[3]Luzerner Kantonsspital, Unit of Urology, Milan, Italy

Study question: We investigated the prevalence of kidney function impairment in a homogeneous cohort of white-European primary infertile men.

Summary answer: Mild kidney function impairment characteristics were found in 9% of asymptomatic and unaware patients presenting for primary infertility investigation.

What is known already: Infertile men have shown a worse overall health status compared to the fertile counterpart. We investigated the prevalence of kidney function impairment in a homogeneous cohort of white-European primary infertile men.

Study design, size, duration: In this corss-sectional study, complete clinical and laboratories data from a cohort of 557 consecutive men aged >18 years, presenting for primary infertility investigation were analyzed.

Participants/materials, setting, methods: Comorbidities (as scored with the Charlson Comorbidity Index (CCI)) were collected in each patient. Primary outcome was the presence of functional impairment of the kidney (defined as an estimated glomerular filtration rates <90 ml/min/1.73m², according to the Kidney Outcomes Quality Initiative). The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) function was used for eGFR calculation. Logistic regression analyses tested the association between kidney function impairment and clinical and semen features.

Main results and the role of chance: Of 557, 51 (9.3%) patients depicted at least a mild loss of kidney function (eGFR<90 ml/min /1.73m²). Median [interquartile (IQR)] age was 38 (35-42) years for normal kidney function group vs. 41 (36-46.5) years for those with impaired renal function (p<0.001). Those with impaired renal function had also a higher BMI [26.1 (24.4-27.8) vs. 24.9 (23.2-26.8); p=0.002] and higher numbers of comorbidities [CCI≥ 1 in 11 (21.5%) vs. 40 (7.9%) patients (p<0.001)]. Of note, they had more frequently history of hypertension [10 (19.6%) vs. 31 (6.1%), p=0.001]. Groups did not differ in terms of hormonal and semen features. At logistic regression analysis, older age and CCI≥1 were associated with a higher risk of impaired eGFR (OR 1.06; 95%CI 1.01-1.11; p=0.016 and OR 2.41; 95%CI 1.06-5.15; p=0.028, respectively)(table). No association was found between sperm parameters and eGFR impairment (all p>0.05), after accounting for age, CCI, BMI, FSH, testicular volume, and varicocele**.**

Limitations, reasons for caution: Mild kidney function impairment characteristics were found in 9% of asymptomatic and unaware patients presenting for primary infertility investigation. Age and the rate of comorbidities are associated with reduced eGFR. Wider implications of the findings: This novel finding confirms growing data on a significant association of male infertility with a poorer overall male health status.

Trial registration number: not applicable

P-095 Outcomes and predictive factors of successful salvage microdissection testicular sperm extraction (mTESE) after failed TESE in men with non-obstructive azoospermia: results from a multicenter study

Study question: We assessed the outcome and predictors of successful salvage microdissection testicular sperm extraction (mTESE) in non-obstructive azoospermia (NOA) men previously submitted to unfruitful classic (cTESE).

Summary answer: The sperm retrieval rate at salvage mTESE was almost 50%. Hypospermatogenesis and low FSH values were associated with positive outcomes at salvage mTESE

What is known already: In men with NOA testicular sperm can be retrieved using cTESE in approximately 50% of cases. mTESE has been proposed as a salvage treatment option for men with a previously failed TESE, but data are scarce.

Study design, size, duration: Multicenter, cross-sectional study. Complete data from 61 NOA men who underwent mTESE after a failed cTESE between 01/2014 and 10/2020, at 6 tertiary referral centers in Italy were analysed.

Participants/materials, setting, methods: All men underwent testicular ultrasound, hormonal and genetic blood testing. Histopathological diagnosis from TESE was collected in every man. Semen analyses were based on the 2010 WHO reference criteria. mTESE was performed according to the technique of Schlegel et al. (1999). Descriptive statistics and logistic regression models were used to investigate potential predictors of positive sperm retrieval (SR+) after salvage mTESE.

Main results and the role of chance: Overall, median (IQR) age and testicular volume were 35 (31-38) years and 10 (6-15) ml, respectively. Baseline serum FSH and total testosterone levels were 17.1 (8.6-30.4) mUI/mL and 4.7 (3.5-6.4) ng/mL, respectively. Sertoli-cell-only (SCO) syndrome, maturation arrest (MA) and hypospermatogenesis were found in 24 (39.3%), 21 (34.4%) and 16 (26.2%) men after cTESE, respectively. Spermatozoa were retrieved in 30 (49.2%) men at salvage mTESE. Patients with a diagnosis of hypospermatogenesis had a higher rate of SR+ [12/16 (75%)] than those with MA [12/21 (57.1%)] and SCOS [6/24 (25%)] after salvage mTESE (p<0.01), which was bilateral in 36 (59%) cases. FSH

was higher [16.5 (8-22) vs. 8.9 (5-13) mUI/mL, p<0.01] in SR- patients compared to SR+. No difference in clinical characteristics was found between patients with SR+ and SR- at salvage mTESE. There were no significant complications after mTESE. Multivariable logistic regression analysis showed that hypospermatogenesis (OR 9.7; p<0.01) and low FSH levels (OR 0.9, p<0.001) were independent predictors of SR+ after salvage mTESE, after accounting for age.
Limitations, reasons for caution: Despite we analysed one of the largest series of salvage mTESE, the samples size is too small to draw general conclusions. Because of the multicenter nature of the study we cannot rely on standardization of surgical techniques for TESE.
Wider implications of the findings: This is one of the larger studies on salvage mTESE. The selection of patients for salvage mTESE is of critical importance.
Trial registration number: na

P-096 Real-time ranking of single spermatozoa using artificial vision analysis of complex motility patterns during ICSI aimed at improving fertilization and blastocyst development

A. Chave. Badiola[1,2,3], G. Mendizabal[4,5], J. Cohen[6,7,8], A. Flores-Saiffe[5], V.M. Roberto[5], A. Drakeley[5,9]

[9]Hewitt Centre for Reproductive Medicine, Reproductive Medicine, Liverpool, United Kingdom

Study question: Can real-time artificial vision identify beneficial movement patterns of single spermatozoa in a cohort visualized in PVP during ICSI possibly enhancing fertilization and embryo development?
Summary answer: Artificial vision seems able to identify advantageous movement patterns of individual spermatozoa having a significant impact on both normal fertilization and blastocyst formation.
What is known already: Spermatozoa isolated from poor semen may reduce the quality of embryo development and blastocyst formation. Normal motility is dependent on general sperm morphology and characteristic movement of the flagellum enabling forward mobility. Spermatozoa roll as they swim. It is known that this rotational motion around their longitudinal axis promotes rheotaxis, which is a mechanism that allows the sperm to navigate to the site of fertilization. Therefore, it is possible that the characteristics of the rotational movement are related to sperm quality.
Study design, size, duration: Non-intervention study based on a cohort of 132 videos of in-vitro fertilization treatments with ICSI during which the sperm selection process was recorded up to sperm injection. The study was performed at one IVF center within a 6-month period. Injected spermatozoa and their corresponding oocytes were individually assessed from fertilization to blastocyst formation. Videos, where spermatozoa selected for injection could not be identified, were excluded. Relevant outcomes included normal fertilization (2PN), and blastocyst formation.
Participants/materials, setting, methods: Using a digitizer attached to an optical microscope (640 x 480 pixels), videos were recorded to include the sperm selection process, immobilization, and subsequent injection following standard ICSI protocols. Individual spermatozoa motility features were extracted using a proprietary computer-vision algorithm (SID, IVF 2.0 LTD). The rotational movements of spermatozoa were inferred by computing the variations of the mean intensity of the sperm in the video-sequence across time (MI).
Main results and the role of chance: Based on SID's analysis, we found statistically significant differences between the median prominences of the MI of those injected spermatozoa that resulted in successful fertilization in comparison to those with failed fertilization (p-value=0.029, 28 negative fertilization, and 71 positive fertilization) using a one-tailed t-Student test with a significance level of 5%. We also found statistically significant differences between the median prominences of the MI of those spermatozoa that resulted in blastocysts in comparison with the spermatozoa-oocyte cohorts which didn't reach the blastocyst stage (p-value 0.004, 51 with negative blastocyst formation and 48 with blastocyst formation).
Limitations, reasons for caution: The size of this database is modest, therefore a larger study with multiple clinics will be necessary to confirm the findings. Large prominence does not necessarily assurance successful fertilization or blastocyst formation since there may be other factors such as oocyte quality or the ICSI technique.
Wider implications of the findings: Objective assessment of sperm rotational movement is difficult to quantify and to be objectively assessed during standard sperm selection. Real-time artificial vision tools such as SID could assist embryologists during the sperm selection process for ICSI.
Trial registration number: NA

P-097 The impact of SARS-CoV-2 on male gonadal function. A longitudinal study

M.P. Lauritsen[1], T.D. Leineweber[2], C.B. Hansen[1], U.V. Schneider[2], H. Westh[2], A. Zedeler[1], N. L. Cou. Freiesleben[1], H.S. Nielsen[1]

[1]Copenhagen University Hospital Hvidovre- DK-2650 Hvidovre- Denmark, Department of Obstetrics and Gynaecology- The Fertility Clinic-, DK-2650 Hvidovre, Denmark ;
[2]Copenhagen University Hospital Hvidovre- DK-2650 Hvidovre- Denmark, Department of Clinical Microbiology-, DK-2650 Hvidovre, Denmark

Study question: Can severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) be detected in the semen of SARS-CoV-2 positive men, and does SARS-CoV-2 infection affect male reproductive function?
Summary answer: No SARS-CoV-2 RNA was detected in semen. An impact of SARS-CoV-2 infection on semen quality and reproductive hormone profile awaits evaluation at 3+6 months follow-up.
What is known already: SARS-CoV-2 may use angiotensin-converting enzyme (ACE)2 as an entry point into the cell. As ACE2 is expressed in testicular tissue, it has been speculated that SARS-CoV-2 may affect the male reproductive system. A cohort study including 38 male COVID-19 patients showed that SARS-CoV-2 was present in the semen of six patients (15.8%) [Li *et al*., 2020]. Later studies including a total of 223 patients have not provided evidence of transmission of SARS-CoV-2 via semen. There are to date no available longitudinal studies on semen quality following SARS-CoV-2 infection.
Study design, size, duration: Longitudinal cohort study including 50 non-hospitalized men from the general population in the Capital Region of Denmark. All participants had a confirmed SARS-CoV-2 infection by reverse-transcription polymerase chain reaction (RT-PCR) on oropharyngeal swab material within the last week. The presence of SARS-CoV-2 in semen samples by RT-PCR, semen parameters and reproductive hormone profile were assessed at inclusion and at 3 + 6 months follow-up. SARS-CoV-2 antibody levels were assessed 3-5 weeks after inclusion.
Participants/materials, setting, methods: SARS-CoV-2-positive males (age 18-60 years) were included. Oropharyngeal and semen samples were tested by RT-PCR applying the E-Sarbeco primers and probe published by Corman *et al.* 2020 and adapted to TaqMan Fast Virus 1-step master mix and LightCycler 480 as previously reported by Jørgensen *et al.* 2020. SARS-CoV-2 antibodies were detected using the serological immunoassay from Shenzhen YHLO Biotech on the iFlash 1800. Semen quality parameters were analysed according to World Health Organisation (WHO) standards.
Main results and the role of chance: To date, 25 men with a mean age of 35 years have been included in the study. SARS-CoV-2 RNA could not be detected in the semen samples of any of the 25 men at the time of inclusion. Twenty-one of the 25 men (84,0%) had a same day RT-PCR-confirmed SARS-CoV-2 infection in an oropharyngeal swab. RT-PCR cycle threshold (ct) values were distributed as follows: four (19,0%) were strongly positive (ct <25), 16 (76,2%) intermediately positive (ct 25-35) and one (4,8%) weakly positive (ct 35-45). The four men without PCR-confirmed SARS-CoV-2 infection all had a positive IgG response to SARS-CoV-2 at the time of inclusion. Longitudinal semen and reproductive hormone profiles analyses will be performed. Further studies are needed to prove whether SARS-CoV-2 can be transmitted to the male reproductive tract and whether SARS-CoV-2 infection may cause alterations of spermatogenesis and endocrine function.

Limitations, reasons for caution: Strengths of this study are the unselected population of men examined within a week after confirmed SARS-CoV-2 infection and the follow-up of semen parameters and endocrine profile. Limitations are the limited sample size and the fact that semen quality was not known before the participants were diagnosed with COVID-19.
Wider implications of the findings: Knowledge of viral detection and semen persistence of SARS-CoV-2 is essential for clinical practice and public health. There is a need for evidence-based counselling on the impact of SARS-CoV-2 infection for patients undergoing assisted reproduction technology and patients who have a need for semen cryopreservation.
Trial registration number: H-20027362

P-098 Use of Dimethylxanthine Theophylline in surgical retrieved sperms that do not recover motility after thawing

N. Calza[1], P.M. Ciotti[1], M.L. Tranquillo[1,2], L. Notarangelo[2], S. Zuffa[1], G. Damiano[1], L. Cipriani[1], M. Dirodi[1], A. Franceschelli[3], E. Porcu[1],

[1]Infertility and IVF Unit- IRCCS Azienda Ospedaliero Universitaria di Bologna- Italy, Department of Women- Children and Urological Diseases, Bologna, Italy ;
[2]University of Bologna - DIMEC- Bologna- Italy, Department of Women- Children and Urological Diseases, Bologna, Italy ;
[3]Andrology Unit- IRCCS Azienda Ospedaliero Universitaria di Bologna- Italy, Department of Women- Children and Urological Diseases, Bologna, Italy

Study question: Can the use of Theophylline recover motility of frozen surgically retrieved sperms in case of absence of motility after thawing?
Summary answer: Theophylline allows to recover motility of thawed surgically retrieved sperms. The utilization of sperms with or without pharmacological activation gives comparable clinical outcomes.
What is known already: Testicular sperm motility is usually poor. A method is needed to detect viable sperm for ICSI when motility is totally absent after freezing/thawing. Hypo-osmotic swelling test, mechanical touch technique, laser-assisted immotile sperm selection, birefringence-polarization microscopy and exposure to pharmacological stimulation are techniques used for this purpose. Among pharmacological agents Dimethylxanthine Theophylline is a phosphodiesterase inibitor that improves sperm motility by promoting an increase in intracellular cyclic AMP levels. Few studies report that it is efficient for recovery of sperm motility in cases of thawed testicular and retrograde ejaculation samples improving reproductive outcomes.
Study design, size, duration: Retrospective analysis of sixty frozen surgical sperm cycles (45 patients) utilized from February 2018 to November 2020. After thawing, samples were divided in two Groups according to motility recovery. Group A: presence of motility, Group B: absence of motility. Group B was treated with Theophilline and motility was re-assessed after incubation. Activated sperms were utilized for ICSI when available. Sperm motility recovery, fertilization, pregnancy rate/transfer, implantation and miscarriage rate were evaluated in both Groups.
Participants/materials, setting, methods: Surgical specimens were treated and concentrated in SpermRinse™ Medium (Vitrolife) and then cryopreservated in nitrogen vapor in TEST Yolk Buffer (Irvine Scientific). After thawing, only samples with no motility recovery were treated with a brief incubation in Theophylline (GM501 SpermMobil, Gynemed) and washed in Polyvinylpyrrolidone (ICSI™ Vitrolife) before injection. ICSI was performed in all cases approximately 4-5 hours after sperm thawing. After fertilization check, transfer was scheduled in day 2.
Main results and the role of chance: Women's age Group A (34,39±2,29 M±SD) and group B (35,87±4,34 M±SD) and men's age Group A (37,31±5,12 M±SD) and group B (40,89±8.15 M±SD) were not significantly different (*P*=.328 and *P*=.218) respectively.

Group A: 13/60 cycles (21.7%) (9 patients). Pre freezing and post thawing total motility percentage were 34.0±19.0 (M±SD) and 13.5±15.6 (M±SD) respectively (39.8% recovery). Group B: 47/60 cycles (78.3%) (36 patients). Pre freezing total motility percentage was 5.3±8.5 (M±SD) and no motility was recovered post thawing (0%). After treatment with Theophylline total motility was 1.8±1.8 (M±SD) (33.5% recovery). Motile sperms were utilized in all cases except from two in the Group B.

Number of injected oocytes was 2.8±1.1 (M±SD) in Group A and 4.3±3.1 (M±SD) in Group B (*P*=.004) respectively.

Fertilisation rate (63.1% and 45.4%, *P*=.066), Number of embryos transferred (1.8±0.7 M±SD and 1.6±0.7 M±SD, *P*=.271), Pregnancy rate/Transfer (54.5% and 37.1%, *P*=.502), Implantation rate (30.0% and 27.8%, *P*=.919) and Miscarriage rate (33.3% and 30.7%, *P*=.675) were not statistically significant between Group A and B respectively.

In the two cases of group B injected with immotile sperm, fertilization rate was 0% (0/3) and 50% (2/4).
Limitations, reasons for caution: A larger study is needed to investigate the recovery of sperms motility (and/or their activation) and clinical outcomes, in particular referring to the origin of sampling (epididymal aspirate and testicular tissue) and type of azoospermia (obstructive and non-obstructive).
Wider implications of the findings: Theophylline is an effective tool for sperm motility recovery after thawing allowing to inject viable sperm and facilitating laboratory handling.
Trial registration number: not applicable

P-099 MYD88 dependent pathway through TLR 1,2 and 6 activation play a role in interaction of high DNA fragmented human sperm with fallopian tube epithelial cells

A. Govahi[1], Z. Zahra[1], A. Fatemehsadat[1], A. Azin[2], A. Reza[3]

[1]Department of Anatomy- School of Medicine- Iran University of Medical Science- Tehran- Iran, Anatomy, Tehran, Iran ;
[2]Department of Immunology- Iran University of Medical Sciences- Tehran- Iran., Immunology, Tehran, Iran ;
[3]Royan Institute for Reproductive Biomedicine- Bani Hashem Square- Tehran- Iran., Reproductive Biomedicine, Tehran, Iran

Study question: How does sperm with high DFI disrupt the female reproductive system?
Summary answer: Sperm with damaged DNA could disrupt the female reproductive system by production of high inflammatory factors through activation of TLRs and MyD88-dependent pathway .
What is known already: Previous studies have also shown that the interaction between sperm and fallopian tube is a complex process and activates a number of immune mechanisms. Many TLRs, including TLR1, TLR2, and TLR6 are expressed in fallopian tube epithelial cells. TLRs have an important role in the immune interaction between fallopian tube and sperm. They are also involved in sperm capacitation, fertilization and pregnancy. Examining this interaction may lead us to valuable data.
Study design, size, duration: In this study, 10 Recurrent Implantation failure couples with high DFI (>30% by SCSA evaluation) and 10 healthy donors men with low DFI (<30%) were considered as high DFI group and low DFI group respectively. After fresh semen preparation, sperm were co-cultured with human fallopian tube epithelial cell line(OE-E6/E7) for 24 hours**.**
Participants/materials, setting, methods: RNA were extracted from the cell line and PCR array for human innate and adaptive immune responses was performed by RT2 profiler PCR array.
Main results and the role of chance: Analysis of PCR array data showed that the expression of TLR-1, TLR-2, TLR-6, MYD88, TIRAP, IRAKS,TRAF6, MAPKS, NF-KB, G-CSF, GM-CSF, CXCL8, CXCL10, CCL2, IL-6, IL-1, TNFa in high DFI group was significantly higher than control group. All these factors are involved in the MyD88-dependent pathway. Our research suggests that the MyD88-dependent pathway through TLR1,2 and 6 activation may be the main inflammatory pathway activated by sperm with high DFI. The released DAMPs through damaged sperms were recognized by TLRs on the epithelial cells. Following the TLR1,2 and 6 signaling, and MYD88 activation, epithelial cells were producing the inflammatory cytokines which result in the neutrophils infiltration. In the lumen of the fallopian tube, the neutrophils were activated via TLR1/TLR2, complexes that lead to the neutrophils activation, phagocytosis, NET formation, and apoptosis.
Limitations, reasons for caution: Studying with a larger sample size and examining the final factors at the protein level will be better to detect the effect of sperm DNA fragmentation on fallopian tube.
Wider implications of the findings: MyD88-dependent pathway could be one of the mechanisms that involved in interaction of high DNA fragmented sperm with female reproductive tract.
Trial registration number: not applicable

P-100 Metabolic, hormonal, and inflammatory status in sub-fertile men with obesity and diabetes

S. Abbasihormozi[1], A. Kouhkan[2], A. Shahverdi[1], A. Parhizkar[3], Z. Zolfaghary[4], Z. Mohamma. Alipoor[4]

[1]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Embryology, Tehran, Iran ; [2]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of diabetes- Obesity and Metabolism, Tehran, Iran ; [3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Andrology, Tehran, Iran ; [4]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran, Department of Epidemiology & Reproductive Health, Tehran, Iran

Study question: To evaluate the association between sperm functionality parameters and biochemical, hormonal, and inflammatory indices in obese and diabetic men.
Summary answer: Metabolic changes,hormonal dysfunction,and the presence of inflammatory mediators might be considered possible mechanisms in the development of sub-fertility in obese and diabetic sub-fertile men
What is known already: Although the higher prevalence of subfertility in obese and diabetic men during the reproductive age is evident, the mechanisms by which obesity and diabetes mellitus (DM) cause male infertility are not entirely understood. Several pathways might be involved in the role of obesity in semen quality, thereby inducing alterations in hormonal profiles, abnormal lipid metabolism, and possibly the formation of inflammatory cytokines, ultimately leading to impaired sperm function
Study design, size, duration: We enrolled normal weight (BMI<25 kg/m2) and non-type-2 diabetic (control=40), obese and non- type-2 diabetic (obese=40), non-obese and type-2 diabetic (Lean-DM=35), and obese and type-2 diabetic (Obese-DM=35) sub-fertile men, aged 20-50 years, referring to Royan infertility clinic (Tehran, Iran) from March to September 2014
Participants/materials, setting, methods: After enrollment and receiving informed consent, all men underwent face-to-face private interviews. The obesity-associated markers, insulin resistance, beta-cell function, hormonal and lipid profile, inflammatory indices, and semen analysis were assessed in four experimental groups. Semen analysis was examined after 2–5 days of sexual analysis). abstinence based on WHO-recommended methods by CASA system (computer-assisted sperm
Main results and the role of chance: Main results and the role of chance: Our finding showed that diabetic markers were significantly increased in two diabetic groups, while obesity indices were markedly increased in two obese groups. Conventional sperm parameters were significantly lower in obese DM, lean DM, and obese groups compared with the control (p<0.05). Serum levels of total testosterone (TT) and sex hormone-binding globulin (SHBG) were significantly lower in men with obesity and DM compared with the control (p< 0.05).There was a significant difference in the concentration of high-sensitivity C-reactive protein (hs-CRP) among four experimental groups.

Moreover, serum leptin was significantly increased in obese DM, lean DM, and obese groups. Serum insulin levels had a positive correlation with metabolic-associated indices (WC, BMI, FBS,HbA1c,and HOMA-IR), as well as hs-CRP levels, whereas it had a negative correlation with count, motility, and morphology. There is also a negative association between metabolic-associated indices (WC, BMI, FBS, HbA1c, and HOMA-IR) and semen parameters.
Limitations, reasons for caution: It was better to evaluate inflammatory biomarkers be examined in other tissues
Wider implications of the findings: The results of this study demonstrated the association of metabolic changes, hormonal dysfunction, and inflammatory responses with the semen parameters of sub-fertile men with obesity and diabete.
Trial registration number: not applicable

P-101 Comparative assessment of laparoscopic, microsurgical varicocelectomy, and antioxidant therapy alone in Infertile men with pathozoospermia

V. Bozhedomov[1], A. Shomarufov[1], G. Bozhedomova[2], D. Kamalov[3], N. Sorokin[3], A. Kamalov[4]

[1]Faculty of Fundamental Medicine of Lomonosov Moscow State University, Urology and Andrology, Moscow, Russia C.I.S. ; [2]Polyclinic №3- Presidential Administration, Clinical laboratory, Moscow, Russia C.I.S. ; [3]Medical Research and Educational Center Lomonosov University Clinic, Urology and Andrology, Moscow, Russia C.I.S. ; [4]Medical Research and Educational Center Lomonosov University Clinic, Director, Moscow, Russia C.I.S.

Study question: Which treatment option is better in men with clinical varicocele and pathozoospermia: laparoscopic, microsurgical varicocelectomy, or antioxidant (nutrient) therapy alone?
Summary answer: Microsurgical varicocelectomy and laparoscopy are more effective in pathozoospermia treatment than observation and nutrient therapy alone. Simultaneously, there are no differences between these surgical methods.
What is known already: It is known that varicocele may cause testicular dysfunction and infertility due to increased oxidative stress and sperm DNA damage. In recent meta-analyses comparing surgery versus follow-up in men with clinical varicocele and pathozoospermia, semen quality was better in the surgery group. However, it is unclear why varicocelectomy leads to sperm quality improvement only in 60-70% of cases, and real fertility in 30-40% of couples. The microsurgical technique leads to fewer complications compared with others, but there are no powerful RCTs to compare various techniques' efficacy. Simultaneously, the use of antioxidants may give a similar increase in pregnancy rates.
Study design, size, duration: This retrospective case-control study recruited 218 men from infertile couples with clinical varicocele and pathozoospermia who underwent microsurgical, laparoscopic varicocelectomy and antioxidant therapy alone at clinics of Moscow from January 2010 to December 2019.
Participants/materials, setting, methods: Clinical, laboratory data of patients in the groups: A) the observation group (n = 33), B) the group treated with nutrients alone (n = 63), C) the group of patients after microsurgical varicocelectomy (n = 86), and D) the group of patients who underwent laparoscopy (n = 36), were obtained. The sperm was evaluated according to WHO-2010, DNA fragmentation by chromatin dispersion in an agarose gel. We calculated standardized effect (Es) to determine study power.
Main results and the role of chance: After 3 months, varicocelectomy led to an increase in sperm concentration and motility: the median of the total progressively motile sperm count (TPMSC) increase in the group A was +0.4 million; B - +1.9 million; C - +17.1 million (p <0.05); D - +21.2 million (p <0.05). A clinically significant increase in this indicator after varicocelectomy was found in 2/3 of cases: 65% (; p<0.05) and 67% (D; p<0.05) with 38% (A) and 42% (B). Varicocelectomy led to a decrease in sperm DNA fragmentation by an average of 5.5% (p<0.05) with an improvement in 59% of patients. Simultaneously, a 3-month therapy with nutrients similarly decreased DNA fragmentation: 5.5% (p <0.05), 66% of improvement cases. The differences in surgery efficacy between C and D were insignificant (p>0.05). The laparoscopic surgery demonstrated higher standardized effect (Es) than microsurgical operation (Es = 0.70 and 0.44, with 0.29 in the patients receiving nutrients and 0.22 in the patients of the control group).
Limitations, reasons for caution: The main limitations were: 1) different sample (group) sizes and 2) insufficient power of the performed study (Es<0.8), which does not allow us to exclude a type II error – unreasonable rejection of differences.
Wider implications of the findings: In selected patients with varicocele and pathozoospermia, antioxidant therapy can be used as a monotherapy or as adjuvant therapy.
Trial registration number: Not applicable

P-102 GM-CSF (granulocyte-macrophage colony-stimulating factor) as a sperm medium supplement improves sperm quality in Oligoastenoteratospermia (OAT) men by activating the PI3K/Akt pathway

F. Tanhay. Kalat. Sabz[1], M. Ashrafi[2], F. Amjadi[1], Z. Zandieh[1], E. Hosseini[3], R. Aflatoonian[2]

[1]Iran University of Medical Sciences, Department of Anatomical Science, Tehran, Iran ; [2]Royan Institute, Department of Endocrinology and Female Infertility- Reproductive Biomedicine Center, Tehran, Iran ;

[3]Zanjan University of Medical Sciences, Department of Obstetrics and Gynecology- IVF Clinic- Mousavi Hospital, Zanjan, Iran

Study question: Can GM-CSF as a sperm medium supplement improve sperm quality in OAT men?
Summary answer: GM-CSF can be used to improve sperm quality in OAT men by activating the PI3K/Akt pathway.
What is known already: OAT patients have very low sperm parameters, including morphology, count, and motility, which can adversely affect the results of assisted reproduction technologies. It seems the development of sperm media is necessary to improve the sperm parameters of these patients. GM-CSF is a natural growth factor produced by the reproductive organs, culture media supplemented with GM-CSF is widely commercially available and enhances the embryo development and implantation rate. Studies show that this growth factor in the semen of infertile men is lower than that of fertile men. However, there is no study to assess the effect of GM-CSF on sperm quality.
Study design, size, duration: In the present study, Semen specimens were collected from 20 OAT patients who have male infertility factors, according to WHO criteria. After the swim-up washing procedure, each of the samples is divided into two groups; experiment, and control. In the experimental group, samples are incubated with a medium containing 2 ng/ml GM-CSF for one hour, yet, in the control group, the sperms are incubated without GM-CSF for the same time.
Participants/materials, setting, methods: The sperm motility was examined with phase-contrast microscopy, Eosin-nigrosin staining method was used to assess sperm viability. The expression of sperm glucose transporters (GLUT 1, 3) was determined using immunofluorescent staining, the ratio of pAkt to total Akt was assessed by the Western blotting method. Image J software was used to quantify results; the data was analyzed by SPSS software. P-value<0.05 was considered statistically significant.
Main results and the role of chance: As compared to the control group, supplementation with GM-CSF improved sperm progressive motility, enhanced GLUT 1 and 3, and p-AKT/AKT expression (P<0.05). There was no significant difference between the viability of the control and experimental groups.
Limitations, reasons for caution: This study needs further investigations, including Real-time PCR for the genes of this signaling pathway which is ongoing.
Wider implications of the findings: We showed for the first time that GM-CSF can improve sperm quality by influencing motility and energy metabolism in spermatozoa which can be affected by increasing the phosphorylation of AKT. This growth factor could be an appropriate supplement in sperm media for OAT patients.
Trial registration number: IRCT20200519047508N1

P-103 Novel sperm preparation techniques compared with conventional preparation method

N. Vahidi[1], F.S. Amjadi[1], F. Kalat. sabz[1], Z. Zandie[1], N. Narimani[2]

[1]Anatomy- School of Medicine- Iran University, medical, tehran, Iran ;
[2]Iran University, Urology, tehran, Iran

Study question: Which sperm preparation technique separate the best quality sperm?
Summary answer: Microfluidic method improved the sperm parameters and decreased sperm DNA damage.
What is known already: About 40% of infertility issues are due to male factor. One of the known causes of male infertility is associated with low sperm parameters and high level DNA fragmentation. Sperm preparation techniques in ICSI procedures is used in order to obtain the best-quality sperm**.**
Study design, size, duration: The present study was designed to compare Microfluidic, Zeta potential, Magnetic Activated Cell Sorting (MACS) and Swim-up methods for sperm preparation and the effect of these methods on semen parameters and sperm DNA integrity in infertile men (n = 25) with a mean age of 38.
Participants/materials, setting, methods: In this study, each sample was divided into 4 groups, one part for preparing by Microfluidic method, one of them for preparing by Swim -up method, the other one was prepared by MACS and the last one was prepared by zeta potential. Then sperm count, viability, motility and morphology were assessed according to WHO 2010. DNA damage were assessed by Sperm DNA Fragmentation assay and sperm chromatin packaging assessed by CMA3 staining test
Main results and the role of chance: Sperm parameters including viability, motility, and morphology in the Microfluidic method were significantly improved and sperm DNA damage were significantly lower than three other methods (P-value <0.05). The sperm parameters and sperm DNA damage after preparation by MACS and Zeta potential methods were not significantly different however in the Swim-up method sperm parameters were lower than three other methods (P-value <0.05).
Limitations, reasons for caution: The fertilization and pregnancy rate of the resulting embryos are not available.
Wider implications of the findings: Our results showed that Microfluidic can be an effective way to improve sperm quality of infertile male compared to conventional preparation methods. We also found instead of the MACS method, we can use the Zeta potential method according to their costs, for sperm preparation during ART cycle.

P-104 Assessment of sperm motility according to WHO classification using convolutional neural networks

T.B. Haugen[1], S.A. Hicks[2], O. Witczak[1], J.M. Andersen[1], L. Björndahl[3], M.A. Riegler[2]

[1]OsloMet – Oslo Metropolitan University, Department of Life Sciences and Health, Oslo, Norway ;
[2]Simula Metropolitan Center for Digital Engineering, Department of Holistic Systems, Oslo, Norway ;
[3]Karolinska University Hospital and Karolinska Institutet, Anova, Stockholm, Sweden

Study question: How does convolutional neural network (CNN)-predicted sperm motility correlate with manual assessment according to the WHO guidelines.
Summary answer: CNN predicts sperm motility comparable to reference laboratories in the ESHRE-SIGA External Quality Assessment Programme for Semen Analysis.
What is known already: Manual sperm motility assessment according to WHO guidelines is regarded as the gold standard. To obtain reliable and reproducible results, comprehensive training is essential as well as running internal and external quality control. Prediction based on artificial intelligence can potentially transfer human-level performance into models that perform the task faster and can avoid human assessor variations. CNNs have been groundbreaking in image processing. To develop AI models with high predictive power, the data set used should be of high quality and sperm motility assessment based on WHO guidelines.
Study design, size, duration: Videos of 65 fresh semen samples obtained from the ESHRE-SIGA External Quality Assessment Programme for Semen Analysis (from the period 2006-2018) were used in the development of the model. One video was captured for each semen sample. Sperm motility data was obtained from manual assessment of the videos according to WHO criteria by reference laboratories in the programme. Rapid progressive motility was also included. Ten-fold cross-validation was used to compensate for the relatively small dataset.
Participants/materials, setting, methods: The mean values of the reference laboratories were used. Sparse optical flow of the sperm videos was generated from each second of each video and fed into a ResNet50 convolutional neural network. For training, Adam was used to optimize the weights and mean squared error (MSE) to measure loss. For baseline, ZeroR (pseudo regression) was performed. Results are reported as MAE. For correlation analysis, Pearson's r was used.
Main results and the role of chance: Predicting sperm motility based on the optical flow generated from the videos, achieved an average MAE of 0.05 across progressive (0.06), non-progressive (0.04) and immotile sperm (0.05). The ZeroR baseline was 0.09, indicating that the method is able to capture the movement of the spermatozoa and predict motility with low error. Pearson's correlation between manually and AI-predicted motility showed r of 0.88, p<0.001 for progressive, 0.59, p<0.001 for non-progressive and 0.89, p<0.001 for immotile sperm. When predicting rapid progressive motility, the average MAE was 0.07 across rapid progressive (0.11), slow progressive (0.09), non-progressive (0.04) and immotile sperm (0.05). Pearson's correlation analysis between manually and AI-predicted motility showed r of 0.67, p<0.001 for rapid

progressive, 0.41, p<0.001 for slow progressive, 0.51, p<0.001 for non-progressive and 0.88, p<0.001 for immotile sperm. The results show that differentiating between rapid progressive and slow progressive motility is difficult, but the model is still able to do this better than the ZeroR baseline, which was 0.15 for rapid progressive and 0.11 for slow progressive. This is interesting since rapid progressive motility has been regarded challenging to assess. The next step would be to compare the results of the algorithm to the human performance.

Limitations, reasons for caution: The sample size is small. The model is based on videos of high quality, and the performance may not transfer well to videos of lower quality. The performance for rapid progressive motility, which may have an important clinical value, has to be improved.

Wider implications of the findings: This CNN model has a potential to assess sperm motility according to WHO guidelines for progressive motility and immotility. The error values for the automatic predictions are low, and the model shows a good performance taking into account that only videos were used to perform the prediction.

Trial registration number: Not applicable

P-105 Clinical validation of mojo AISA, an artificial intelligence robotic CASA system

M. Monteiro[1], D. Thomas[1], R. Maillot[1], Z. Simon[1], L. Björndahl[2], J. Flanagan[2], M. Taha[1]

[1]mojo fertility, mojo fertility, Lyon, France ;
[2]ANOVA, Karolinska University Hospital, Stockholm, Sweden

Study question: Can a CASA system based on Artificial Intelligence perform as well as manual semen assessment, within the WHO error margins?

Summary answer: The AI-based CASA systems that mimic high quality assessments show great potential for reducing clinical workloads while increasing treatment efficacy.

What is known already: The field of male-factor fertility investigation is still lacking an automated semen analysis system that can be widely clinically adopted. By leveraging state-of-the-art robotics and Artificial Intelligence (AI), it was possible to build mojo AISA which is an AI and robotic platform designed according to WHO recommendation for semen analysis. This system is based on AI software with a unique convolutional neural network (CNN) that detects and measures sperm concentration and motility while ruling out unwanted cells and debris in raw samples.

Study design, size, duration: This study presents and validates the mojo AISA device. A total of 60 patient samples at ANOVA Karolinska University Hospital were collected and results from manual assessment were compared to mojo AISA for concentration and motility. Semen samples were assessed manually (WHO 2010) and concurrently with Mojo AISA. Manual measurements ranged from 1-206M/ml. This study lasted from May 2020 to December 2020 following informed consent and ethics committee practices of ANOVA.

Participants/materials, setting, methods: Sample preparation protocol for mojo AISA consisted of placing two 10ul drops and covering with two 22x22mm coverslip. Manual assessment followed ANOVA EQA procedures akin to the WHO. A CNN was trained using videos captured with mojo AISA as input data. Images were annotated to form a validation set by which the AI was trained. To account for sampling error, videos of Hamilton Thorne Accubeads+ were captured using mojo AISA and the mojo counting chambers.

Main results and the role of chance: Comparing the concentration measured by mojo AISA with the known value for each microbead, results are in agreement of 86%, within the confidence interval of the microbeads. The mean relative error was 6.7% and maximum error was 11%. Therefore, Accubeads+ validation proved no observational error regarding the use of mojo AISA microscope. As for comparing mojo AISA to manual assessment for concentration, Pearson (Spearman) correlation was 0.95 (0.97). The mean relative error was 24.8% and maximum relative error was 71.1%, where 90% of samples were below 50% error. By looking at the concentration range between 10 and 20 M/ml, mojo AISA displayed a mean error of 18.5%. For motility, as comparing mojo AISA to manual assessment, a result of 35.4% mean relative error was obtained. To conclude, mojo's robotic solution shows promise for clinical practice as the AI continues to improve. In 6 months, sperm concentration correlation improved by 3-fold. Next, the AI will be further clinically trained for low concentration.

Limitations, reasons for caution: mojo AISA requires further development, especially for very low concentration ranges, below 5M/ml, due to high sensibility to false positive detections. The same applies to post-vasectomy samples. Additionally, the necessity to compute the motility of each sperm scales poorly with high concentration generating a poor experience for high volume clinics.

Wider implications of the findings: Automation is crucial in several industries. It enables fertility clinics & andrologists to standardize male factor infertility measurements (if paired with widespread standardization of protocols for automation) while enabling them to put more focus on demanding activities of their profession and removes human biases of inter-laboratory performance.

Trial registration number: Not applicable

P-106 The evaluation of dietary score representing the overall effect of men's diet to semen quality on couple's fertility

M. Mitsunami[1], A. Salas-Huetos[1], L. Mínguez-Alarcón[2], J. Attaman[3], J. Ford[4], M. Kathrins[5], I. Souter[3], J. Chavarro[6]

[1]Harvard T.H.Chan school of Public Health, Nutrition, Boston, U.S.A. ;
[2]Harvard T.H.Chan school of Public Health, Environmental Health, Boston, U.S.A. ;
[3]Massachusetts General Hospital, Fertility Center- Vincent Department of Obstetrics and Gynecology, Boston, U.S.A. ;
[4]Harvard T.H.Chan school of Public Health, Epidemiology, Boston, U.S.A. ;
[5]Brigham and Women's Hospital, Urology- Surgery, Boston, U.S.A. ;
[6]Harvard T.H.Chan school of Public Health, Nutrition- Epidemiology, Boston, U.S.A.

Study question: Is men's diet associated with assisted reproductive technology (ART) outcomes?

Summary answer: An empirical dietary score representing the overall effect of men's diet on semen quality was unrelated to ART outcomes.

What is known already: Multiple studies have related various aspects of men's diet to semen quality. Generally, healthier foods, such as fish, vegetables, and fruits, have been related to better semen quality, whereas unhealthy foods, like processed and red meats, have had the opposite relationship. Nevertheless, while bulk semen parameters are important biomarkers of male fertility and a diagnostic cornerstone for male factor infertility, they are imperfect predictors of a couple's fertility.

Study design, size, duration: Couples presenting to the Massachusetts General Hospital Fertility Center between April 2007 and April 2018 were invited to participate in the Environment and Reproductive Health (EARTH) study, a prospective cohort study. Men's diet was assessed with a previously validated food frequency questionnaire. A dietary score reflecting the overall relation of men's food intake with semen quality parameters was empirically derived using reduced rank regression (RRR). The resulting dietary score was related to ART outcomes.

Participants/materials, setting, methods: We used information from 349 men (908 semen samples) to derive the empirical diet pattern and data from 231 couples (407 ART cycles). The primary outcome was the probability of live birth per treatment cycle; secondary outcomes were semen quality, and fertilization, implantation, and clinical pregnancy rates. We evaluated the association between the dietary score and these outcomes using logistic generalized linear mixed models to account for repeated cycles while adjusting for confounders.

Main results and the role of chance: Men had a median baseline age and BMI of 36.8 years and 26.9 kg/m^2, respectively. The empirical diet pattern was significantly associated with all semen parameters. One standard deviation increase in the empirical diet pattern was associated with lower volume (-0.10 standard units [95% CI: -0.17 to -0.04]) and to higher sperm total sperm count (0.13 standard units [0.06 to 0.20]), concentration (0.17 standard units [0.10 to 0.24]), total motility (0.14 standard units [0.07 to 0.20]), progressive motility (0.08 standard units [0.01 to 0.15]), and normal morphology (0.18 standard units [0.11 to 0.25]). Couples with men in the lowest quartile of the empirical score were more likely to have a diagnosis of male infertility than couples with men in the highest quartile (49% vs 24%). Despite the association with semen parameters, the empirical diet score was not related to any clinical outcome of infertility treatment with ART. The adjusted probabilities of implantation, clinical pregnancy and live birth in the lowest and highest quartile of the empirical score were 0.62 (0.50-0.73) and 0.55 (0.45-0.66), 0.57 (0.46-0.69) and 0.50 (0.40-0.61), and 0.49 (0.37-0.62) and 0.36 (0.25-0.48), respectively. Analyses excluding couples with a diagnosis of male factor infertility yielded similar results.

Limitations, reasons for caution: We evaluated the relationship only among couples presenting to a fertility center and therefore it is unclear whether findings can be generalized to couples trying to conceive without ART.
Wider implications of the findings: Given ART is a robust intervention including stringent sperm selection procedures, any effect that empirical diet may have on a couple's chances of conceiving through assisted reproduction is unlikely to reflect the effect of these factors on bulk semen quality parameters.
Trial registration number: The project was funded by ES009718, ES022955, ES026648, and ES000002 from the National Institute of Environmental Health Sciences, and P30DK46200 from the National Institute of Diabetes and Digestive and Kidney Diseases

P-107 Does hematological cancer have the same impact on sperm quality as testicular cancer?

M. Badalotti[1], I. Badalotti-Teloken[2], V. Dornelles[2], C. Teloken[1], M. Hentschke[1], B. Cunegatto[1], E. Pimentel[2], A. Maciel[2], F. Justo[2], A. Petracco[1]

[1]Fertilitat - Reproductive Medicine Center, Clinical, Porto Alegre, Brazil ; [2]Pontifical Catholic University of Rio Grande do Sul- PUCRS, School of Medicine, Porto Alegre, Brazil

Study question: Does hematological cancer have the same impact on sperm quality as testicular cancer before chemo or radiotherapy? Summary answer: Hematological cancer has no impact on sperm quality before treatment.
What is known already: The deleterious effects of chemo and radiotherapy on testicular function are well known. Furthermore, testicular cancer causes a negative impact on sperm quality, even before treatment, probably due to local action. Hematological cancer, particularly Hodgkin lymphoma, seems to produce inflammatory alterations in the testis. However, it is not clear if hematological cancer can compromise spermatogenesis, as does testicular cancer.
Study design, size, duration: Observational, cross-sectional, retrospective study using data from 360 patients seen at a private infertility clinic between 1992 and 2019 for sperm cryopreservation before treatment. The data were collected from electronic records in a prospective database.
Participants/materials, setting, methods: Seminal samples from patients that cryopreserved semen due to hematological or testicular cancer were compared. Sperm analyses were performed according to the 2010's World Health Organization (WHO)'s parameters. Seminal volume, total sperm number, sperm concentration, total and progressive motility, and vitality were analysed. In the hematological group, leukemia and lymphoma, and Hodgkin and non-Hodgkin lymphoma were compared. Student t-tests and Chi-Square were used, considering $p<0.05$ statistically significant.
Main results and the role of chance: This study included 295 patients with testicular cancer (TEST) and 100 with hematological cancer (HEMAT). Patients that had already started chemo or radiotherapy (4 HEMAT and 12 TEST) were excluded, and 4 HEMAT and 15 TEST were azoospermic or cryptozoospermic (41.7% vs. 53,0%, p = 0,792). The other parameters were analysed in 92 HEMAT and 268 TEST. The mean age of the HEMAT group was 28.2 years and 27.9 for the TEST group (p = 0,858). The TEST group had higher rates of oligozoospermia (50.7% vs 31.5%, p = 0.001) and of severe oligozoospermia (29.5% vs 15.2%, p = 0.006) than the HEMAT group. Furthermore, 69.6% HEMAT had normal concentration, compared to 45.9% TEST ($p<0.001$). The mean concentration of the HEMAT group was 35 mi/mL, normal according to the WHO's standards, and the TEST group was 12 mi/mL, below the WHO's normal standards ($p<0.001$). No difference was found when comparing leukemia and lymphoma, or Hodgkin and non-Hodgkin lymphoma.
Limitations, reasons for caution: Besides the fact that this study is retrospective, it also has a small sample size. Furthermore, no analyses regarding sperm morphology were made.
Wider implications of the findings: In this study, testicular cancer had a negative impact on spermatogenesis and sperm quality, whereas hematological cancer did not. However, counseling regarding fertility preservation using sperm banking prior to chemo or radiotherapy should be reinforced in all young cancer patients.
Trial registration number: not applicable

P-108 Which infertile men with normal semen analysis deserve a second semen analysis in the real-life setting?

L. Boeri[1], P. Capogrosso[2], E. Pozzi[3], L. Candela[3], F. Belladelli[3], W. Cazzaniga[3], G. Fallara[3], D. Cignoli[3], N. Schifano[3], E. Ventimiglia[3], M. Alfano[3], G. Colandrea[3], C. Abbate[3], F. Montorsi[3], A. Salonia[3]

[1]UOC Urologia Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico-Dipartimento di Scienze Cliniche e di Comunità- Università degli Studi di Milano, Urology, Milan, Italy ; [2]ASST Sette Laghi – Circolo e Fondazione Macchi Hospital, Urology, Varese, Italy ; [3]Università Vita-Salute San Raffaele- Division of Experimental Oncology/Unit of Urology- URI- IRCCS Ospedale San Raffaele, Urology, Milan, Italy

Study question: Guidelines suggest that one semen analysis is sufficient during the diagnostic work-up of an infertile man in the case of normality as for WHO criteria.
Summary answer: We investigated the rate and the clinical features of men with abnormal sperm parameters at a second test, after a normal first semen analysis.
What is known already: A second test is recommended when the first semen analysis depicted abnormal sperm parameters.
Study design, size, duration: Complete demographic, clinical and laboratory data from 1358 consecutive primary infertile men (infertility as for WHO definition) were analysed. Health-significant comorbidities were scored with the Charlson Comorbidity Index (CCI). Serum hormones were measured in every patient. Patients underwent two consecutive semen analyses at the same laboratory, which followed 2010 WHO reference criteria.
Participants/materials, setting, methods: Descriptive statistics and logistic regression models tested the association between clinical variables and semen parameters. Receiver operative characteristic (ROC) curves were used to assess the relationship between clinical variables and to create a composite risk score for pathological sperm parameters at a second test.
Main results and the role of chance: At first analysis, 212 (15.6%) infertile men had normal semen parameters. Of 212, 87 (41.0%) had a second normal semen analysis, while 80 (37.7%), 35 (16.5%) and 10 (4.7%) men showed 1, 2 and 3 pathological sperm parameters at second test. Men with a pathological second semen analysis had higher CCI scores ($p<0.001$), smaller testicular volume ($p<0.001$) and higher FSH values ($p<0.01$) than those with normal second samples. Overall, despite being within normal ranges, sperm concentration was lower [34 (23-57) vs. 62 (35-94); $p<0.01$] in men with an abnormal second sample compared to those with confirmed normality. At multivariable logistic regression analysis, smaller testicular volume (OR 0.9, p=0.03), FSH (OR 1.2, $p<0.01$), and lower sperm concentration (OR 0.9, $p<0.01$) were associated with pathological second semen analyses, after accounting for age and CCI. ROC curves showed that testicular volume <15 ml, FSH values >6 mUI/ml and sperm concentration <40 mil/ml had good predictive ability for pathologic second sperm parameters (all AUC >0.8). Considering 1-point for each of the previous variables, the chances of a pathological second analysis increased from 38.8% to 74.6%, 77.3% and 100% among patients with risk scores of 0, 1, 2 and 3, respectively ($p<0.001$).
Limitations, reasons for caution: It is a retrospective analysis at a single, tertiary-referral academic centre, thus raising the possibility of selection biases. In spite of this, all patients have been consistently analysed over time with a rigorous follow-up, thus limiting potential heterogeneity in terms of data reporting.
Wider implications of the findings: Approximately 60% of infertile men with a normal semen analysis depicted a pathological second test. Smaller testicles, higher FSH, lower sperm concentrations were independently associated with a pathologic second test. These features could be useful to identify those infertile men with a normal semen analysis who deserve a second test.
Trial registration number: not applicable

P-109 Comparison between the outcome of sperm vitrification protocol and conventional slow freezing protocol for semen cryopreservation

K. Patel[1], N. Sharma[2], V. Mishra[3], R. Aggarwal[3], A. Suthar[2], H. Sheth[2]

[1]IKDRC-hospital, IVF UNIT, ahemdabad, India ; [2]IKDRC Hospital - IVF Unit, Embryology, Ahmedabad, India ; [3]IKDRC Hospital - IVF Unit, obs and gynae, Ahmedabad, India

Study question: Does sperm vitrification technique helps in increasing sperm survival and low DNA fragmentation index post warming.

Summary answer: Sperm vitrification protocol results in better motility, high progression and low DNA fragmentation index as compared to slow freezing.
What is known already: Cryopreservation is ceasing and resuming the cell metabolism, which can be achieved by different techniques like slow freezing and vitrification .Vitrification allows solidification of the cells and extracellular milieu into a glass like state without formation of ice which protects intracellular and extracellular ice formation, and further helps in avoiding different types of cryo-injuries and cellular damage. Study design, size, duration: Comparative study from July 2019 to Oct 2020 in IVF unit of IKDRC Hospital. Two hundred and ten patients were randomized by computer generated list and divided into two groups. Group 1 (n= 110) samples cryopreserved by vitrification and Group 2 (n=100) samples cryopreserved by conventional slow freezing.
Participants/materials, setting, methods: Semen sample were analyzed by WHO 2010 laboratory manual, including all normozoospermic samples , other abnormal samples were excluded from the study . Method of semen preparation before cryopreservation is similar for both the groups, double density gradient method of preparation was used . Semen sample with high viscosity, hypo and hyper-spermia were also excluded. Similar cryovials of 2ml volume were used for both groups.
Main results and the role of chance: In group 1 where samples were cryopreserved by vitrification sperm motility was (54.3 % vs 49.2%)vs in group 2 where samples were cryopreserved by slow freezing , non- significant difference were observed , but progressive motility was significantly higher in group 1 as compared to group 2 (36.8%vs17.9%) and DNA fragmentation index is significantly lower in group 1 vitrification than in group 2slow freezing (9.7% vs 20%).
Limitations, reasons for caution: Technical proficiency of the operator to avoid human errors and still larger randomized control studies are needed to strengthen these results
Wider implications of the findings: Our study demonstrates that vitrification is better than slow freezing of human sperm, improved survival rates with high progression were found with vitrification and low DNA fragmentation index were also observed in samples cryopreserved with vitrification protocol.
Trial registration number: not applicable

P-110 Does the Body Mass Index affect sperm quality?

I. Badalotti-Teloken[1], C. Teloken[2], V. Dornelles[1], A. Arent[2], A. Petracco[2], M. Badalotti[2]

[1]Pontifical Catholic University of Rio Grande do Sul - PUCRS, School of Medicine, Porto Alegre, Brazil ;
[2]Fertilitat - Reproductive Medicine Center, Clinical, Porto Alegre, Brazil

Study question: Does the body mass index (BMI) have an impact on semen analysis results?
Summary answer: The increase in BMI has a negative impact on sperm motility.
What is known already: Obesity is an increasingly prevalent health condition worldwide and can affect male fertility in various ways. It is known that obesity can cause testicular inflammation, higher testicular temperature, hypogonadism, sperm DNA fragmentation, and erectile dysfunction. However, there are still conflicting data regarding the correlation between BMI and semen parameters in the seminal analysis.
Study design, size, duration: Observational, cross-sectional, retrospective study using data from 1147 patients seen at a private infertility clinic between 2010 and 2020. The data were collected from electronic records in a prospective database.
Participants/materials, setting, methods: Patients were divided according to BMI (healthy weight, overweight, obesity classes I, II, III), and their seminal profiles were compared, according to 2010's World Health Organization's parameters. Cancer, cryptorchidism, viral orchitis, altered karyotype, Y chromosome microdeletions, vasectomy reversion, and testosterone use were excluding factors. Student t-tests and multiple linear regression were used for statistical analysis. The results were adjusted for age, alcohol, tobacco, and drug use, medication intake, physical activity, comorbidities, and scrotum heat factors.
Main results and the role of chance: From a total of 1384 patients, 219 were excluded. The BMI varied between 18,9 and 50,8 kg/m². From the 1147 patients, 297 had BMI 18.5-24.9 kg/m² (healthy weight, group 1), 611 had BMI 25-29.9 kg/m² (overweight, group 2), 179 had BMI 30-34.5 kg/m² (obese, group 3), 60 had BMI ≥ 35 kg/m² (extremely obese, group 4). The mean age for groups 1 through 4 was 37.6, 38.5, 38.2, and 36.5 years old. The comparison of the groups' seminal parameters shows a significant decrease in progressive and total motility in patients with BMI ≥ 35 kg/m².The progressive motility was 43.8% in group 1, 44.1% in group 2, 42.4% in group 3, and 35.2% in group 4 (p=0.07) and the total motility was 54.4%, 54.1%, 53.6%, and 45.9%, respectively (p=0.012). The complementary analysis determined BMI 29 kg/m² as the cutoff for negative impact on progressive motility (p=0.044) and 31 kg/m² on total motility (p=0.036). The results were still significant after age, use of cannabis, and hypertension adjustments – the other possible interfering factors were not significant.
Limitations, reasons for caution: Besides the fact that this was a retrospective study, it also has a smaller sample size of patients with extreme obesity. This is probably related to the fact that the patients seeking reproductive treatment in a private clinic have a greater purchasing power and lower prevalence of obesity.
Wider implications of the findings: In this study, sperm quality is negatively affected by BMI, with impairment since 29 kg/m² for progressive and 31 kg/m² for total motility. Our data support the potential deleterious role of obesity on semen parameters, reinforcing the importance of weight control in infertility prevention.
Trial registration number: not applicable

P-111 Development of a flow cytometric assay for membrane lipid oxidation in human sperm

L. Bosman[1], P. Ellis[1], S. Homa[1], D. Griffin[1]

[1]University of Kent, School of Biosciences, Canterbury, United Kingdom

Study question: Is a commercially available lipid peroxidation assay sensitive enough to detect sperm lipid membrane damage and thus provide a novel indicator of male fertility status?
Summary answer: Provisional results demonstrate the novelty of creating a protocol to identify and quantify sperm lipid membrane damage and indicate possible insight into individual male fertility.
What is known already: Cytotoxic lipid aldehydes such as 4-hydroxynonenal (4HNE) created by the damaging effects of reactive oxygen species (ROS) have been studied extensively in sperm, as an indicator of male fertility. This is due to their connection with detrimental effects on sperm function such as morphology, acrosome reactions, motility and fertilization of the oocyte. Although literature states the mechanisms of damage caused to the lipid membrane of the sperm cell, there is no evidence of its quantification or usage as a commercial fertility indicator for human males.
Study design, size, duration: Since the assay is still being developed, there is no formal study size or duration. The goal of this pilot study is to determine whether a commercial lipid peroxidation assay can detect the difference between sperm with high levels of oxidative damage and control sperm cells. We used the remains of sperm samples initially collected for standard semen analysis, which were flash-frozen and then assayed with / without hydrogen peroxide treatment to induce oxidative damage.
Participants/materials, setting, methods: Frozen sperm from consenting donors (n=21) were washed, optionally treated with hydrogen peroxide to induce oxidative damage, stained with a commercially available lipid peroxidation sensor (LPS, Abcam ab243377), and the resulting fluorescence quantitated by flow cytometry. Assay optimization varied the numbers of sperm input to the protocol, the concentration of the peroxidation sensor, the amount and duration of hydrogen peroxide treatment and the effect of paraformaldehyde (PFA) fixation of samples before or after staining.
Main results and the role of chance: Successful detection of lipid damage in control samples

We observed a significant difference at a p-value < 0.05 between untreated samples and all positive controls with hydrogen peroxide concentrations stronger than 500uM ($p < 0.038$) . This indicates that we can detect sperm bearing oxidative damage, and establishes the conditions required to make a positive control sample.

Establishment of assay parameters

Results indicate the concentration of sperm input to the protocol is not a significant factor for concentrations below 5 million/ml. Low concentration samples thus do not require further dilution before testing.

Correlation with DNA damage

A significant direct strong positive Pearson correlation coefficient (R = 0.93, p < 0.023) was found between samples with low DNA fragmentation index (DFI (%), measured by flow cytometric staining with acridine orange) and the LPS flow cytometric data (%).
Limitations, reasons for caution: As yet our data only addresses high level lipid damage induced by peroxide treatment. It remains to be established whether it is possible to detect endogenous LPO damage due to oxidative stress in semen. Future work will correlate our data with motility information and oxidative stress data (measured by MiOXSYS).
Wider implications of the findings: If we are able to develop a direct assay for sperm LPO, this will allow an additional avenue for testing patients with unexplained male infertility, which could in turn affect treatment choices and ART methodology. Improved diagnosis and treatment will potentially improve the lives of families with their fertility matters.
Trial registration number: Not applicable

P-112 Association between dietary total antioxidant capacity and semen quality parameters in male partners of couples attempting fertility

G. Eslamian[1], S. Rohani[2], N. Shoaibinobarian[2]

[1]Shahid Beheshti University of Medical Science, Department of Clinical Nutrition and Dietetics, Tehran, Iran ;
[2]School of Medical Sciences and Technologies- Islamic Azad University- Science and Research Branch, Department of Nutrition, Tehran, Iran

Study question: Is there any association between dietary total antioxidant capacity (TAC) and semen quality parameters in male partners of couples attempting fertility?
Summary answer: Greater adherence to diets high in TAC was significantly associated with higher total sperm count, sperm concentration, and sperm motility.
What is known already: Among multiple factors that affect the etiology of poor semen quality and male infertility, dietary factors have an important contribution. Also, chronic oxidative stress negatively effects semen quality. Whether adherence to the diet rich in antioxidants is associated with better semen quality remains largely unexplored.The concentration of single antioxidant cannot show the total antioxidant power of the diet, therefore the concept of dietary total antioxidant capacity (TAC) was invented.Dietary scores are useful approach to evaluate the degree of adherence to specific dietary pattern and its benefits in regard to health
Study design, size, duration: This was a cross-sectional study of 350 men from couples attending a fertility center in Tehran, Iran, recruited between June 2015 and September 2019. Men aged 25–50 years with complete dietary data were analyzed.
Participants/materials, setting, methods: Diet was assessed via a reproducible and valid 168-item semi-quantitative food frequency questionnaire to determine the entire antioxidants of the usual diet in order to calculate dietary TAC. Semen quality was assessed according to World Health Organization 2010 guidelines. The association between dietary TAC and semen parameters were assessed adjusting for potential confounders through multiple logistic regression analysis.
Main results and the role of chance: The average age of study participants was 34.9 ± 7.6 years and their BMI was 28.5 ± 4.3 kg/m^2. Participants in the lower tertile of the dietary TAC were lower educated ($p < 0.01$), more physically active ($p < 0.05$), and predominantly had abnormal sperm progressive motility ($p < 0.01$). In the multivariable adjusted models, men in the lowest tertile of the dietary TAC Score had 2.9 times higher likelihood of having abnormal sperm motility, total sperm count and concentration, compared to men in the highest tertile of the TAC score ($p < 0.05$).
Limitations, reasons for caution: The main limitation of our study was its cross-sectional design, limiting our ability to derive causal association.
Wider implications of the findings: Our study suggests that dietary pattern comprising mainly of antioxidant nutrients may help improve semen quality. Our results are consistent with previous studies showing that plant-based diet contains higher levels of antioxidants are associated with better measures of semen quality.
Trial registration number: not applicable

P-113 α-tubulin and tyrosine phosphorylation immunolocalization on human sperm from a globozoospermic patient with proper embryo development after ICSI

L. Robles-Gómez[1], P. Sáez-Espinosa[1], L. López-Ortega[2], J. Aizpurua[2], M.J. Gómez-Torres[1]

[1]University of Alicante, Biotecnology, San Vicente del Raspeig, Spain ;
[2]IVF Spain, IVF Spain, Alicante, Spain

Study question: Can novel sperm biomarkers, such as α-tubulin and tyrosine phosphorylation, help to predict the fertilizing potential osf a globozoospermic sample?
Summary answer: The characterization of α-tubulin and tyrosine phosphorylation provide additional information that could be useful to determine the fertilizing capacity of the globozoospermic samples.
What is known already: Globozoospermia is a severe disorder characterized by the acrosome absence and other sperm alterations such as tail structural disorders and chromatin condensation abnormalities. This set of defects makes globozoospermia correlates with primary infertility and low fertilisation rates. Therefore, additional studies are necessary to know how the globozoospermia affects the disposition of α-tubulin and tyrosine phosphorylation and the relationship between embryo development and pregnancy. In this context, previous studies have independently described different patterns of α-tubulin and tyrosine phosphorylation in normozoospermic samples. Specifically, the continuous α-tubulin distribution along the flagellum and tyrosine phosphorylation have been recently linked to proper sperm functionality.
Study design, size, duration: We conducted a prospective study. The sample was obtained from a globozoospermic patient in October 2019. This sample was divided into two fractions, one proceeded to ICSI and the another was fixed to characterize α-tubulin and tyrosine phosphorylation using confocal microscopy. A total of 200 sperm were analyzed for each biomarker.
Participants/materials, setting, methods: A 38-year-old man requested assisted reproduction in IVF Spain after a failed treatment with no fertilized oocytes. The clinical procedure was performed at IVF Spain and the characterization studies were made at the University of Alicante. The flagellar cytoskeleton was assessed using anti-α-tubulin antibody (Sigma-Aldrich) at a 1:600 dilution. Besides, tyrosine phosphorylation was detected using anti-phosphotyrosine primary antibody (PY20, Sigma-Aldrich) at a 1:500 dilution. Spermatozoa were evaluated using a confocal microscope (Zeiss LSM 800).
Main results and the role of chance: Regarding the α-tubulin characterization, only the 33% of spermatozoa showed continuous labelling in the tail and in the 67% the fluorescence appeared in the terminal piece of the flagellum. Otherwise, we only observed 0.5% of positive tyrosine phosphorylation in the studied cells, whereas the 99.5% of sperm analyzed did not show positive fluorescence. The clinical parameters showed a fertilization rate of 20% with only one embryo after the MII oocyte artificial activation by calcium ionophore. The embryo development was further adequate, and it acquired Bt5AA status on day five. Unfortunately, the pregnancy did not ensue after the embryo transfer.
Limitations, reasons for caution: The main limitation of this study was that due to the very low frequency of globozoospermia (<0.01%) this research was conducted only in one patient. Thus, the present results are preliminary. We need to characterize the aforementioned biomarkers in additional globozoospermic samples to establish relationships with clinical parameters.
Wider implications of the findings: The study of potential candidate biomarkers like α-tubulin and tyrosine phosphorylation in globozoospermia and the linkage with clinical parameters would facilitate the diagnosis and improve the selection of more effective treatment techniques.
Trial registration number: not applicable

P-114 Correlation of GSTM1 polymorphism and oxidative stress with male infertility

D. Mavrogianni[1], A. Voitse[1], L. Evgeni[2], S. Stavros[1], P. Drakakis[1]

[1]University Of Athens School Of Medicine, First Department of Obstetrics and Gynecology, Athens, Greece ;
[2]Cryogonia, Sperm Cryopreservation Bank, Athens, Greece

Study question: Is GSTM1 polymorphism a putative biomarker of male infertility. Is there a possible correlation between GSTM1 presence, oxidative stress and male infertility?
Summary answer: A possible correlation may be established between GSTM1 polymorphism, and sperm mobility and morphology. Additionally oxidative potential may also be associated with fertility.
What is known already: Approximately 7% of men worldwide are affected by male infertility, which contributes to 40-50% of all infertility cases. Basic sperm analysis remains the main procedure of diagnosing male infertility, although there is still doubt whether it provides accurate clinical outcomes More accurate tests are essential for the diagnosis of male infertility. Oxidative stress is involved in the etiology of male infertility, with 30% to 80% of infertile men having increased levels of sperm free radicals. Recent research has shown that oxidative stress when combined with GSTM1-null genotype negatively affected the sperm quality of infertility group compared to the control group.
Study design, size, duration: Ninety semen samples were collected and divided into 2 groups. The study group consisted of sperm samples from 51 men identified as infertile according to WHO guidelines(case group).Sperm samples from 39 men with normal sperm count parameters (control group) were used for the control group.
Participants/materials, setting, methods: For all samples a sperm diagram was performed. and DNA was extracted. Polymerase chain reaction with specific for GSTM1 gene primers followed by agarose electrophoresis was applied to detect the presence of polymorphism. The MiOXSYS method was used to detect the oxidative potential.
Main results and the role of chance: This study shows that in the control group the presence of polymorphism was associated with a reduced number of immobile sperm cells (p= 0,035) while it appears to affect the normal morphology of the sperm(p=0,042). In the infertility group the presence of the gene was significantly correlated with age(p = 0.046). No statistically significant difference was observed for the presence of the polymorphism between the 2 groups.In addition, we investigated the effect of oxidative potential with the MiOXSYS system and its relationship with sperm parameters. It was found that the two groups differed significantly when measuring oxidative potential, and that oxidoreduction potential affects sperm concentration/ml, total sperm count, type B motility and viscosity in the infertile male group.
Limitations, reasons for caution: A larger sample size could increase the accuracy of the results.
Wider implications of the findings: Studying the relation of the oxidative stress with sperm parameters may lead to the establishment of a genetic profile of increased risk of infertility, which would be of major importance especially in cases of idiopathic infertility.
Trial registration number: Not applicable

P-115 Supplementation of healthy Sertoli cells into culture media containing follicle stimulating hormone (FSH)/testosterone (T) has no advantage in germ cell maturation

S. Aydos[1], Y. Yukselten[1], T. Ozkan[1], S. Ozkavukcu[2], M. Erdogan[1], A. Sunguroglu[1], K. Aydos[3]

[1]Ankara University- School of Medicine, Department of Medical Biology, Ankara, Turkey ;
[2]Ankara University- School of Medicine, Department of Histology and Embryology, Ankara, Turkey ;
[3]Ankara University- School of Medicine, Department of Urology, Ankara, Turkey

Study question: In nonobstructive azoospermia (NOA) cases, whether supplementation of healthy Sertoli cells (SCs) has an effect on spermatogenic differentiation in culture medium containing FSH/T.
Summary answer: Expression of Crem and Acrosin increased significantly in both medium with FSH/T and medium with additional healthy SCs but there was no difference between them
What is known already: In NOA the induction of spermatogonial stem cells (SSCs) proliferation and differentiation has been demonstrated using different culture systems. SCs have vital roles in the regulation of spermatogenesis. Hormonal control of spermatogenesis is through FSH and T activity on SCs. Growth factors secreted by SCs via FSH, stimulate proliferation and colonization of SSCs. Although germ cells do not express androgen receptors, FSH receptors are localized on spermatogonia. It is not clear whether native SCs are sufficient for FSH/T added to the culture medium to be effective in induction of spermatogenesis, and whether supplementation of healthy SCs will increase this activity.
Study design, size, duration: 34 NOA and 12 obstructive azoospermia (OA) cases were included. Testicular tissue samples were taken with testicular sperm extraction (TESE) in the study and control groups. In a group of fertile cases, healthy Sertoli cells were identified and purified and then cryopreserved. Tissue samples of each case prepared in standard DMEM/F12 medium were processed in 2 separate environments containing FSH/T and FSH/T plus thawed healthy SCs for 7 days.
Participants/materials, setting, methods: The characterization of healthy SCs isolated from fertile cases was done by flow cytometry (FC) and immunohistochemistry using antibodies specific for GATA4 and vimentin. FITC-conjugated annexin V/PI staining and MTT assay were performed to compare the viability and proliferation of SCs before and after freezing. FC was used to measure the 7th day levels of specific markers expressed in spermatogonia (Vasa), meiotic cells (Crem) and post-meiotic cells (Protamine-2 and Acrosin).
Main results and the role of chance: In Annexin V staining, no difference was found in percentages of live and apoptotic SCs, and MTT exhibited that cryopreservation didn't inhibite the SCs proliferation compared to the pre-freezing state. Vasa and Acrosin basal levels were found to be lower in infertile patients compared to the control group (8.2% *vs.* 30.6% and 12.8% *vs.* 30.5%, $p<0.05$). Compared to day 0 measurements, on the 7th day in FSH/T environment, Crem level increased by 58.8% and Acrosin level increased by 195.5% ($p<0.05$). Similarly, in medium supplemented with healthy SCs, by day 7, the Crem and Acrosin levels were increased to 92.2% and 204.8%, respectively ($p<0.05$). Although Vasa and Protamine levels increased in both groups, they did not reach a significant level. No significant difference was found between the 7th day increase rates of Crem, Vasa, Acrosin and Protamine-2 in either FSH/T-containing medium or in medium additionally supplemented with healthy SCs (58.8% *vs.* 92.2%, 120.6% *vs.* 79.4%, 195.5% *vs.* 204.8% and 232.3% *vs.* 198.4%, respectively, $p>0.05$). Our results suggest that freezing-thawing process would not impair the viability and proliferation of SCs, and adding healthy SCs to the culture medium to correct impaired gene expression does not have an advantage over FSH/T.
Limitations, reasons for caution: The 7-day culture period we determined might be not sufficient for spermatogenic differentiation completion. This period could be extended in order to see further morphological differentiation may need.
Wider implications of the findings: The failure of the culture media containing FSH/T to show the expected effectiveness could be thought to be due to the SCs' inadequate response to these hormones. Therefore, healthy SCs supplementation would be needed, but this could pose ethical issues. Our findings show that it is not necessary.

[4]Hôpitaux Universitaires de Strasbourg, Centre d'aide médicale à la procréation, Strasbourg, France ;
[5]Hôpitaux Universitaires de Strasbourg- Unistra, Service d'urologie, Strasbourg, France ;
[6]IGBMC- Hôpitaux Universitaires de Strasbourg- Unistra, Functional genomics and cancer, Strasbourg, France ;
[7]IGBMC- CECOS- Hôpitaux Universitaires de Strasbourg- Unistra, Functional genomics and cancer, Strasbourg, France

Study question: What is the outcome of testicular sperm extraction (TESE) after microinjection of frozen–thawed sperm and the correlation with histological analysis in azoospermic patients?
Summary answer: In our cohort of 240 azoospermic patients, sperm could be retrieved in 167 patients (69.6%).
What is known already: Testicular biopsy is a crucial assessment in reproductive practice with diagnostic and prognostic importance for ICSI. Divers histological procedures are used throughout the centres. There is increasing need to accurately analyse histological biopsies in order to characterise different type of spermatogenic failure and allows data storage of value in clinical practice and research. Compared with Bouin's and formalin, glutaraldehyde fixed and semithin section of testicular biopsies have the advantage of yielding not only good cellular morphology but also it allows the possibility of performing electron microscopy.
Study design, size, duration: This is a monocentric retrospective study of TESE practice in azoospermic patients in Strasbourg University Hospital from February 2011 to December 2019.
Participants/materials, setting, methods: A total of 240 azoospermic patients underwent TESE followed by sperm cryopreservation when sperm were present and data of histological analysis and clinical outcome of ICSI were analysed. The analysis include initial hormonal status, type of azoospermia, body max index, classification of histological findings, freezing rate and outcome of ICSI-IVF procedure.
Main results and the role of chance: The mean age of 240 patients was 34.5 years. Out of all patients, 42% were diagnosed with obstructive azoospermia (OA) and 58% patients with non-obstructive azoospermia (NOA). There was no correlation of sperm retrieval with the body mass index. Overall, sperm could be retrieved in 69.6% patients. Spermatozoa were always successfully recovered in patients with normal testicular histological findings, 41.7% patients (n 100). Histological analysis revealed a Sertoli cell-only (SCO) syndrome in 27.5% cases (n 66), hypospermatogenesis in 14.2% (n 34), germ cell arrest in 7.9 (n 19) and mixed pattern in 8.3% (n 20).

In patients with serum FSH concentrations >12 IU/l, 46% of patients (n 42) sperm were present at TESE. In patients with no sperm retrieval, 31.5% had normal FSH levels. Out of all men with elevated FSH, 63% had SCO pattern, 4% germ cell arrest, 21% hypospermatogenesis and 12% mixt patterns. In the group of patients with no sperm retrieved at TESE, histological analysis showed SCO in 69.9% cases, germ cell arrest in 15% and hypospermatogenesis in 9.6% of cases. Out of 167 patients with TESE and sperm cryopreservation, 126 patients undergone ICSI-IVF procedure and 80 babies were born.
Limitations, reasons for caution: This study is a retrospective analysis in a single centre. The cohort was not compared with groups of patients with different histological and fixation techniques.
Wider implications of the findings: Accurate histological diagnosis is a prerequisite for research and clinical data collection and open the possibilities to include patients with NOA in subsequent detailed genetic screen.
Trial registration number: NA

P-117 Bioinformatic analysis of NRF2 in the study of association of NRF2 variant and male infertility related to smoking status

D. Aydos[1], O.S. Aydos[2], Y. Yukselten[2], A. Sunguroglu[2], K. Aydos[2]

[1]Ankara University Stem Cell Institute, Department of Stem Cells and Regenerative Medicine, Ankara, Turkey ;
[2]Ankara University Faculty of Medicine, Department of Medical Biology, Ankara, Turkey

Study question: Could *Nrf2* polymorphism (-617C>A; rs6721961) and oxidative stress (OS)-induced changes of signature seminal plasma (SP) miRNAs related to Nrf2 provide possible biomarkers of male infertility?
Summary answer: -617C>A SNP is associated with infertility through sperm OS DNA damage and miR-582-5p and miR-20a-5p, differentially represented between spermatozoa of smokers-non-smokers, might regulate Nrf2/ARE axis.
What is known already: As an extrinsic factor causing OS, smoking decreases male infertility by causing sperm membrane damage and DNA fragmentation. Expression of proteins related to the antioxidant defense system and phase 2 detoxifying enzymes controlled mainly by Nrf2/ARE pathway components is vital in managing OS-induced DNA damage. miRNAs, which multiple of are produced abundantly in male germ cells throughout spermatogenesis, have been detected in SP and contribute to multiple biological processes related to male reproductive events. miRNA-expression alterations may be induced in response to OS and without involving DNA sequence changes, miRNAs can provide additional mechanism of regulating the *Nrf2* gene expression.
Study design, size, duration: Wild-type (WT) and SNP (-617) alleles in the *Nrf2* gene were studied in 100 infertile cases and 100 controls and their associations with seminal parameters in relation to smoking status were assessed. In infertile cases, sperm DNA damage level was determined and compared among *Nrf2* genotypes. Interactions between differentially expressed miRNAs (DEMIs) in response to smoking and Nrf2/ARE pathway components were visualized on a miRNA-mRNA regulatory network using CluePedia (v1.5.7) plugin of Cytoscape software (v3.8.2).
Participants/materials, setting, methods: Polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) was utilized to genotype the *Nrf2* SNP (-617). DNA damages were analyzed by Comet assay. DEMIs were identified by a comprehensive bioinformatics analysis using the miRNA expression dataset GSE44134 downloaded from the GEO database. Predicted targets of DEMIs in smokers were identified by mirDIP portal. Known interactions between Nrf2 and its first neighbors were visualized after selecting STRING-actions, miRTarBase and miRecords validated miRNA source files from CluePedia panel.
Main results and the role of chance: There was significant difference for *Nrf2* polymorphism between fertile and infertile males. The A allele was detected more frequently in the patient group; ($P = 0.001$). The frequencies of the C and A alleles of the *Nrf2* were 62% and 38% in patients, and 78% and 44% in control group. The AA genotype was higher in the infertiles; 14% vs. 3% ($P = 0.001$). In smokers, sperm quality decreased significantly in AA genotype. The risk of DNA damage was highest with 224.58 AU in the AA genotype group, whereas it is the lowest with 164.56 AU in those carrying the CC genotype ($P < 0.005$). 21 differentially expressed miRNAs (including 7 downregulated and 14 upregulated in smokers) were identified. Among the upregulated DEMIs, miR-582-5p, miR-20a-5p, miR-573, miR-186-5p, miR-499a-5p were found to target the *Nrf2* mRNA, suggesting their usage as biomarkers capable of indicating the antioxidant ability of the male reproductive system. The interrelations between Nrf2/Nrf2 direct interactors and DEMIs revealed the regulatory role of hsa-miR-20a-5p in SQSTM1/p62-Keap1-Nrf2 axis linked to selective autophagy. hsa-miR-582-5p was found to regulate the JNK/Jun/caspase-3 pathway, previously shown to be activated in response to OS, in which JUN can activate or suppress the *Nrf2* expression.
Limitations, reasons for caution: Small number of cases while evaluating the effect of smoking weakens our ability to generalize the results. Including other coexisting factors and larger patient groups carrying other functional variants of *Nrf2* as well as confirming the results at the protein level would further strengthen the results of the study.
Wider implications of the findings: This study is the first to report -617C>A polymorphism in the *Nrf2* gene in the Turkish population and such a SNP may cause impaired fertility in men, especially in smokers, through oxidative metabolism. Considering these data may be valuable in determining risk groups.
Trial registration number: N/A

P-118 A sperm selection technique to mitigate paternal contributions to embryo aneuploidy

D. Keating[1], M. Haddad[1], D. Tavares[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can microfluidic sperm selection (MFSS) select male gametes without sperm chromatin fragmentation (SCF) and double-stranded DNA breaks (dsDNA) in order to generate euploid conceptuses?
Summary answer: Couples treated by ICSI with MFSS had significantly improved embryo ploidy rates and pregnancy outcomes, demonstrating the efficacy of this novel selection method.
What is known already: SCF has been linked to infertility, specifically to embryo developmental and implantation failure. This damage can be both single-stranded (ssDNA) or double-stranded (dsDNA). Recent studies have shown that dsDNA in particular causes chromosomal aberrations and contributes to embryo aneuploidy, which leads to implantation failure.

Study design, size, duration: Consenting couples treated at our center by intracytoplasmic sperm injection (ICSI) with spermatozoa selected by MFSS were included. The majority of these couples had a medical history significant for elevated SCF, recurrent implantation failure, and embryo aneuploidy. ICSI clinical outcome, as well as preimplantation genetic testing for aneuploidy (PGT-A) and frozen embryo transfer (FET), was recorded and compared to the couples' historical treatments following sperm selection by density gradient centrifugation (DGC).
Participants/materials, setting, methods: From 2016 to 2020, 51 consenting men had their ejaculates screened for SCF levels by terminal deoxynucleotidyl dUTP transferase nick-end labeling (TUNEL) using a commercially available kit. At least 500 spermatozoa were assessed per patient, with a normal threshold of ≤15%.

To screen for dsDNA, neutral Comet using a modified in-house protocol was also performed in a pilot study. At least 200 spermatozoa were assessed per patient, with a normal threshold of ≤3%.
Main results and the role of chance: A total of 51 men (average age, 41.0±8 years) had mean sperm concentrations of 39.0±33x106/mL, 38.4±12% motility, and 2.1±1% normal morphology. Following DGC and MFSS, the concentrations were 4.7±8 and 4.3±8x106/mL and the motility was 64.0±33 and 98.0±3%, respectively (P<0.0001). The average SCF decreased from 20.1±18% in the ejaculate to 16±3% following DGC, but was 2.9±4% after MFSS. The dsDNA fell from 3.4±3% in raw specimens to 2.9±1% after DGC, and to only 0.5±0.7% following MFSS (P<0.0001).

These men underwent ICSI with their female partners (average age, 37.3±4 years), with sperm selected by DGC; they achieved a fertilization rate of 56.4% (337/597) with 26.0% euploid embryos (36/139). FET cycles from these embryos yielded an implantation rate of 8.3% (2/24) and a clinical pregnancy rate (CPR) of 15.4% (2/13), but both miscarried.

These couples then underwent ICSI with MFSS, with a fertilization rate of 78.0% (588/754; P<0.0001) and 50.0% (172/344; P<0.0001) euploid embryos after PGT-A. A total of 37 embryos have been replaced, with an implantation rate of 67.6% (25/37; P<0.0001) and a CPR of 73.5% (25/34; P<0.001), with an ongoing/delivery rate of 70.6% (24/34; P<0.0001).
Limitations, reasons for caution: While the oocyte contribution cannot be discounted, MFSS was able to yield spermatozoa that had the highest motility and ability to produce euploid embryos following ICSI.
Wider implications of the findings: The genome and epigenome of the spermatozoon, and their contribution to reproductive outcomes, are being vigorously explored and scrutinized. Alternative approaches to gamete selection, such as MFSS, in couples with elevated SCF and dsDNA provide the best chances for future pregnancies by mitigating embryo aneuploidy.
Trial registration number: not applicable

P-119 The correlation between sperm chromatin fragmentation and intrauterine insemination outcome

M. Haddad[1], D. Tavares[1], P. Xie[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Does sperm genomic integrity affect the intrauterine insemination (IUI) outcomes in couples with unexplained infertility and young maternal age?
Summary answer: Spermatozoa with higher genomic integrity are correlated with higher clinical pregnancy rates in couples with unexplained infertility undergoing IUI.
What is known already: It is known that elevated sperm chromatin fragmentation (SCF) on the male gamete affects embryo development and implantation. This is particularly relevant in IVF as well as programmed intercourse and IUI. By complementing the standard semen analysis with an SCF assay, we can assess the competence of the male gamete and its ability to generate euploid embryos and healthy offspring. Elevated SCF has been used as a way to identify subtle male factor infertility in couples undergoing IUI with poor pregnancy outcomes in order to plan for further treatments.
Study design, size, duration: This is a retrospective cohort study of IUI outcomes of couples with young maternal age and a negative infertility workup treated at our center from 2016–2020. Terminal deoxynucleotidyl dUTP transferase nick-end labeling (TUNEL) assay was used to assess sperm genomic integrity. Couples were grouped based on SCF level: normal (≤15%) or abnormal (>15%). Rates of clinical pregnancy, defined as the presence of a fetal heartbeat, were compared between the groups following IUI.
Participants/materials, setting, methods: A total of 189 consenting couples, in which the female partner had a normal uterine cavity and patent fallopian tubes, underwent 454 IUI attempts. Only women ≤37 years old were included to control for age-related confounding factors. At least 500 spermatozoa were assessed per patient, and a threshold of ≤15% was considered normal. Women were either untreated for natural cycle IUI or stimulated with clomiphene citrate, gonadotropins, or Letrozole.
Main results and the role of chance: A total of 454 IUI cycles were reported at our center; 302 of these were carried out in 132 couples in which the male partner had normal SCF averaged at 9.29%. The average maternal age was 34.1±3 years, and the average paternal age was 37.1±5 years. These men had the following semen parameters: a concentration of 46.2±5x106/mL, 43.8±3% motility, and an average SCF of 9.3±3%. There were 45 documented clinical pregnancies (45/302, 14.9%) as confirmed by the presence of at least one fetal heartbeat detected by ultrasound; 26 delivered, 9 are ongoing, 5 were spontaneous abortions, and 5 were lost to follow-up. A total of 57 couples in which the male partner (37.2±5.9 years) had abnormal SCF underwent 152 IUI cycles (maternal age, 34.0±2.7 years). The men had the following semen parameters: an average SCF of 23.8±10 (p<0.0001), a concentration of 26.0±10 x106/ml, and 40.1±4% motility. These IUI attempts yielded a clinical pregnancy rate of only 4.6% (7/152; P<0.0001); 4 delivered and 3 were spontaneous abortions.
Limitations, reasons for caution: This study is a retrospective cohort analysis of a relatively small number of patients. Furthermore, most patients were screened for SCF due to at least one prior IUI failure. A prospective, randomized trial, in which men are concurrently screened for SCF levels at the first IUI attempt, would be ideal.
Wider implications of the findings: Assessment of SCF at the initial male infertility screening can be a useful tool to investigate the competence of the male gamete. Screening couples with idiopathic infertility for a subtle male factor would guide those with higher SCF toward alternative reproductive treatments to avoid unnecessary IUI treatments.
Trial registration number: Not applicable

P-120 Selecting spermatozoa with the highest genomic integrity in order to enhance clinical outcomes in men with high DNA fragmentation levels

D. Tavares[1], P. Xie[1], M. Haddad[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: What are the best methods of selecting spermatozoa with the highest genomic integrity in order to improve embryo implantation and term pregnancy rates with ICSI?
Summary answer: Testicular or ejaculate spermatozoa isolated by microfluidic sperm selection (MFSS) were characterized by superior genomic integrity with improved clinical pregnancy and delivery rates.
What is known already: In couples with unexplained infertility, a subtle male factor can often be identified. Both single-strand (ss) and double-strand (ds) DNA nicks and breaks hinder the ability of the male gamete to support embryonic development. Surgical retrieval of spermatozoa from the proximal male genital tract can prevent their exposure to oxidative stress. Moreover, use of membrane-based microfluidics chips has been shown to allow for selection of the most progressively motile spermatozoa with higher genomic integrity.
Study design, size, duration: Over the course of 48 months, 86 consenting men presenting with high sperm chromatin fragmentation (SCF) in their ejaculate with prior ART failure underwent a subsequent cycle with specimens retrieved by testicular biopsy or ejaculate processed by MFSS. A concurrent TUNEL assay was performed on samples collected or selected by each method. Sperm specimens of both origins were utilized for ICSI cycles. Semen parameters, chromatin integrity, and pregnancy outcomes were compared between the two methods.
Participants/materials, setting, methods: Fresh ejaculates from consenting men were collected for standard semen analysis (WHO 2010). Testicular biopsy and MFSS were used to isolate spermatozoa with a higher genomic integrity after previous ART failure. SCF was assessed by terminal deoxynucleotidyl transferase dUTP nick-end labeling (TUNEL) on at least 500 spermatozoa under a

fluorescent microscope with a threshold of ≥15%. MFSS was carried out by Zymot® chips. ICSI was performed in the standard fashion.

Main results and the role of chance: A total of 86 men (36.5±5 years) had the following semen parameters: volume of 2.6 ±1mL, concentration of 27.0±33 x 106/mL, 35.6±15% motility, and high SCF (24.1±10%). They underwent 146 ICSI cycles with their partners (maternal age, 33.7±3) resulting in a high incidence of pregnancy loss (100%; 13/13). Of those who failed to conceive, 22 couples used surgically retrieved spermatozoa (SRS) with a concentration of 1.8 ± 4 x 106/mL (*P*<0.01), 5.0±11% motility (*P*<0.01), and an SCF of 12.6 ± 6% (*P*<0.0001). SRS was used in 37 ICSI cycles, yielding a fertilization rate of 61.6% (204/331, *P*<0.01), an implantation rate of 10.6% (9/85, *P*<0.01), a CPR of 23.5% (8/34, *P*<0.01), and a delivery rate of 17.6% (6/34, *P*<0.01). Another 24 couples underwent ICSI cycles with ejaculated spermatozoa processed by MFSS with a concentration of 1.8±3 x 106/mL *(P*<0.01), but an increased motility of 99±1% (*P*<0.01) and an SCF of 1.2 ±1%, lower than both the raw and testicular specimens (*P*<0.0001). MFSS-processed specimens resulted in a fertilization rate of 76% (335/441, *P*<0.01), an implantation rate of 26.3% (15/57, *P*<0.05), and a CPR of 67.9% (19/28, *P*<0.01), of which 15 patients delivered and 2 pregnancies are ongoing (89.5%; *P*<0.01).

Limitations, reasons for caution: This is a preliminary study on a small number of subjects. A randomized prospective study conducted on a larger cohort would be required to confirm our findings.

Wider implications of the findings: SCF severely affects pregnancy by impairing embryonic development, consequently promoting implantation failure. While retrieving spermatozoa from the germinal epithelium is a viable option, MFSS provides an alternative. Although MFSS requires an adequate number of sperm with good kinetic characteristics, it provides a more palatable option, reducing surgical risk and costs.

Trial registration number: Not Applicable

P-121 Selection and separation of X- and Y- chromosome-bearing mammalian sperm using SPERMAN technology

B. Özkösem[1], A. Fiori[2], O. Sami[3]

[1]Pera Labs, Founder, Philadelphia, U.S.A. ;
[2]Pera Labs, r&d, Philadelphia, U.S.A. ;
[3]Pera Labs, Product, Philadelphia, U.S.A.

Study question: How can we select and separate X and Y-chromosome bearing sperm cells without causing cellular damage and reduced fertility?

Summary answer: AI powered SPERMAN technology can sort X and Y-chromosome bearing sperm populations without using harmful fluorescent dyes and lasers.

What is known already: Most common and reliable method to sex sorting (separation of X and Y- chromosome bearing sperm cells) is by using fluorescence activated cell sorting (FACS) which takes advantage of the difference of amount of DNA in X and Y-chromosomes. Unfortunately this method causes reduced fertility and cellular damages due to the lasers and fluorescent dyes that are used. There are new and experimental developments in sex-sorting such as using immunological approaches to separate sperm cells. Current sorting method damages sperm cells. However, there is no automated and easy to use sperm sorting technology available.

Study design, size, duration: In this study, we have compared the quality parameters (motility, viability, AR status, DNA packaging) of sorted sperm cells to unsorted sperm cells. We have used epididymal sperm samples from 10 C57BL/6 mice (Charles River) and frozen semen samples from 6 Holstein bulls (Sexing Technologies) and frozen semen samples from 8 human sperm donors (Fairfax Cryobank). Samples were divided into two groups: sex-sorted and unsorted sperm.

Participants/materials, setting, methods: Sperm samples from 8-week-old C57BL/6 mice were collected from epididymal region, frozen bull semen samples and human semen samples were thawed at 37°C then separated into two groups as sorted and unsorted sperm. Sorted samples in modified SP-TALP medium were loaded on the microfluidic chip of Sperman device, after the 30min long sorting process ended, all samples were centrifuged gently at 100g for 5 min, quality parameters were measured by using CASA and FACS.

Main results and the role of chance: Sperman device sorted X-bearing sperm cells at 81% purity and Y-bearing cells at 73% in mouse samples. Sperman device was able to sort X-bearing sperm cells at 78% purity and Y-bearing cells at 70% in bull samples.S perman device sorted X-bearing sperm cells at 85% purity and Y-bearing cells at 76% in human samples.

Our study shows that in mouse, bull and human sperm samples, sperm DNA quality, sperm concentration, progressive motility and AR status results from the sorting with SPERMAN device are comparable with the unsorted samples. For sperm DNA quality, both the Spearman rank correlation coefficient and concordance correlation coefficient are above 0.97, indicating a high agreement between the unsorted samples and SPERMAN sorted samples.

Limitations, reasons for caution: In this study we only compared sperm quality parameters between unsorted sperm cells and Sperman-sorted sperm cells. Ideally a follow up study would be to look in detail at fertilization success rates and embryo growth. Also, genomic and proteomic profiles of unsorted and sorted sperm cells could be different.

Wider implications of the findings: In livestock, sperm sex sorting has high value in terms of economic impact on the livestock management. Unfortunately, there is one expensive single technology dominates the sex-sorting market causing high fees poor outcomes. We believe that Sperman technology provides farmers more cheaper and better sex-sorting technology.

Trial registration number: not applicable

P-122 Benefit of use of theophilline in ICSI with testicular sperm

M. Be. Khelif. Jerbi[1], I. Chabchoub[1], S. Sfaxi[1], M.H. Be. aribia[1], S. Mnallah[1], M. Khrouf[2], K. Terras[2], F. Zhioua[2], K. Mahmoud[2], H. Elloumi[1]

[1]Clinique la ROSE, Biology department of FERTILLIA center, Tunis, Tunisia ;
[2]Clinique la ROSE, Gynecology department of FERTILLIA Center, Tunis, Tunisia

Study question: Would the use of theophylline have an effect on ICSI outcomes?

Summary answer: The cumulative pregnancy rate after the transfer of fresh and frozen embryos (FET) becomes more important justifying the addition of theophylline as an efficacy variable.

What is known already: Absolute immotile spermatozoa is one of the most important causes of reduced fertilization and pregnancy rates after ICSI, immotility of testicular spermatozoa is a physiological event resulting from metabolic sperm immaturity. Over the years, there have been numerous attempts to resolve this problem by identification of pharmacological agents that might improve sperm motility. In particular, theophylline turned out to be an effective tool in stimulating motility in human semen and identifying viable sperm in testicular sperm extraction sperm (TESE) patients. aim of this study is to evaluate ICSI outcomes after the use of theophylline to select viable spermatozoa

Study design, size, duration: This prospective, comparative randomised study was conducted in Fertillia ART center in Tunisia, between november 2017 to november 2020. All patients underwent ICSI cycles with testicular sperm were included. The exclusion criteria consist of cycles with female partner age >42 years and/or cycles with no information about pregnancy outcomes. In our study, the cycles were categorized into two groups according to sperm selection method used in ICSI procdure.

Participants/materials, setting, methods: The present study include 678 cycles. This cohort was randomly divided into two groups according to method of spermatozoa selection. Treatements arms were performed by theophylline to improve sperm motility (Group A) and the Hyposmotic swelling (HOS) test to indicate sperm vitality (Group B). Clinical and biological parameters, the duration of sperm selection and ICSI outcomes were compared between the two groups. A statistical significant difference was accepted when the p value was <0.05.

Main results and the role of chance: Baseline clinical parameters were found to be comparable in the two groups. No differences regarding number of oocytes retrieved or MII oocytes were reported . he sperm selection was easier in the group A (time interval : 12±7,2 minutes) than group B (time interval : 22±10 minutes) (p<0,05). No significative difference was observed between goups in the Fertilization rate (group A : 66% vs group B : 68%) ; Cleavage rate (group A : 76.20% vs. Group B : 75.56%) and Blasulation rate (group A : 63.60% vs. Group B 60.61%) p>0 ,05. The Cumulative Pregnancy rate for group A (31. 5%) was higher than group B (30%, p>0 ,05). Indeed, The rate of frozen cycles is significantly higher for group A compared to group B (30% vs. 4.5% p<0,05).

Limitations, reasons for caution: Need large sample size.
Wider implications of the findings: Theophylline reduces significantly the time needed for sperm selection, Which positively affects the ICSI result.
Trial registration number: Not applicable

P-123 How to develop accurate Computer Assisted Sperm Analysis (CASA) AI in the absence of protocol standardization and abundance of human error when performing semen analyses?

Z. Simon[1], R. Maillot[1], M. Monteiro[1], S. Rogers[2], A. Mania[3], L. Bjorndahl[4], S. Homa[5], D. Thomas[1], M. Taha[1]
[1]mojo, lyon, lyon, France ;
[2]The Hospital Fertility Group, Alder Close, Eastbourne, United Kingdom ;
[3]Kings Fertility, London, London, United Kingdom ;
[4]ANOVA- Karolinska University Hospital, Stockholm, Stockholm, Sweden ;
[5]Kent University, Kent, Kent, United Kingdom

Study question: How can an automation & artificial intelligent tools be developed to perform according to WHO recommendations?
Summary answer: Developing CASA performs at < 20% error margin requires AI trained with high quality datasets and a robotic system adheres to WHO guidelines.
What is known already: A survey of 40 andrology laboratories, in 22 countries, revealed that > 90% had nonconformities in correct use of equipment, standardisation of protocols and quality control, leading to a lack of compliance to WHO protocols. Conventional CASA systems can standardize analysis, but controversy has occurred due to differences between manual and automated analyses stemming from: 1) all cells in a semen sample are detected including debris; 2) protocol variation when compared to top-notch manual analysis. The first point can be addressed by AI. The second point can be addressed by robotics designed to adhere to WHO guidelines.
Study design, size, duration: A mojo AISA (AI-powered semen analysis) system was placed in four clinical laboratories mentioned above capturing images of over 300 samples, one million images were generated over a course of 2 years. Mojo AISA's AI was trained on data collected from the four clinics using robotic system is developed according to WHO guidelines.
Participants/materials, setting, methods: For an AI to detect sperm accurately, sperm samples were captured using mojo AISA smart microscopy and then the extracted sperm images expertly annotated. To evaluate the system-ability for semen analysis, fresh sample were analysed for concentration and motility by a manual operator and compared to a mojo AISA test.
Main results and the role of chance: To train the sperm detection AI, representative sperm images were carefully captured using mojo AISA and processed according to the following criteria:

- the number of images and videos to train and to test the model: 50,000 spermatozoon head and tails with various variations
- the variety of images: data used to train the AI has to be representative of the population that will undergo the analysis: 1) wide concentration ranges from 0 to 300 M/ml, 2) high and low density of debris and cells, 3) Presence of slight aggregations
- careful and precise annotation: expert andrology scientists annotated sperm images and identify objects to exclude, such as debris in seminal plasma, Mojo AISA is an attempt strictly build CASA AI system to WHO-guidelines. The marriage of AI and robotics automation has shown a promising results to mimic humans when measuring a semen sample and attempt to obtain results comparable to the manual analysis.

mojo AISA's performance improved three-fold (from 0,85 to 0,95 Pearson sperm count correlation and from >100% means relative error to 25% mean relative error).
Limitations, reasons for caution: Lack of standardization for semen analysis laboratory process globally is a bottleneck towards building a robust multi-center study, on-site CASA testing and generating an actionable data pool for studying the causes behind male fertility declineWider implications of the findings: Key learnings for parties advancing developing AI based on images and videos for application in the fertility space.
Trial registration number: not applicable

P-124 The beneficial effects of novel quercetin delivery system (loaded on bigel) on male fertility parameters of Non-alcoholic fatty liver model: an in-vivo (rat model) study

E. Hosseini[1,2], S.N. Mousavi[2,3], M.S. Seye. Dorraj[4], S. Sheik. Mohammadi[4], Z. Pourmansoori[5], M.H. Rasulifard[4], M. Doosti[4], H. Chiti[2]
[1]Department of Obstetrics and Gynecology, IVF Clinic- Mousavi Hospital- School of Medicine- Zanjan University of Medical Sciences, Zanjan, Iran ;
[2]Zanjan Metabolic Diseases Research Center, Zanjan University of Medical Sciences, Zanjan, Iran ;
[3]Department of Nutrition- School of Medicine, Zanjan University of Medical Sciences, Zanjan, Iran ;
[4]Applied Chemistry Research Laboratory- Department of Chemistry, Faculty of Science- University of Zanjan, Zanjan, Iran ;
[5]Department of Pharmacology- School of Medicine, Zanjan University of Medical Sciences, Zanjan, Iran

Study question: Dose quercetin encapsulated in a bigel slow- release delivery system improve male fertility parameters in Non-alcoholic fatty liver (NAFLD) model
Summary answer: Quercetin in a bigel slow- release delivery system can boost semen parameters in NAFLD rat model
What is known already: Recent molecular and physiological studies have shown that adverse effects of NAFLD extend far beyond the liver. NAFLD can impair male reproductive function by increasing Reactive Oxidative Stress (ROS) levels, reducing the expression of antioxidant genes and inducing damage in testes immune privilege.

Antioxidant therapy and its effectiveness depend on whether the exogenous antioxidant will be readily absorbed to reach high enough that are required to decrease the pathological damages.

Quercetin, as an antioxidant, is able to ameliorate oxidative stress. The design of new drug delivery systems using encapsulating antioxidant can boost its durability and effectiveness.
Study design, size, duration: Bigels were prepared using cottonseed oil/cannabis oil/alginate/ferula gum. Sprague-Dawley rats are housed for 2 weeks, then NAFLD was induced by 58% of dietary calorie as lard and 42 g/L fructose for 16 weeks. The experimental protocol was approved by the ethical committee of Zanjan University of Medical Sciences, Zanjan, Iran.
Participants/materials, setting, methods: After confirming the NAFLD induction, animals divided into five groups: Control, control NAFLD, received 2 mg/kg Quer loaded on bigels, free bigels, free Quer for 45 days as daily gavage. Semen parameters (count, motility, and morphology), viability (Eosin-nigrosine staining) and serum testosterone levels were analyzed. In addition, histological sections of testicular tissues were investigated by Hematoxylin-Eosin (H&E) staining method. In situ detection of apoptosis was performed using terminal deoxynucleotidyl-transferase dUTP nick end labeling (TUNEL) assay.
Main results and the role of chance: The sperm count, sperm motility, normal morphology and testosterone level were significantly lower in the NAFLD group than those the controls. Moreover, higher head and tail abnormality percentages were seen in the sperm of these groups. Bigel-Quer significantly improved the serum testosterone level, sperm count, motility, and morphology compared with the NAFLD group. Spermatogenic cells in all stages of differentiation (spermatogonia, primary spermatocytes, early spermatids, late spermatids) are observed and preserved normally in the testicular tubules and lumen filled with mature sperms in the control group. Interestingly, atrophic changes in the testicular tubule architecture with swelling in spermatogonia cells, detachment from tubule membrane, reduced number of mature sperm, and reduced lumen thickness were seen in the NAFLD. In the Quer, bigel and bigel-Quer-treated groups, swelling and vacuolation rate of germ cells decreased. The testicular morphology, and tubule structure were significantly normalized, especially in the bigel-Quer-treated group. Serum testosterone levels significantly increased and reached the healthy control group in the bigel-Quer group. TUNEL-positive cells in testes increased significantly after NAFLD induction. Quantitative analysis showed a significant decrease in testicular TUNEL-positive cells following bigel-Quer treatment, but not in other groups.
Limitations, reasons for caution: Keeping and daily handling of animals for long-time in animal house for diet-induced NAFLD. NAFLD requires long

periods of treatment to get the desired outcome especially in the case of sperm parameters investigation.
Wider implications of the findings: The bigel showed synergistic effects with Quer for treating infertility in male rats with NAFLD. Stability and bio-availability of Quer are important aspects that should be considered to justify its supplementation. Empowering antioxidant shield of NAFLD patients by Quer supplementation can improve various damage effects and clinical status of diseases.
Trial registration number: Not Applicable

P-125 Evaluation of N-acetylcysteine (NAC) effect on in vitro culture of immature mouse testis following vitrification

P. Nikoosokhan[1], B. Ebrahimi[1], A. Alizadeh[1], S. Hajiaghalou[1]

[1]Royan Institute for Reproductive Biomedicine- ACECR-, Department of Embryology- Reproductive Biomedicine Research Center, Tehran, Iran

Study question: Can the Culture of cryopreserved immature mouse testicular tissue in the presence of NAC improves the developmental process and prevent apoptosis induction during the culture?
Summary answer: An appropriate dosage of NAC in the culture medium of immature mouse testicular tissue was associated with increased cell survival and spermatogonia stem cell regeneration.
What is known already: Spermatogonial stem cells (SSCs) are the most advanced type of stem cells in the testes of prepubertal boys which are the main targets of oncological treatments. Therefore, the only possible alternative to maintain fertility in prepubertal boys is to preserve SSCs before their depletion by cryopreserving the testicular tissue. Despite the possibility of obtaining viable spermatozoa using cryopreserved testicular tissue cultivated in vitro,cryopreservation methods and damages caused by the culture procedure would be obstacles for maintaining the testicular tissueand it seems that optimizing the culture condition is vital.
Study design, size, duration: Testis tissues were harvested from 6-days-old immature NMRI male mice (n=100) after cervical dislocation and vitrified. After 3 days testicular biopsies were warmed and distributed into control, culture I (not supplemented with NAC) and culture II (supplemented with NAC) groups. To determine the appropriate NAC concentration 8 different dosages of NAC were evaluated in terms of cell survival and the best dose, a culture medium containing 125mmol/L NAC was selected to continue the study.
Participants/materials, setting, methods: Vitrified-warmed fragments (2mm3) obtaining from immature NMRI mice were cultured in vitro for 7 days on agar gel. The effects of culture conditions were assessed by Morphological evaluation of seminiferous tubules (using Hematoxylin-eosin staining). Cell viability, protein expression (caspase-3), and gene expression (Bax, Bcl2, Caspase-3, plzf) were evaluated by flow cytometry, immunofluorescence staining, and real time polymerase chain reaction respectively. Additionally, Malondialdehyde (MDA) concentration in the culture medium was measured by MAD Assay Kit.
Main results and the role of chance: Significant ($p<0.01$) increase in cell viability was observed in the culture II group after 7 days of culture compared to the culture I. Bax/Bcl2 ratio was significantly ($p<0.01$) lower in the culture II group compared to the control and culture I group. The expression of caspase-3 showed a significant ($p<0.001$) increase in the culture II group while immunofluorescence analysis showed low expression of it in all groups. These results were consistent with the high level of Bcl2expression that inhibited Caspase-3 expression and consequently the inhibition of apoptosis, and on the other hand, the presence of NAC showed that plzf expressions significantly ($p<0.001$) increased in culture II group compared to the control and culture I group. Although the presence of NAC did not inhibit all the deleterious effects of culture medium on tissue morphology, NAC was able to maintain better integrity of tissue and seminiferous tubules within central regions compared to the group without NAC. The decrease in MDA level in the presence of NAC (culture II) was also a good indicator to confirm the desired results obtained from the presence of NAC in the culture medium.
Limitations, reasons for caution: Although the findings of the study were satisfactory in mice tissue after 1 week of culture, it is essential to replicate the experiments using human tissue and evaluate the quality and reproductive potential of surviving spermatogonia after long-term storage to become clinically applicable.
Wider implications of the findings: This study highlights the necessity for further experiments to improve the testicular tissue culture conditions for better spermatogonial survival and differentiation to sperm, as the prepubertal fertility restoration methods are promising to be implemented in the clinic in the near future.
Trial registration number: Not Applicable

P-126 A comparison of the efficacy of sperm freezing using high security tubes versus high security straws

A. Bañuelo. Linares[1], K. Berrisford[1], L. Kellam[1], A. Campbell[2]

[1]CARE Fertility Nottingham, Embryology, Nottingham, United Kingdom ; [2]CARE Fertility, Embryology, Nottingham, United Kingdom

Study question: Are there any advantages in using High security tubes rather than High Security straws for conventional slow sperm freezing?
Summary answer: Freezing sperm in High Security tubes (HST) improved post-thaw recovery rate and motility, and also reduced processing and handling compared to High Security straws (HSS).
What is known already: The use of High Security freezing consumables (HSFC) in an IVF setting is a safe and effective way of eliminating concerns related to viral cross-contamination during storage. The lower diameter of HSS does make them susceptible to warming during handling. The HSFC used in this study is the only CE marked products that are made of resin, leak-proof and shatter-proof in all cryogenic temperatures even in LN2. No previous studies have compared the use of HST with HSS for conventional human sperm freezing. This study sets out to investigate the performance of HST compared to HSS.
Study design, size, duration: The study was designed as a controlled split-sample study with blind post-thaw analysis. Following the routine WHO analysis of 20 semen samples, the remainder of each of the samples was evenly divided and cryopreserved by conventional slow freezing in each of the two different HSFC. The freeze was conducted simultaneously by the same practitioner, employing the same freezing protocol and cryoprotectant. The pre-freeze and post-thaw concentration, total and progressive sperm motility were recorded.
Participants/materials, setting, methods: At one IVF clinic, semen samples with sperm density ≥15million/ml, ≥40% motility, ≥1.5ml were included. Cryoprotectant (SpermFreeze, Fertipro) was added dropwise to unprepared semen and kept at room temperature for 10 minutes before loading into HSFC (0.5ml CBS™HSS; CBS™HST). HSFC were heat-sealed (SYMS; SYMSIII sealers) and placed in vapour for 30 minutes before plunging into LN2. Samples were thawed by immersion in a 37C° water bath for 5 minutes and analysed using WHO methods.
Main results and the role of chance: Paired-t test was used to compare the percentage motility between the different HSFC. All analysis was considered statistically significant when $p<0.01$.

We demonstrated that the sperm recovery rate (Percentage total motility post-thaw/ Percentage total motility pre-freeze) in HST was 66.63 ± 14.94 (mean ± standard deviation) compared to 40.80 ± 14.69 in HSS.

In the HSS, the percentage post-thaw total motility was 19.99 ± 7.21 and the percentage post-thaw progressive motility was 12.26 ± 2.59. In the HST, the percentage post-thaw total motility was 32.57 ± 8.33 and the percentage post-thaw progressive motility was 23.08 ± 5.53. The overall improvement when using HST against HSS was 12.53 ± 5.69, 10.44 ± 5.29 for the total motility and the progressive motility respectively.

Comments were recorded regarding the handling and the condition of the HSS and HST for each freeze event. Neither device displayed any leakage of LN2 or any explosion during the warming. The freezing process was easier and faster using HST rather than HSS. It was also noted that the entire sample can be recovered from the HST, unlike the HSS.
Limitations, reasons for caution: The study looked at sperm recovery in terms of motility only. DNA damage was not considered as a parameter of sperm quality. Also, fertilization, pregnancy rates, live birth rates and the use of poorer quality sperm samples have not been investigated.
Wider implications of the findings: For conventional sperm freezing, the use of HST resulted in improved sperm motility and progression post-thaw, when compared to HSS. This finding supports the use of HST to improve the post thaw quality of sperm, benefitting patients with own frozen samples, recipients of donor sperm and donor sperm banks.
Trial registration number: Not applicable.

P-127 Does sperm quality really matter for conceiving through an intrauterine insemination program? A retrospective analysis of 5920 attempts taking into account repetition of cycles

A. Torre[1], F. Boitrelle[2], N. Swierkowsk. Blanchard[3], K. Fathallah[4], M. Bendayan[5], M. Benchaib[6]

[1]Centre Hospitalier Universitaire de Rouen, Service de Gynécologie Obstétrique - Département de Médecine de la Reproduction, Rouen, France ;
[2]Université s de Versaille Saint Quentin en yvelines, Biologie de la Reproduction, Poissy, France ;
[3]Centre Hospitalier Intercommunal de Poissy Saint Germaine en Laye, Medecine de la Reproduction, Poissy, France ;
[4]Centre Hospitalier Intercommunal de Poissy Saint Germain en Laye, Médecine de la Reproduction, Poissy, France ;
[5]Université de Versaille Saint Quentin en Yvelines, Médecine de la Reproduction, Poissy, France ;
[6]Université Claude Bernard Lyon 1, Médecine de la Reproduction, Lyon - Bron, France

Study question: Are parameters of sperm quality part of the prognosis factors for an infertile couple to obtain a live birth when entering an intrauterine insemination program considering repetition of attempts?
Summary answer: Paradoxically, a lower sperm morphology independently predict quick live birth through IUI, as well as younger female age, lower D3 FSH, and higher triggering estradiol.
What is known already: Many studies have highlighted different prognosis factors for obtaining a live birth after IUI involving:

- male parameters (semen),
- female parameters (age, parity, ovulation, tubal, and endometriosis status, history of pelvic surgery),
- couple parameters (duration of infertility, number of previous attempt),
- IUI parameters (follicle number, endometrial thickness, estradiol at triggering, day of IUI, number of spermatozoa inseminated).

However, most of these studies have included small number of attempts, semen parameters were either not collected or assessed with heterogeneity, and repetition of attempts (although iconic for IUI) was not considered, allocating inappropriate weight to cycles which failed in conceiving.
Study design, size, duration: We retrospectively studied the entire cohort of IUI attempts carried out with partner's sperm at our center between 09/09/2003 and 01/17/2017. We included all male, female, couple and IUI parameters available. Each basic semen analyzes included have been carried out by a restricted number of skilled andrologists from our center. The closest semen assessment performed before IUI was considered as male parameter. IUI attempts were considered repeated unless a live birth or IUI abandonment occurred.
Participants/materials, setting, methods: Our primary outcome was live birth occurrence. We included 2228 couples having performed 5920 IUI attempts, with 636 live births obtained. A mixed logistic regression model was used to take into account IUI repetition before obtaining a live birth. A survival analysis using Cox model, with IUI rank as time variable, live birth as endpoint, and taking into account recurrences was carried out to determine which parameter best predict a quick live birth through IUI.
Main results and the role of chance: Included women were 33.7 ± 4.6 years old in mean. Baseline semen assessment was available for 64% of couples.
Muti-variate analysis showed that live birth was more frequent when:

- Femal factors: age was young (33 to 38yo, OR 0.76 [0.60;0.96], >38 yo OR 0.49 [0.35;0.67], p=0.0001), FSH ≤ 8.0 (OR 0.59 [0.45;0.79], p=0.0002), AMH > 8.9ng/mL (OR 0.59 [0.45;0.79], p=0.0001), endometriosis was absent (OR 0.56 [0.36;0.88], p=0.0109), the patient already delivered (OR 1.36 [1.06;1.74], p=0.0034)
- Male factors: sperm motility ≤26.0% (OR 0.71 [0.53;0.96], p=0.0062), sperm vitality ≤72.0% (OR 0.65 [0.47;0.90], p=0.0032), sperm typical form ≤ 25.0% (OR 0.51 [0.34 ; 0.78], p=0.0016),
- IUI attempt factors: total dose of gonadotropin > 495.0 (OR 1.54 [1.26;1.88], p=0.0001) follicle number > 2 (OR 1.23 [1.69;2.21], p=0.0296), Estradiol at trigerring > 215.0pg/ml (OR 1.90 [1.53;2.36], p=0.0001), Endometrial thickness >9.6mm (OR 1.43, p=0.0024), day of IUI >13 (1.53 [1.24;1.89], p=0.0001).

Using Cox model, couples obtained quickly a livebirth if:

- woman age was below 33yo: For 33 to 38 yo, OR 0.37 [0.25;0.54], p=0.0001, >38yo OR 0.19 [0.11;0.32], p=0.0001
- D3 FSH<8 (if above, OR 0.55 [0.34;0.90], p=0.0160) - Sperm typical form ≤25.0 (if above, OR 0.34 [0.20;0.58], p=0.0001)
- Triggering estradiol >215.0pg/ml, OR 1.99 [1.51;2.63], p=0.0001)

Limitations, reasons for caution: Baseline semen assessment was missing a bit more when cycles were successful, so that a bias connot be excluded. This weird result concerning semen parameters which appear to lower the live birth rate when they are good should thus be considered with caution.
Wider implications of the findings: Good baseline semen parameters do not appear as primordial for obtaining an IUI live birth, and were even found deleterious. However, thresholds highlighted in the present study were high, i.e. of limited clinical mean, and semen below them to remain normal. After confirming, explanations should be investigated: excessive acrosome reaction.
Trial registration number: Not applicable

P-128 Audit of testicular sperm in assisted conception for non-azoospermic infertile couples

C. Merrett[1], D. Schlager[2], E. Yasmin[3], S. Seshadri[4], P. Serhal[3], D. Ralph[1], P. Sangster

[1]University College London Hospital, Andrology, London, United Kingdom ;
[2]University of Freiburg, Department of Urology, Hugstetter, Germany ;
[3]University College London Hospital, Reproductive Medicine, London, United Kingdom ;
[4]The Centre for Reproductive & Genetic Health, Reproductive Medicine, London, United Kingdom

Study question: What live birth rate do we see when we use testicular sperm in ART for non-azoospermic couples after at least one previous failed cycle?
Summary answer: In our cohort of couples 24% had a live birth using testicular sperm and therefore was not higher than national average ART rates.
What is known already: There is increased interest in using testicular sperm in assisted reproduction technology (ART) to improve outcomes after previous failed cycles. Mehta et al. reported results of a 50% live birth rate using testicular sperm in the first cycle for couples with oligospermia and a history of failed cycles with ejaculated sperm. We aim to audit our results in a similar population of couples.
Study design, size, duration: St Peters Andrology Centre in London, United Kingdom completed 128 surgical testicular sperm retrievals reviewed between the two-year period of 2018-2019. We conducted a retrospective audit of their paper-based records to identify those couples with injectable sperm on their semen analysis and who had previous cycles attempts using ejaculated sperm.
Participants/materials, setting, methods: We identified 27 couples who underwent testicular sperm extraction despite having an ejaculated semen analysis with injectable sperm and at least one previous failed cycle. A systematic review of their paper and electronic medical record was conducted to assess live birth rates and fertilization rates from ART.
Main results and the role of chance: Couples had an average male age of 41 (range 31-60) and an average female age of 38 (range 30-45). The men had an average serum testosterone of 15 nmol/L (range 8-35 nmol/L) and an average serum FSH of 8.9 IU/L (range 1.7-30 IU/L). 59% (n=17) of men had a DNA fragmentation index completed with an average score of 41% (range 31%-51[Y1]%). In the women the mean serum anti-Müllerian hormone (AMH) was 15.8 pmol/l (range 1-64 pmol/l). With ejaculated sperm the fertilization rate was 59% (95% CI [27%, 59%]) and blastocyst conversion rate was 43% (95% CI [50%, 69%]). There was no statistical significance with testicular sperm where the fertilization rate was 58% (95% CI [51%, 65%]) and blastocyst conversion rate was 54% (95% CI [40%, 67%]). Overall, there were 7 clinical pregnancies in this population of couples. Of these clinical pregnancies, 2 miscarried and 5 progressed to a live birth. This audit yielded a live birth rate per cycle of 15% and a live birth rate per couple of 24%.
Limitations, reasons for caution: Limitations of the study are low number of patients and absence of a control group.

Wider implications of the findings: We recommend caution and further analysis going forward using testicular sperm in ART where ejaculated sperm in available.
Trial registration number: not applicable

P-129 Follicular extracellular vesicles of women with polycystic ovarian syndrome inhibit oocyte maturation

C. Liu[1], M. Wang[1], H. Yao[1], M. Cui[1], X. Gong[1], H. Zhang[1], C. Sui[1]
[1]Tongji Hospital- Tongji Medical College- Huazhong University of Science and Technology, Reproductive Medicine Center, Wuhan, China

Study question: Does follicular extracellular vesicles of women with polycystic ovarian syndrome (PCOS-EVs) interfere with the quality of oocytes?
Summary answer: PCOS-EVs induced oxidative stress in the oocytes and inhibited oocyte maturation by increasing the abnormal mitochondria distribution and abnormal spindle rates.
What is known already: Polycystic ovarian syndrome (PCOS) is a common endocrine disorder in women of reproductive age, with a prevalence up to 10%. Women with PCOS are characterized by a clustering of features, including hyperandrogenism, polycystic ovarian morphology, and notably, anovulation. Although international guidelines recommend assisted reproduction techniques to be an effective resort for PCOS patients to conceive. However, even after overcoming ovulatory dysfunction via ovulation induction, the pregnancy outcomes of patients with PCOS were far from satisfying with lower fertilization, cleavage, and implantation rates, implicating that theoocyte quality of these patients are affected. Whereas the mechanisms have not been elucidated yet.
Study design, size, duration: Follicular fluid of PCOS patients (n=10) and healthy controls (n=10) were collected and used for extracellular vesicles (EVs) isolation via ultracentrifugation. Germinal vesicle (GV) oocytes collected from female ICR mice were cocultured with RIF-EVs or FER-EVs, respectively, and PBS served as a blank control. GV breakdown (GVBD) rate and maturation rate were calculated at two-hour and fourteen-hour of co-culture, respectively. Besides, oocyte mitochondria distribution, meiosis spindle morphology, and oxidative status were assessed in different groups.
Participants/materials, setting, methods: EVs were determined by western blotting, nanoparticle tracking analysis, and transmission electron microscopy. Fluorescence labeled EVs were used to visualize internalization by oocytes. Oocytes mitochondria and mitosis spindles were stained with fluorescence, and abnormal mitochondria rate or abnormal spindle rate was calculated. Reactive oxygen species (ROS) level was detected in the differently treated oocytes. Moreover, the expression of CAT, GSS, and SOD was determined in the oocytes using quantitative reverse transcription polymerase chain reaction.
Main results and the role of chance: Both PCOS-EVs and CTRL-EVs are bilayered vesicles, ranging from 100 to 150 nm, and enriched in Alix, TSG101, and CD9. EVs could be internalized by oocytes within one hour. After coculture, the GVBD rate was similar among the three groups; whereas the maturation rate was significantly decreased in the PCOS-EV group compared with CTRL-EV group or PBS group. In addition, the abnormal mitochondria distribution rate or abnormal spindle rate were significantly increased in the PCOS-EV group compared with PBS or CTRL-EV group. The ROS level was increased in the PCOS-EV group compared with CTRL-EV group, and the expression of CAT, GSS, and SOD was increased in the PCOS-EV-treated oocytes.
Limitations, reasons for caution: Our study did not identify the contents of PCOS-EVs and CTRL-EVs, and the molecular mechanisms of dysregulations induced by PCOS-EVs need further researches to investigate.
Wider implications of the findings: This work confirmed that EV-conducted cellular communication played an important role in oocyte development in women with PCOS. The dysregulation of oocytes induced by PCOS-EVs might be related to the poor oocyte quality of women with PCOS, which may provide a novel target to improve pregnancy outcomes of these patients.
Trial registration number: not applicable

P-130 The effect of time of ejaculation and time of processing of semen on fertilization and ongoing pregnancy in IVF/ICSI treatments.

A. Badal[1], G. Pilgram[1], D. Diaz de Pool[1], L. Van der Westerlaken[1]
[1]LUMC, Leiden university medical center, Leiden, The Netherlands

Study question: Does time between ejaculation and processing, and time between processing and insemination/injection affect fertilization rate (FR) and ongoing pregnancy rate (OPR) in IVF/ICSI treatments?
Summary answer: Increasing time between processing and insemination significantly decreased the OPR after IVF. FRs after IVF/ICSI and OPR after ICSI were not affected by different time-intervals.
What is known already: The choice for IVF or ICSI depends on semen quality, however, this doesn't affect the outcome of IVF/ICSI treatments (Mariappen et al 2018). After ejaculation, the percentage of motile spermatozoa decreases progressively at a rate of about 10%/hour (Makler 1979). According to the ESHRE-guideline, semen should be processed within 1 hour after ejaculation. In our laboratory, a validation was performed that confirmed a decrease in sperm motility after ejaculation. During incubation at 37°C after processing, the sample remained stable in incubation medium (unpublished data). Therefore, we analyzed the effect of handling time and incubation time with regard to IVF/ICSI outcomes.
Study design, size, duration: This retrospective data analysis examines the effect of time between ejaculation and processing using density-gradient centrifugation (handling time) and time between processing and insemination (IVF)/injection (ICSI) (incubation time) on the FR and OPR, irrespective of the initial semen quality. A total of 1488 oocyte pickups (844 IVF, 644 ICSI) were included from 1060 patients undergoing fertility treatment between 2017 and 2019. Oocyte pickups without oocytes, with oocyte vitrification, or with donor oocytes were excluded.
Participants/materials, setting, methods: Anonymized data were obtained from the laboratory database ProMISe. Handling time and incubation time of the semen incubated at 37°C and 5% CO2 were analyzed in relation to the occurrence of TFF (Total Fertilization Failure), FR and OPR. Linear and logistic regression was performed in SPSS version 25. In case of significant association, the data were adjusted for potential confounders, such as woman's age, semen quality before and after preparation, and number of oocytes.
Main results and the role of chance: This study shows that increasing the incubation time of the semen significantly reduced the OPR per ET in IVF treatments (from 30,8% within 3,5 hours to 24,1% after 6 hours) even after adjusting for the potential confouders. However, the OPR in ICSI treatments was not significantly affected by the incubation time (rather, there was an opposite trend). Also, the handling time of the semen did not significant effect the FR per OPU and the OPR per ET in IVF/ICSI treatments. The overall percentage of TFF was 3,5% and did not differ significantly between the IVF and ICSI treatments. Both handling time and incubation time did not have a significant effect on the occurrence of TFF. An explanation for the decrease in OPR in IVF treatments may be that increasing the incubation time at 37°C reduces the sperm quality as the capacitation reaction takes place too early, energy levels are reduced, DNA damage increases, or vacuoles arise in the sperm heads (Thijssen et al 2014, Jackson et al 2010, Peer et al 2007). Incubation at room temperature and reduction of the insemination time may improve OPR.
Limitations, reasons for caution: Retrospective study limitations (bias), no data on DNA fragmentation, incubation of semen only at 37°C after preparation.
Wider implications of the findings: Although it is recommended to produce semen at the IVF-department, our results show that an exception can be made, when production of a semen sample in a clinical setting is stressful, with no negative effect on the outcome. Furthermore, incubation-time at room temperature may have a positive effect on OPR.
Trial registration number: not applicable

P-131 Significance of the phenomenon of blastomere exclusion from compaction: Its relation to irregular cleavage, blastocyst development rate, and pregnancy rate

S. Watanabe[1], M. Tomida[1], S. Suzuki[1], Y. Matsuda[1], K. Yoshikai[1], E. Nakano[1], T. Sawada[1]
[1]Sawada Women's Clinic, ART Lab., Nagoya, Japan

Study question: When does blastomere exclusion from compaction increase and what effect does it have on the embryo?
Summary answer: More blastomere were excluded from compaction in embryos with irregular cleavage, resulting in lower blastocyst development rates, but no decrease in pregnancy rates at transfer.
What is known already: It has been reported that many of the chromosome analysis results of blastomere excluded from compaction were aneuploid, and pointed out that this exclusion may be related to the repair of blastocyst euploidy, but the effect of the number of excluded blastomere has not been reported.
Study design, size, duration: This is a retrospective study of 578 embryos that developed into morula with time-lapse monitoring by EmbryoScope (Vitrolife) in 2018-2019.
Participants/materials, setting, methods: The target embryos were classified into two groups: embryos with normal first and second cleavage (normal cleavage group) and embryos with irregular cleavage (dynamics of one cell dividing into three or more cells), called "direct cleavage", at either cleavage (DC group), and the number of blastomere excluded from compaction during morula formation was recorded and compared. The blastocyst development rate and single blastocyst transfer pregnancy rates of the two groups were compared.
Main results and the role of chance: There are 286 in the normal cleavage group and 292 in the DC group. The mean number of excluded blastomere was 0.76 and 3.55, respectively, which was significantly higher in the DC group (P<0.01). Good blastocyst (Gardner classification 4 or higher) development rate was 84.5% (239/283) and 65.8% (181/275), respectively, and high grade blastocyst (Gardner classification BB or higher) development rate was 43.9% (105/239) and 14.9% (27/181) of them, both significantly higher in the normal cleavage group (P<0.01). The single blastocyst transfer pregnancy rates were 31.6% (25/79) and 32.4% (11/34), and the miscarriage rates were 24.0% (6/25) and 27.3% (3/11), respectively, neither was there a significant difference between the two groups. So, direct cleavage increased the number of blastomere excluded from compaction, decreased the rate of morula to good blastocyst development and reduced blastocyst grade, but did not affect blastocyst transfer pregnancy rate and miscarriage rate.
Limitations, reasons for caution: Please note that all target embryos must have developed into morula or larger (embryos that did not develop into morula will not be included in the study).
Wider implications of the findings: Severe chromosomal aberrant blastomeres formed by direct cleavage were excluded from compaction, and the blastocyst development rate decreased due to a decrease in the amount of viable cells, but it is suggested that this blastomere exclusion mechanism is not related to euploidy after blastocyst development.
Trial registration number: not applicable

P-132 Centralized versus local embryologists scoring of blastocyst quality obtained in a large European multicenter clinical trial

M. Montag[1], E. Va. de. Abbeel[2], T. Ebner[3], P. Larsson[4], B. Mannaerts[5]

[1]ilabcomm GmbH, Reprolab consulting, Sankt Augustin, Germany ;
[2]University Ghent, Department of Human Structure and Repair, Ghent, Belgium ;
[3]Kepler University Hospital, Department of Gynecology Obstetrics and Gynecological Endocrinology, Linz, Austria ;
[4]Ferring Pharmaceuticals, Global Biometrics, Copenhagen, Denmark ;
[5]Ferring Pharmaceuticals, Reproductive Medicine & Maternal Health, Copenhagen, Denmark

Study question: Does blastocyst quality scoring by central assessment deviate from local assessment and potentially lead to the selection of a different single blastocyst for transfer?
Summary answer: Central and local assessment provided the same quality classification (poor / good / top) in 69% of all blastocysts and 63% of all transferred blastocysts.
What is known already: Blastocyst quality is scored most frequently by three morphological parameters, namely expansion and hatching (EH) status, inner cell mass (ICM) grading and trophectoderm (TE) grading. The score is used to define the quality classification (poor / good / top) which determines which embryo is to be transferred or cryopreserved. Blastocyst scoring and grading can be highly subjective, which does influence the choice for transfer and cryopreservation. Time-lapse imaging technology captures additional input about embryo development as well as enables centralized data storage and sharing for independent central assessments.
Study design, size, duration: Pooled embryo analysis from a prospective, randomized, multicenter trial (RAINBOW) of 619 women undergoing ovarian stimulation with an individualized dose of follitropin delta in a long GnRH agonist protocol between May 2018 and January 2020. Blastocysts were centrally assessed using time-lapse images by two independent assessors and one adjudicator . Selection of the blastocyst for transfer by local assessment was based on morphological scoring and not on morphokinetic time-lapse parameters.
Participants/materials, setting, methods: Oocytes were fertilized by ICSI and cultured in the Embryoscopeâ (Vitrolife) up to day 5 for transfer or day 5/6 for cryopreservation. Embryos were assessed as either non-blastocyst or blastocyst. Blastocysts were graded centrally and locally at 116 hrs of development, based on EH status (1-6), ICM (A-D) and TE grading (A-D). Central assessors were blinded to local assessment and embryo transfer selection.
Main results and the role of chance: In total 4282 embryos were assessed centrally, of which 2046 day 5 embryos (48%) were adjudicated due to a scoring difference of at least one parameter between the two central assessors. In total 38% of day 5 embryos were judged as non-blastocysts and 62% as blastocysts of which 61% (i.e. 38% of all embryos) were determined to be of good or top quality.

Identical results in terms of quality classification (poor / good / top) were obtained for 69% of blastocysts between local and central assessment and in 78%, between the two central assessors. Moreover, central and local scoring were identical in 62% for EH status, 53% for ICM grading and 57% for TE grading.

For all transferred blastocysts (n=508), central and local quality assessment was aligned for 63%. The ongoing pregnancy rate following single blastocyst transfer (SBT) was 41% (202/489), and similar to when considering only the transfers for which the central assessment had the same or a higher classification than the local assessment (166/411=40%). In 16% of all SBT, central quality assessment gave a lower score for the transferred blastocyst than the central assessment. This discrepancy could potentially have led to transfer of a different blastocyst.
Limitations, reasons for caution: This trial included assessments made by embryologists from 20 IVF centres. Some centres has limited experience with time-lapse technology for morphological blastocyst scoring. Scoring could therefore have been affected by differences in focal planes, magnification and contrast compared to inverted microscopy, with potential influence on blastocyst scores and quality classification.
Wider implications of the findings: Local and central blastocyst quality classification based on morphology aligns well but remains subjective. Embryo assessment may benefit from using tools like artificial intelligence-based algorithms for a more objective analysis.
Trial registration number: NCT03564509

P-133 Monopronuclear (1PN) embryos can derive in healthy pregnancies

E. Brinkmann[1], C. Demmers. va. d. Werken[2], L. Ramos[2]

[1]Radboudumc, Obst. & Gynacology- Div. Reprod. Medicine, Nijemgen, The Netherlands ;
[2]Radboudumc, Obst. & Gynaecology- Div. Reprod. Medicine, Nijmegen, The Netherlands

Study question: Should 1PN embryos be considered suitable for transfer when normal development is observed at day 3 or day 5?
Summary answer: In IVF/ICSI cycles, 1PN zygotes are encountered in 2.7% of inseminated oocytes. Transfer of 1PN-embryos should be considered in the absence of suitable 2PN embryos.
What is known already: During in vitro fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) zygotes containing only a single pronucleus (monopronuclear, 1PN) are encountered in 1-7.7% of cases, while the display of two pronuclei is expected in a normally fertilised oocyte. A 1PN zygote can be of gynogenetic or androgenetic origin, but it can also be biparental. Gynogenetic and androgenetic 1PN embryos can be haploid or diploid, so a diploid 1PN embryo is not guaranteed to be normally fertilised. Generally, 1PN are discarded, as they have an increased risk for aneuploidy. However, sporadically they can develop into healthyl babies.

Study design, size, duration: 1PN-zygotes (n=1287, 2.7% from all inseminated oocytes) from 1-1-2016 up to 15-12-2020 were retrospectively evaluated. The development and fate (discarded/transferred/cryopreserved) of all embryos were recorded. Embryos were evaluated at day 2, 3 or 5 of development. The policy of our unit is that, in absence of 2PN embryos, normal developed 1PN-embryos can be transferred on day 3. Supernumerary 1PN embryos can be cryopreserved at blastocyst stage. Ongoing pregnancies from fresh embryo transfers (ET) were analysed.

Participants/materials, setting, methods: In 946 IVF/ICSI cycles, at least one 1PN zygote was observed (total 1287 embryos). ICSI with ejaculated, PESA or TESE sperm counted for a total of 795 embryos, IVF cycles for 494 embryos. Embryo evaluation was performed using a home-made numerical algorithm: A (top embryo; 150-200 points), B (regular embryo; 100-149 points) or C (poor embryo; 0-99 points). Monopronuclear embryos always scored lower than equal developed 2PN embryos. Blastocyst evaluation was according to Gardner score.

Main results and the role of chance: From the 795 ICSI embryos, 49 (6.1%) were used for fresh ET (26 scored quality A or B), and a total of 60 embryos developed to blastocyst and were cryopreserved. From these 49 ICSI transfers, 4 (8.1%) ongoing pregnancies were obtained, all 4 from DET (1PN+2PN embryo), from which one twin pregnancy was confirmed. From the 494 IVF embryos, 41 (8.3%) were used for fresh ET (24 scored A or B), and 62 blastocysts were cryopreserved. A total of 9/41 (22%) ongoing pregnancies were obtained: 5 from SET (1PN) and 4 from DET (1PN+ 2PN embryo). Therefore, in only five IVF cycles a confirmed pregnancy was observed from a 1PN embryo (all A-quality embryos).

Considering six ongoing pregnancies with complete certainty of monopronuclear origin from fresh tranfers could be confirmed from our retrospective data, we can conclude that although the live birth rate of these embryos is very low (around 0,5- 1.0%), they should not be discarded when development is normal and no dipronuclear embryos are present.

Limitations, reasons for caution: Cryo-thawing data is missing as these embryos were not differentially marked at freezing. Therefore, the cumulative pregnancies from monopronuclear embryos could be higher. Embryos were not evaluated in a time lapse system, so asynchronicity of PN formation could explain missing the right moment for evaluation, while normal fertilized.

Wider implications of the findings: Notably, IVF monopronuclear embryos display a higher developmental potential than those derived from ICSI. We suggest that, in absence of dipronuclear embryos, culture to blastocyst stage before considering fresh ET or cryopreservation will help differentiate viable 1PN embryos, reducing the higher chance of genetic anomalies and miscarriages.

Trial registration number: N.A.

P-134 Zygote morphokinetic parameters (ZMP) differs between fertilized and non-fertilized (in vitro maturation) oocytes

M. Zhao[1], H. Li[2], S. Wang[1], O. Alqawasmeh[1], M. Xu[1], J. Chung[1], D.Y.L. Chan[1]

[1]The Chinese University of Hong Kong, ART Unit- Department of Obstetrics and Gynaecology- Faculty of Medicine, Shatin, Hong Kong ;
[2]Guilin University of Electronic Technology, School of Computer Science and Information Security, Guilin, China

Study question: Is there any difference on the ZMP between the fertilized and the non-fertilized oocytes in an IVM cohort?

Summary answer: The zona pellucida (zp_g) , cytoplasm greyscale（cm_g),the cytoplasm size (cm_size), radius (cm_r) and deviation (cm_d) showed different patterns from the two groups.

What is known already: We developed a convolutional neural network (CNN) based algorithm that provides instant and bias-free analytical outcomes of oocyte morphological segmentation. The mature but not-fertilized oocytes tend to be static while the fertilized oocytes are more dynamic for preparing its following biological events.

Study design, size, duration: This was a case-control study on oocytes including 631 normal fertilized oocytes and 100 IVM oocytes from 01/08/2017 to 31/12/2019 conducted in the Prince of Wales Hospital, The Chinese University of Hong Kong.

Participants/materials, setting, methods: We used the convolutional neural network (CNN) algorithm to segment the ZMPs of the cytoplasm and zona pellucida of the oocytes. The ZMPs include cm_g, cm_size, cm_r, cm_d, zp_g, thickness of zona pellucida and the area of perivitelline space. For the ZMPs that did not change with time, we used t-test to test the significance and for the parameters changed with time we used dynamic warp timing and similarity test to find the difference.

Main results and the role of chance: The IVM group had a higher intensity of zp_g of 142.03 (128.52-158.70) compared with the fertilized group of 137.04 (121.69-154.37). The cm_g of IVM group was higher than fertilized group [122.55 (114.87-137.62) vs 119.37(108.88-132.87)]. The cm_size, cm_r and cm_d as parameters changed with time and showed a different pattern in two groups. The IVM group decreased the cm_size faster than the fertilized group but the fertilized group had a more dynamic change in the shape of cytoplasm (cm_d) during the development. The cm_r changed with the same pattern of cm_size provided evidence supporting the finding above.

Limitations, reasons for caution: The ZMPs in the IVM group was captured for 21 hours from the first polar body extrusion. Though the duration was similar to the one from fertilized to the first cleavage. The morphology change during that period may not represent the holistic one of IVM oocytes.

Wider implications of the findings: The IVM oocytes have different morphokinetic performance from fertilized oocytes. We used a novel method based on CNN to confirm the differences between the two groups showing that our algorithm was able to describe the morphokinetic changes in a quantitative way and corresponded with embryologist's experience.

Trial registration number: The Hong Kong Obstetrical & Gynaecological Trust Fund

P-135 Artificial neural networks (ANNs) for live birth prediction in frozen embryo transfers: the strength of post-warmed blastocyst dynamics

L. Alegre[1], L. Bori[1], A. Coello[1], A.S. Ferreira[2], J.C. Rocha[2], A. Cobo[1], M. Meseguer[1]

[1]Instituto Valenciano de Infertilidad IVI, In Vitro Fertilization, Valencia, Spain ;
[2]Universidade Estadual Paulista, Research department, Sao Paulo, Brazil

Study question: Does the post-warmed blastocyst dynamics have an impact over the likelihood of achieving a live birth?

Summary answer: Variables related to dynamics of vitrified/warmed blastocysts have shown a greater effect on the live birth prediction than only embryo morphological quality through artificial intelligence.

What is known already: Morphological dynamics of vitrified/warmed blastocysts were described by Coello et al., in 2017. The investigated markers were the thickness of zona pellucida (µm) and blastocysts area (µm2) after warming and before transfer, the area of the inner cell mass (µm2), time of initiation of reexpansion (in minutes), and presence of collapse or contraction. They found a correlation between blastocyst reexpansion and implantation rate and developed a hierarchical model for implantation prediction. In our study, we evaluated the post-warmed blastocyst dynamics for live birth prediction by using novel artificial intelligence techniques.

Study design, size, duration: This retrospective analysis included 415 vitrified/warmed blastocysts with known live birth data. Blastocysts after warming were placed in EmbryoScope (Vitrolife) immediately until embryo transfer. Embryo evaluation and selection were performed by senior embryologists according to fresh blastocyst morphology (before vitrification). Then, parameters related to post-warmed blastocyst dynamics were calculated. Finally, these variables and the embryo morphological grade before the vitrification were used as input data for ANNs optimized with genetic algorithm for live birth prediction.

Participants/materials, setting, methods: Blastocysts were vitrified and warmed by the Cryotop method (Kitazato,Biopharma). During the period between the warming procedure and the embryo transfer, the following variables were measured with the drawing tools provided by the EmbryoViewer workstation: zona pellucida thinning (µm), blastocyst expansion (um) and the speed of these two events (µm/h). Finally, multilayer perceptron neural networks were trained with data of 331 embryos by using the backpropagation learning algorithm and tested with data of 84 embryos.

Main results and the role of chance: We trained and tested three architectures of ANNs with different input variables as follows: post-warmed variables (thinning of the zona pellucida, blastocyst expansion, thinning speed and

expansion speed) and morphological grade (A, B or C) for ANN1, only post-warmed variables for ANN2 and only morphological grade for ANN3. The highest success rate when ANNs classified embryos as positive and negative live birth (LB+ and LB-) was achieved by combining post-warmed variables and morphological grade before embryo vitrification. The general accuracies for the blind tests were: 73.8% for ANN1, 66.7% for ANN2 and 71.4% for ANN3. Likewise, this combination achieved the highest AUC on test dataset to predict LB- (0.76 for ANN1, 0.74 for ANN2 and 0.67 for ANN3). However, the ANN2 trained with only post-warmed variables showed the best capacity to predict LB+ with an AUC of 0.73 (versus 0.46 for ANN1 and 0.5 for ANN3).
Limitations, reasons for caution: The main limitation is the subjectivity of manual annotations, although only one embryologist participated in this task.
Wider implications of the findings: The dynamics of vitrified/warmed blastocysts prior to embryo transfer could be more relevant variables than the morphological quality on day 5 before the cryopreservation. The analysis of embryo behavior after warming could improve clinical outcomes in frozen embryo transfers.
Trial registration number: none

P-136 Factors predicting clinical outcomes of 511 recipients of vitrified oocyte donation from an UK-regulated egg bank

V. Pataia[1], S. Nair[2], M. Wolska[1], E. Linara-Demakakou[2], T. Shah[2], N. Macklon[2], K. Ahuja[2]

[1]London Egg Bank, London Egg Bank, London, United Kingdom ;
[2]London Women's Clinic, London Women's Clinic, London, United Kingdom

Study question: Do established donor and recipient clinical markers predict recipient clinical pregnancy and live birth rates (LBRs) in a vitrified oocyte donation programme?
Summary answer: Recipient BMI and previous miscarriages predicted cumulative LBR. Likelihood of clinical pregnancy and LBR was higher in recipients of donors aged 23-29 than donors 18-22.
What is known already: The influence of age on ovarian reserve underlies the upper limit of 35 years for UK donors. However, recent evidence suggests that oocyte aneuploidy rates follow an inverse U-shaped curve in relation to a woman's age. Conflicting evidence exists regarding the impact of other donor-related factors including BMI, AMH, oocyte yield and prior reproductive history on recipient outcomes. Moreover, the effect of recipient age, BMI, and reproductive history on oocyte donation outcome remains unclear.
Study design, size, duration: Retrospective cohort study of 325 altruistic oocyte donors matched to a total of 511 recipients. Only first donations taking place between January 2017 and December 2019 were included.
Participants/materials, setting, methods: All oocyte donors were altruistic volunteers aged 18-35 with no prior infertility diagnosis. Donor and recipient screening for suitability and safety was carried out according to the Human Fertilisation Embryology Authority guidelines. Backward stepwise logistic regression was used to identify donor, recipient and embryology parameters predictive of recipient primary outcomes defined as clinical pregnancy and live birth, either cumulative or after the first embryo transfer (ET).
Main results and the role of chance: A total of 705 fresh and frozen/thawed ETs were performed, of which 76% were elective single embryo transfers (eSETs) of blastocysts (96.5%), resulting in a cumulative clinical pregnancy and LBR of 83.5% and 70.5% respectively after 3 ETs. Recipient BMI and previous miscarriages were predictors of cumulative LBR ($p<0.05$). The ratio of transferrable embryos per oocytes received/fertilised and the number of ETs needed to achieve the intended primary outcome were predictors of cumulative clinical pregnancy and LBR ($p<0.05$). Donor age 18-22 was associated with lower incidence of recipient clinical pregnancy and live birth after the first ET, as compared to donor age 23-29 ($p<0.05$).
Limitations, reasons for caution: The present study included only healthy oocyte donors, thus conclusions may not apply to subfertile or less healthy women. Male factors were not accounted for.
Wider implications of the findings: We demonstrate the efficacy of vitrified oocyte donation treatment and identify recipient BMI, previous miscarriages and embryology parameters as predictors of cumulative LBR. Additionally, the choice of donors aged 18-22 instead of older donors is found not to be advantageous for increasing the chance of clinical pregnancy and live birth.
Trial registration number: not applicable

P-137 Male embryos take longer to develop to the blastocysts stage

J. Fraire-Zamora[1], M. Martínez[1], D. García[1], R. Vassena[1], A. Rodríguez

[1]Eugin, Eugin, Barcelona, Spain

Study question: Are there any differences in developmental timings between male and female preimplantation embryos?
Summary answer: There is a tendency for statistical difference in the time to reach blastocyst stage for male embryos compared to female embryos
What is known already: Differences in gene expression and metabolic uptake between male and female preimplantation embryos have been found in animal models and humans. These differences could affect the developmental timings of embryos resulting in differences in either sex. Morphokinetic parameters can precisely assess developmental timings. Only a few studies have analyzed morphokinetic parameters between male and female preimplantation embryos and no consensus has been reached on whether there is any sex-specific difference. The objective of this study is to compare morphokinetic parameters between male and female preimplantation embryos to determine any sex-specific developmental differences.
Study design, size, duration: This is a retrospective study including 102 preimplantation embryos from February 2018 to February 2020. The morphokinetic parameters obtained from time-lapse records of each embryo were: time to pronuclear fading (tPNf), times to 2–8 cells (t2, t3, t4, t5, t6, t7, t8), time to start of blastulation (tSB) and time to full blastocyst stage (tB). A two-tailed Student's *t*-test was used to compare morphokinetic parameters between embryo sexes. A $p<0.05$ was considered statistically significant.
Participants/materials, setting, methods: The study included retrospective time-lapse data from preimplantation embryos giving rise to 51 baby boys and 51 baby girls, as seen at birth. This is a single-center study with standardized culture conditions. Embryos in both study groups issued from cycles with donated oocytes. Only elective blastocyst stage single-embryo transfers (SET) on day 5 were assessed.
Main results and the role of chance: A tendency to statistical difference (p=[0.1-0.05]) was observed for blastocyst-related morphokinetic parameters: tSB (mean time was 89.6±6.3 hours in male embryos vs. 86.9±8.1 hours in female embryos, p=0.06) and tB (100.2±5.9 hours versus 97.9±6.5 hours, p=0.07). Male embryos showed an increased average time of 2.7 hours to tSB and 2.3 hours to tB, while no differences were found in the mean times of all the other morphokinetic paraments measured ($p>0.50$): tPNf (~21.8±3.0 hours) t2 (~24.4±3.2 hours); t3 (~35.6±3.9 hours); t4 (~36.6±4.6 hours); t5 (~46.9±6.0 hours); t6 (~53.5±7.0 hours); t7 (~54.1±7.3 hours) and t8 (~54.1±7.3 hours). This finding suggests a sex-specific difference in reaching blastocyst stages.
Limitations, reasons for caution: The main limitation of the study is its retrospective nature and the small sample size. We analyzed the data of embryos leading to a live birth (high-quality embryos), therefore, caution should be made when generalizing results to non-implanting embryos (of potentially lower quality).
Wider implications of the findings: Sex-specific differences in developmental timings of preimplantation embryos at blastocyst stage, as evidenced by time-lapse data, should be considered to avoid selection biases during embryo transfers in ART clinic.
Trial registration number: not applicable

P-138 When is low quality really low? Should we transfer low-grade blastocysts?

Study question: What is the live birth rate after single, low-grade blastocyst (LGB) transfer?
Summary answer: The live birth rate for LGBs is 28%, ranging between 15-31% for the different inner cell mass (ICM) and trophectoderm (TE) subgroups of LGBs.
What is known already: Live birth rates following LGB transfer are varied and have been reported to be in the range of 5-39%. However, these estimates are inaccurate as studies investigating live birth rates following LGB transfer are inherently limited by sample size (n=10-440 for LGB transfers) due to LGBs being ranked last for transfer. Further, these studies are heterogenous with varied LGB definitions and design. Collating LGB live birth data from multiple clinics is warranted to obtain sufficient numbers of LGB transfers to establish reliable live birth rates, and to allow for delineation of different LGB subgroups, including blastocyst age and female age.
Study design, size, duration: We performed a multicentre, multinational retrospective cohort study in 9 IVF centres in China and New Zealand from 2012 to 2019. We studied the outcome of 6966 single blastocyst transfer cycles on days 5-7 (fresh and frozen) according to blastocyst grade, including 875 transfers from LGBs (<3bb, this being the threshold typically applied to LGB studies). Blastocysts with expansion stage 1 or 2 (early blastocysts) were excluded.
Participants/materials, setting, methods: The main outcome measured was live birth rate. Blastocysts were grouped according to quality grade: good-grade blastocysts (GGBs; n=3849, aa, ab and ba), moderate-grade blastocysts (MGBs; n=2242, bb) and LGBs (n=875, ac, ca, bc, cb and cc) and live birth rates compared using the Pearson Chi-squared test. A logistic regression analysis explored the relationship between blastocyst grade and live birth after adjustment for the confounders: clinic, female age, expansion stage, and blastocyst age.
Main results and the role of chance: The live birth rates for GGBs, MGBs and LGBs were 45%, 36% and 28% respectively (p<0.0001). Within the LGB group, the highest live birth rates were for grade c TE (30%) and the lowest were for grade c ICM (19%). The lowest combined grade (cc) maintained a 15% live birth rate (n=7/48). After accounting for confounding factors, including female age and blastocyst characteristics, the odds of live birth were 2.33 (95% CI = 1.88-2.89) for GGBs compared to LGBs and 1.56 (95% CI = 1.28-1.92) for MGBs compared to LGBs following fresh and frozen blastocyst transfers (p<0.0001, odds ratios confirmed in exclusively frozen blastocyst transfer cycles). When stratified by individual ICM and TE grade, the odds of live birth according to ICM grade were 1.31 (a versus b; 95% CI = 1.15-1.48), 2.82 (a versus c; 95% CI = 1.91-4.18) and 2.16 (b versus c; 95% CI = 1.48-3.16; all p<0.0001). The odds of live birth according to TE grade were 1.33 (a versus b; 95% CI = 1.17-1.50, p<0.0001), 1.85 (a versus c; 95% CI = 1.45-2.34, p<0.0001) and 1.39 (b versus c; 95% CI = 1.12-1.73, p=0.0024).
Limitations, reasons for caution: Despite the large multicentre design of the study, analyses of transfers occurring within the smallest subsets of the LGB group were limited by sample size. The study was not randomised and had a retrospective character.
Wider implications of the findings: LGBs maintain satisfactory live birth rates (averaging 28%) in the general IVF population. Even those in the lowest grading tier maintain modest live birth rates (15%; cc). It is recommended that LGBs not be universally discarded, and instead considered for subsequent frozen embryo transfer to maximize cumulative live birth rates.
Trial registration number: Not applicable

P-139 The role of hormones and LH receptor expression of granulosa cells collected from large and small follicles in natural/minimal stimulation cycle IVF

T. Okubo[1], H. Teruaki[1], O. Noriyuki[1], O. Kenji[1], S. Tomoya[1]
[1]Shimbashi Yume Clinic, Advanced medical research institute of fertility, Tokyo, Japan

Study question: Do different follicle sizes influence gonadotropins (LH, FSH) and sex steroid (estradiol) in follicular fluids and LH receptor expression (LHCGR) in cumulus oocyte complexes (COCs)?
Summary answer: It was found that differences in levels of FSH, estradiol values and LHCGR mRNA expression level in COCs between small and large follicles.
What is known already: The maturity rate in oocytes of small follicle is significantly lower compared to that of large follicles.
Study design, size, duration: After obtaining written consents from 78 infertile patients, we aspirated the large (>15 mm) and small (<5 mm) follicles, and collected follicular fluids at oocyte retrieval.
Participants/materials, setting, methods: We measured levels of LH, FSH and estradiol by enzyme immunoassay from large and small follicular fluids after oocytes retrievals. All collected oocytes were distinguished from large and small follicles, we confirmed the maturity of retrieved oocytes by the presence of first polar body. Then we extracted total RNA from granulosa cells and measured mRNA expression of *LHCGR*, encoding the human LH receptor, by quantitative real-time PCR. Each value was normalized to *ACTB* mRNA levels.
Main results and the role of chance: LH levels were nearly equal between small and large follicles (P=0.8356). Whereas FSH and estradiol levels were significantly lower in small follicles (P<0.0001). The expression levels of *LHCGR* mRNA were significantly lower in small follicles than in large follicles during natural cycles. The maturity rate in oocytes of small follicle was significantly lower compared to that of large follicles (96.0% vs. 21.7%, P<0001).
Limitations, reasons for caution: The main limitation of the present study was collected by 42 natural cycles and 36 mild stimulation cycles with letrozole following low-dose clomiphene.
Wider implications of the findings: In spite of almost the same LH levels between two groups, the reason why the significantly lower maturation rates of oocytes collected from small follicles is poor LHCGR mRNA expression due to insufficient granulosa cells glowth because of low FSH and estradiol levels.
Trial registration number: not applicable

P-140 Zygote morphokinetics as a predictor of blastocyst quality

M. Kljajic[1], N. Sayme[2], T. Krebs[3], S. Baus[1], M. Kasoha[4], E.F. Solomayer[5]
[1]Saarland University Medical Center, Reproductive Medicine, Homburg, Germany ;
[2]Team Kinderwunsch Hannover, Gynecology, Hannover, Germany ;
[3]Team Kinderwunsch Hannover, Reproductive Medicine, Hannover, Germany ;
[4]Saarland University Medical Center, Research, Homburg, Germany ;
[5]Saarland University Medical Center, Gynecology, Homburg, Germany

Study question: Does the total cytoplasmic volume (TCV) of the zygote and time of pronuclei disappearance (tPNf) affect blastocyst development potential and blastocyst quality?
Summary answer: The total cytoplasmic volume of zygote and the time of pronuclei disappearance strongly affect blastocyst development as well as blastocyst quality.
What is known already: Extended embryo culture with blastocyst transfer is considered a useful method for selecting embryos with a high implantation potential. One of the main concerns in the German Embryo Protection Act is that the choice of embryos that have a high potential for successful implantation must be made at the pronucleus stage. The introduction of time-lapse technology enabled comprehensive information regarding the morphology and kinetics of the embryo. Although for the past years, strong correlations between embryo morphokinetics and positive outcomes have been demonstrated, some disagreement concerning the wide application of these parameters into an early-stage embryo selection is still present.

Study design, size, duration: The injection time of ICSI was designated as "time zero", and computer software was used to calculate the time frame between the injection and the moment of pronuclei disappearance (tPNf). The total cytoplasmic volume was calculated 16–18 h after injection based on manually drawn diameters of the zygotes, by the computer. Obtained measurements were later associated with the blastocyst formation potential as well as with blastocyst quality.
Participants/materials, setting, methods: A total of 187 oocytes from 34 patients undergoing the antagonist cycle for ICSI treatment were evaluated. All blastocysts were cultured in Embryoscope™ according to the manufacturer's specifications (Vitrolife, Sweden). The Gardner and Schoolcraft scoring system was used to describe blastocyst quality. Statistical analyses were performed using IBM SPSS version 24. Data were reported as median and range. Differences between groups were tested using the Mann-Whitney U test. Statistical significance was defined as $p<0.05$.
Main results and the role of chance: Obtained data showed that the total cytoplasmic volume values were significantly higher in zygotes that reached the blastocyst stage compared with those that did not [708376,268μm³ (560564,412μm³ - 838602,605μm³) vs 674349,917 (415749,353- 823640,638) respectively; $p<0.0001$]. Furthermore, this parameter as well significantly affect blastocyst quality where zygotes which formed better blastocyst quality had smaller cytoplasmic volume [685568,079 μm³ (560564,412- 790112,397μm³) vs 745514,662 μm³ (616581,339- 838602,605) respectively; $p<0.0001$]. Time of pronuclei disappearance (tPNf) was significantly different ($p<0.0001$) in successfully formed blastocysts [22.00h (17-29 h)] versus arrested or non-blastulating embryos [23.00h (17-56 h)]. Zygotes who had a shorter time frame between injection and pronuclei disappearance showed better blastocyst quality values compared with those who had longer time frame [21.00h (17-28h) vs 23.00h (18-29h) respectively; $p<0.01$].
Limitations, reasons for caution: The limitation of the presented study was that due to the double-embryo transfer correlation between morphokinetic parameters and pregnancy rate was not possible to be calculated. Further research should link these morphokinetic parameters with pregnancy rate and live birth rate as well.
Wider implications of the findings: The potential of the present findings is considerable, especially for countries with strict Embryo Law Regulation. Obtained results might be highly useful for selecting embryos with high implantation potential. In addition, the present work illustrates the possibility of additional information that can potentially be incorporated into an embryo classification model.
Trial registration number: not applicable

P-141 Artificial intelligence system for the automation of the blastocyst morphology evaluation in GERI Time-lapse Incubator

E. Pay. Bosch[1], L. Bori[1], A. Beltran[2], V. Naranjo[2], M. Meseguer[3]

[1]IVIRMA Global, Research Laboratory, Valencia, Spain ;
[2]Instituto de Investigación e Innovación en Bioingeniería, CVBLab, Valencia, Spain ;
[3]IVIRMA Global, IVF Laboratory, Valencia, Spain

Study question: *Can an Artificial Intelligence (AI) system (hand-crafted vs. deep learning techniques) based on single embryo image analysis from a GERI time-lapse incubator (TL) evaluate the blastocyst morphology?*
Summary answer: Our hand-crafted method trained with blastocyst images from Geri-TL evaluated and classified parameters regarding to embryo quality with a global precision of 63.7% in blind-test.
What is known already: Recent studies have shown that AI can improve automatic grading and embryo selection. The approaches that have been carried out are very different, but all they conclude that there is a great potential (Rad2019, Manoj2020, Thirumalaraju2020). As we know, conventional embryo evaluation is performed manually based on the morphology of the blastocyst, therefore, it should be possible to replicate this process. In this study, we implemented different methods to analyse the behaviour and performance of an AI doing embryology tasks.
Study design, size, duration: Our study consisted of a retrospective analysis for the automatization of embryo evaluation with different approaches. We developed our models based on 715 images extracted from GERI TL Videos (Genea, Australia) from a single IVF center. Database was divided into 3 classes depending on the quality of the embryo according to ASEBIR morphology criteria (high; medium and low-quality). All the images were divided into 70% for training, 15% for validating and 15% for testing.
Participants/materials, setting, methods: We developed an automated AI algorithm to extract and classify features from images at 111,5 hpi of embryos cultured in GERI TL. Hand-crafted features from texture information are extracted to feed the classification algorithm. A statistical analysis is carried out to select the more discriminative variables. Parallelly, a deep neural network was built to compare performance of automatic and hand-crafted features. Additionally, we trained a model to detect embryo in the well.
Main results and the role of chance: High-quality, medium-quality and low-quality sensitivity were 73%, 56% and 72% for hand-crafted method and 76%, 53% and 22% for deep learning approach, respectively. High-quality, medium-quality and low-quality precision were 66%, 56% and 76% for hand-crafted method and 40%, 60% and 55% for deep learning approach, respectively. The global accuracy associated with each method was 64% and 50%. Also, we noticed that results were higher when we applied our embryo masks that avoid irrelevant information. In this initial attempt, our results showed that it is possible to replicate the embryo evaluation process.
Limitations, reasons for caution: The low results obtained in our deep learning model due to the absence of an extent dataset did not allow to obtain a model applicable to the clinic. However, the preliminary study let us to conclude the high potential of the approach.
Wider implications of the findings: Our results showed a potential automatization of the embryo evaluation process in Geri TL where the available software for embryo selection does not provide such option. Our findings leaded to an increase in objectification, a reduction of the workload of the embryologist and the research of new unknown morphological variables.
Trial registration number: not applicable

P-142 Comparison of the IVF outcome in the course of ICSI vs PICSI treatment continuation in exactly the same group of HBA abnormal patients

M. Rusin[1], W. Szecel[1], M. Jagiello[1], J. Liss[2,3], K. Lukaszuk[2,4,5]

[1]Invicta- Fertility and Reproductive Centre, Invicta- Fertility and Reproductive Centre, Wrocław, Poland ;
[2]Invicta- Fertility and Reproductive Centre, Invicta- Fertility and Reproductive Centre, Gdansk, Poland ;
[3]University of Gdansk, Department of Medical Biology and Genetics, Gdansk, Poland ;
[4]Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing- Faculty of Health Sciences, Gdansk, Poland ;
[5]Medical University of Warsaw, Department of Gynecological Endocrinology, Warsaw, Poland

Study question: Does the PICSI have a beneficial effect for men with abnormal HBA on the fertilization rate, blastocysts number and clinical pregnancies in the next attempt?
Summary answer: Patients with HBA <80% choosing to undergo PICSI after ICSI failure see an increase in blastocyst and pregnancy rates.
What is known already: Hyaluronic acid (HA) is a main component of cervical mucus and the extracellular matrix of cumulus cells. The formation of HA-binding sites in sperm cell membranes is one of the markers of sperm maturation indicating completion the spermatogenic process of remodelling the plasmatic membrane, cytoplasmic extrusion and nuclear maturity. Spermatozoa selected by the HA-binding technique (the physiologically selected intracytoplasmic sperm injection – PICSI) have a potentially reduced risk of chromosomal aneuploidy or DNA fragmentation. Recent evidence do not show significant benefits in using PICSI. However, it has not been analysed in the course of treatment continuation in the same patients.
Study design, size, duration: This was a retrospective case-control study. It included exactly the same 58 patients with abnormal HBA, who underwent IVF treatment with ICSI initially and later with PICSI, between January 2014 and October 2020 at INVICTA Fertility Centre, Poland. Median female partner age in PICSI group was 36,2±5,34, without PICSI 35,8 ±5,28.
Participants/materials, setting, methods: 275 cycles (130 ICSI and 145 PICSI) resulted in 793 and 897 MII respectively. Patients were also divided into two groups <80 % and ≥80% depending on the obtained HBA score expressed as the percentage of sperm bound with hyaluronan. The analysis covered the

fertilization rate (FR), TQ and total blastocyst rate on day 5 and clinical pregnancy rate. Patients with poor response to stimulation were excluded from the study.
Main results and the role of chance: FR in ICSI and PICSI groups was not significantly difference (57.00%±31.2 vs 59.87%±30.8) even when taking into account the division of patients according to the obtained HBA score. In the <80% group the FR was 57.04%±29.3 vs 59.54%±30.8 in ICSI vs PICSI group respectively.

There were no significant differences when comparing the under HBA ≥80% subgroups for all analysed outcomes. Fertilization rate was 56.88% in the ICSI group vs 61.03% in the PICSI group. The percentage of blastocysts was 28.61% vs 34.45% and the percentage of TQ blastocysts on day 5 was 15.32% vs 16.81% with ICSI and PICSI respectively, in the group consisting of the same patients.

In the HBA <80% group significant differences were observed in the percentage of obtained blastocysts 37.81% vs 47.61% by comparing the ICSI and PICSI approaches (p<0.05). Also, percentage of TQ blastocyst on day 5 also was higher in patients with <80% HBA score after PICSI and was statistically significant (17.07% ICSI vs 23.92% PICSI, p<0.05). We saw statistically significant (p<0.01) increase in percentage of clinical pregnancies from 29.03% without PICSI to 69.44% in patient's subsequent procedures involving PICSI.
Limitations, reasons for caution: More data is required to confirm that improved results of PICSI procedure are consistent and possible to reproduce in a larger group – and as a result could be included as part of the standard treatment process.
Wider implications of the findings: The presented results show that in patients with normal HBA score, PICSI does not bring a measurable benefit and this may be important factor to consider in decision-making for couples seeking assistance.
Trial registration number: not applicable

P-143 Improved embryonic development and utilization rates with EmbryoScope: A within-subject comparison versus a benchtop incubator

P. Guilherme[1], A. Setti[2,3], D. Braga[2,3], K. Precipito[1], A. Iaconell. Jr.[4], E. Borge. Jr.[3,4]

[1]Fertility Medical Group, IVF lab, São Paulo, Brazil ;
[2]Fertility Medical Group, Scientific research, São Paulo, Brazil ;
[3]Sapientiae Institute, Scientific research, São Paulo, Brazil ;
[4]Fertility Medical Group, Clinical department, São Paulo, Brazil

Study question: In consecutive intracytoplasmic sperm injection (ICSI) cycles, is embryonic development in EmbryoScope better than the previous one obtained in a benchtop (G-185) incubator?
Summary answer: Embryonic development, and oocyte and embryo utilization rates (OUR and EUR) are significantly improved in the EmbryoScope, as compared to G-185.
What is known already: The time-lapse imaging (TLI) system, which allows a non-invasive continuous assessment of embryo morphokinetics parameters in a closed culture system has been developed, promising improved embryo development by reducing oscillations in pH, humidity and temperature. To investigate this hypothesis, one study has already compared embryonic development in a TLI versus a benchtop incubator. However, It has never been investigated whether embryonic development can be improved within-subject, by changing from benchtop incubator in the first intracytoplasmic sperm injection (ICSI) cycle to the EmbryoScope, a TLI incubator, in the following ICSI cycle, and that was the objective of the present study.
Study design, size, duration: This study had a retrospective within-subject design, in which each cycle served as its own control. Data were obtained via chart review of patients undergoing ICSI in a private university–affiliated IVF center that fulfilled the following criteria: second ICSI attempt in which embryos had been cultured in a TLI incubator system (TLI group, n=71), preceded by a first ICSI attempt in which embryos had been cultured in a conventional incubator (Control group, n=71).
Participants/materials, setting, methods: Embryonic development up to the fifth day of development, OUR (transferred embryos plus frozen embryos per retrieved oocytes) and EUR (transferred embryos plus frozen embryos per fertilized oocytes) were compared between the groups using generalized linear models followed by Bonferroni post hoc. The post hoc achieved power was 82.6%, considering the sample size, the effect size obtained for blastocyst development rate and 5% significance level.
Main results and the role of chance: There were significant differences in fertilization rate (76.0% ± 1.3 vs. 80.0% ± 1.4, p=0.044, OR: 1.051, CI: 1.001 – 1.103), non-fertilization rate (14.8% ± 0.6 vs. 6.3% ± 0.4, p<0.001, OR: 0.424, CI: 0.370 – 0.486), day-2 non-cleavage rate (3.8% ± 0.2 vs. 1.1% ± 0.1, p<0.001, OR: 0.285, CI: 0.234 – 0.347), blastocyst development rate (40.9% ± 1.1 vs. 55.6% ± 1.3, p<0.001, OR: 1.358, CI: 1.267 – 1.456), frozen blastocyst rate (31.8% ± 0.8 vs. 37.0% ± 0.9, p<0.001, OR: 1.163, CI: 1. 085 – 1.248), OUR (40.7% ± 1.0 vs. 50.2% ± 1.1, p<0.001, OR: 1.232, CI: 1.155 – 1.314), and EUR (52.4% ± 1.1 vs. 66.6% ± 1.2, p<0.001, OR: 1.269, CI: 1.202 - 1.341), all in favor of TLI group. Pregnancy rate (30.2% vs. 30.8%, p=0.940), implantation rate (24.6% ± 40.0 vs. 26.1% ± 41.6, p=0.830), and miscarriage rate (21.1% vs. 15.0%, p=0.622) were similar between Control and TLI groups, respectively.
Limitations, reasons for caution: (i) Different culture dishes were used in each system; (ii) it is not possible to confirm how much of the embryonic improvement was due to the culture conditions; (iii) the study design is not ideal for the comparison of clinical outcomes and, also, underpowered to do so.
Wider implications of the findings: Even though the clinical outcomes were similar between the groups, the results may also lead to higher cumulative pregnancy outcomes following embryo thawing and transfer.
Trial registration number: Not applicable

P-144 Undisturbed culture in time-lapse systems improves embryo development and quality

T.A. Vilori. Samochin[1], M.A. Valera[2], L. Bori[1], F. Meseguer[2], J.M. D. Lo. Santos[1], M. Meseguer[3]

[1]IVI-RMA Global- Valencia, IVF-Laboratory, Valencia, Spain ;
[2]IVI-RMA Global- Valencia, Health Research Institute La Fe, Valencia, Spain ;
[3]IVI-RMA Global- Valencia, IVF-Laboratory- Health Research Institute La Fe, Valencia, Spain

Study question: Does culture in integrated time-lapse systems (TLS) improve embryo development and blastocyst quality compared to conventional benchtop incubators (CI), within the same IVF laboratory?
Summary answer: Under similar conditions, culture in TLS resulted in a significant increase in blastocyst rate, top quality blastocyst rate and proportion of biopsied embryos per treatment
What is known already: Integrated TLS have the potential of delivering a stable and undisturbed environment throughout the whole embryo culture, avoiding taking them out for assessment. However, there is still lack of quality evidence of the performance of these incubators compared to CI at supporting embryo culture until blastocyst stage. Studies abording this issue are still scarce, heterogeneous and have a small sample size. Although some authors have reported an improvement in embryo development and quality using TLS, global results are inconsistent. To our knowledge, the present study evaluates the effect of TLS on embryo quality on the largest sample size yet.
Study design, size, duration: Unicentric retrospective cohort study including 14248 ICSI treatments from 2016 to October 2020, with both autologous and donated oocytes. We compared blastocyst rate (BR) and proportion of top-quality blastocysts (TQB=Morphology ASEBIR score A) per treatment between those using TLS (N=7500) and CI (N=6748), and the proportion of embryos biopsied (EB) in cycles with pre-implantation genetic testing (PGT-A; N=2642). We performed a sub-analysis in treatments using single-step culture medium (N-TLS=4398, N-CI=1140) in both types of incubators.
Participants/materials, setting, methods: Embryo cohorts were cultured until blastocyst stage in one of 3 TLS: EmbryoScope, EmbryoScope Plus (Vitrolife,) and Geri (Genea Biomedx), or in a CI (ASTEC). Embryo quality was assessed following ASEBIR morphological criteria. Culture protocols and media changed during the included time period. For that reason, we did a sub-study in the treatments performed since the implementation of Gems® (Genea Biomedx) single-step (SS) culture medium in all incubators. Statistical analysis was done using ANOVA tests.
Main results and the role of chance: Treatments were differently distributed and heterogeneous in terms of number of oocytes obtained per patient, so we stratified the analysis according to ovum origin and compared mean rates per cycle instead of total number of embryos per group. BR was statistically higher (*P*<0,001) in the TLS group, in both autologous (62,98±29,37% vs 59,49±31,09%

in CI) and oocyte donation treatments (69,25±22,07% vs 66,27±23,28% in CI). Proportion of TQB was also significantly higher in the TLS in both types of cycles (*P*<0,001): 3,60±12,29% in TLS vs 2,27±9,71% in CI in autologous cycles, 8,68±15,31% in TLS vs 7,32±14,02% CI in ovum donation cycles. Results were corroborated in the SS media sub-study (*P*<0,05): BR was 63,87±29,23% in TLS vs 57,53±30,61% in CI with autologous oocytes, and 70,76±21,63% in TLS vs 67,39±22,68% in CI with donated oocytes; TQB rates were 3,66±12,06% in TLS vs 2,05±9,26% in CI in autologous treatments and 8,81±15,21% in TLS vs 6,84±12,91% in CI in ovum donation treatments. Regarding PGT-A treatments, we found no significant difference in the biopsy rate in the total comparison, although the rate significantly increased in the TLS group since the implementation of single-step medium (52,36±24,69% in TLS vs 48,63±22,56% in CI; *P*=0,007)

Limitations, reasons for caution: Not only culture conditions varied over time, but also the number of TLS in the laboratory, which increased lately. Hence, even though the most recent treatments included in the all-SS sub-study are more homogeneous in terms of culture conditions, they are unbalanced regarding the distribution among incubators.

Wider implications of the findings: Our results demonstrate the superiority of TLS coupled with single-step culture media against traditional embryo culture systems at supporting embryo development. The optimal environment provided by TLS enhances embryo development until blastocyst stage as well as their quality, increasing the cumulative chances of getting a life-birth for each patien.

Trial registration number: not applicable

P-145 usefulness of morphokinetic data to predict pregnancy rates of day-6 blastocyst transfers

M. Shioya[1,2], T. Kobayashi[1,2], T. Sugiura[1], S. Akashi[1], M. Kinoshita-Okabe[1], S. Nakano[1], K. Yamauchi[1], K. Kojima[1], M. Fujita[1], K. Takahashi[1]

[1]Takahashi Women's Clinic, Reproductive Medicine, Chiba, Japan ; [2]Chiba University Graduate School of Medicine, Department of Reproductive Medicine, Chiba, Japan

Study question: Can a scoring model based on morphokinetic data developed to predict pregnancy rates of day-5 blastocyst transfers (KIDSCORE™D5) predict pregnancy rates of day-6 blastocyst transfers?

Summary answer: KIDSCORE™□D5 was able to predict the clinical pregnancy rates of embryo transfers done on day 6 with an area under the curve (AUC) of 0.72.

What is known already: KIDSCORE™□D5 is a scoring model based on morphokinetic data developed to predict the pregnancy rates of day-5 blastocysts. In 2019, Regnier et al. reported that the AUC of KIDSCORE™□D5 for predicting clinical pregnancy rates of day-5 blastocyst transfers was 0.6. However, as KIDSCORE™□D5 is constructed based on morphological characteristics and developmental dynamics of day-5 blastocysts, it is unclear whether KIDSCORE™□D5 can predict pregnancy rates of day-6 blastocyst transfers. Since there are many cases of day-6 blastocyst transfers, it is important to know if KIDSCORE™□D5 can predict pregnancy rates of day-6 blastocyst transfers.

Study design, size, duration: This retrospective single-center study, which included 162 day-5 and 72 day-6 blastocyst transfers, respectively, was conducted at Takahashi Women's clinic from January to December 2019. Blastocysts derived from 146 patients who underwent intracytoplasmic sperm injection. All blastocysts were cryopreserved and were transferred singly.

Participants/materials, setting, methods: We used EmbryoScope+™□ (Vitrolife) for *in-vitro* culture and calculated KIDSCORE™□D5 (ver.3) using Embryoviewer™□ (Vitrolife). Blastocyst scoring was done from 1.0 to 9.9. Clinical pregnancy was defined as the presence of a gestational sac confirmed by transvaginal ultrasonography. Statistical analysis was performed with JMP Pro 15.00 (SAS). The relationship between KIDSCORE™□D5 and clinical pregnancy was evaluated by the AUC using ROC curve analysis and multivariate analysis adjusted for patient age.

Main results and the role of chance: The mean KIDSCORE™□D5 of day-5 and day-6 blastocysts was 7.1±1.7 and 3.7±1.5, respectively. KIDSCORE™□D5 of day-6 blastocysts was significantly lower than that of day-5 blastocysts (p< 0.0001, Wilcoxon test). ROC curve analysis showed that the KIDSCORE™□D5 could predict clinical pregnancy rates with an AUC of 0.62 for day-5 blastocysts and 0.72 for day-6 blastocysts. The cut-off values for KIDSCORE™□D5 were 5.7 and 4.9 for day-5 and day-6 blastocysts, respectively. Blastocysts above the cut off value on both day-5 and day-6 had a significantly higher pregnancy rate than those below the cut off value (day-5: 61.9% vs. 33.3%(p=0.0023), day-6: 47.4% vs. 7.6%(p=0.0003)). Multivariate analysis adjusted for patient age showed that KIDSCORE™□D5 correlated with clinical pregnancy rates of days 5 and 6 of blastocyst transfer with AUCs of 0.66 and 0.73, respectively.

Limitations, reasons for caution: This study had a small sample size, and it was a retrospective single-center study. In addition, the relationship between KIDSCORE™□D5 and clinical pregnancy rates may vary among facilities. Therefore, a prospective multicenter validation is necessary.

Wider implications of the findings: Our study results indicated that KIDSCORE™□D5 predicted clinical pregnancy and that morphokinetic parameters related to clinical pregnancy were similar between day-5 and day-6 blastocysts. Hence, morphokinetic evaluation can serve as a criterion for deciding which of multiple day-6 blastocysts can be transferred.

Trial registration number: Not applicable

P-146 Differential impact of three embryo culture media for IVF on in vitro development and perinatal outcome: a single-center RCT

M. Murakami[1], K. Tanaka[2], H. Otsubo[2], S. Mizumoto[2], Y. Nagao[2], T. Kuramoto[3]

[1]Kuramoto Women's Clinic, Research laboratory, Fukuoka, Japan ; [2]Kuramoto Women's Clinic, IVF laboratory, Fukuoka, Japan ; [3]Kuramoto Women's Clinic, President, Fukuoka, Japan

Study question: This report provides updated data from an RCT determining which embryo culture medium yields optimal IVF outcomes.

Summary answer: Embryo culture systems used for IVF differentially affected preimplantation development and resultant obstetric and perinatal outcomes, including birthweights of live-born singletons.

What is known already: Currently, multiple embryo culture medium systems are in use for IVF, raising questions regarding which is optimal. However, the ability of a medium to yield preimplantation embryos is not necessarily indicative of embryo viability. For example, supplementation of medium with serum was commonly used to increase animal blastocyst yields, but this impaired embryonic, fetal, and offspring health. In humans, medium composition and culture duration can influence IVF efficacy and offspring phenotype. Given the importance of culture systems in determining clinical outcomes, existing data regarding differential culture system impacts are insufficient and additional well-designed studies are required.

Study design, size, duration: Between February 2016 and August 2017, 795 couples undergoing their first autologous clinical IVF cycle and freeze-all strategy were recruited. Participants were randomized via computer-generated tables into three groups. Following standard oocyte retrieval and IVF/ICSI procedures, embryos were cultured using three different culture media, G1 Plus/G2 Plus (G1/G2; Vitrolife), Global Total (GT; LifeGlobal), or Sequential Cleav/Sequential Blast (SC/SB; Origio). Thirty-eight patients exhibiting no 2PN oocytes following insemination or those undergoing fresh embryo transfers were excluded.

Participants/materials, setting, methods: For patients yielding a single good-quality cleavage-stage (day-2 or day-3) embryo, that cleavage-stage embryo was vitrified. For patients yielding two or more good-quality cleavage-stage embryos, two or less good-quality cleavage-stage embryos were vitrified. The culture period of the remaining embryos was extended, and all good-quality blastocyst-stage (day-5 or day-6) embryos were vitrified. This report presents data for vitrified embryo transfer performed until the end of December 2020.

Main results and the role of chance: The mean per-cycle vitrified embryo yield (± SD) was comparable between groups for cleavage-stage embryos, but significantly different for blastocyst-stage embryos (G1/G2: 1.69 ± 2.2, GT: 2.53 ± 3.01, SC/SB: 2.04 ± 2.42; P = 0.001). Following vitrified cleavage- or blastocyst-stage embryo transfers, biochemical pregnancy rates were significantly different between groups (G1/G2: 55.6 %, GT: 59.1 %, SC/SB: 46.2 %; P = 0.011). Furthermore, a between-group trend towards different live birth rates was observed (G1/G2: 41.7 %, GT: 42.1 %, SC/SB: 33.1 %; P = 0.063). Of 382 live births, data for first-borns (n = 323; 295 singletons and 14 twin-pairs) are reported here. Perinatal data did not differ significantly between groups for both cleavage- and blastocyst-stage embryo transfers, including gestational age- and gender-adjusted singleton birthweight (z-score). Following multiple linear regression (including selected covariates), adjusted mean singleton birthweights were

significantly lower in the G1/G2 and GT groups than in the SC/SB group (by 131 g; P = 0.011 and 110 g; P = 0.032, respectively) and tended to be lower for cleavage-stage embryo transfers than for blastocyst-stage embryo transfers (by 102 g; P = 0.053).

Limitations, reasons for caution: A larger cohort size and longer-term follow-up are required to verify and further elucidate the impact of embryo culture methods on child health. Such studies will raise awareness regarding the sensitivity of *in vitro*-cultured human embryos to their environment, ultimately resulting in practices that decrease IVF risks to offspring.

Wider implications of the findings: Pregnancy outcome of the medium yielding fewer blastocysts was comparable or superior to that of other media, highlighting the importance of differentiating between the ability to support pre-implantation development versus the ability to yield viable embryos. Embryo culture medium had a greater impact than embryo transfer stage on live birthweight.

Trial registration number: UMIN000020910

P-147 The impact of blastocyst morphological parameters on live birth and singleton birthweight in single blastocyst transfer cycles

X. Wang[1], S. Zhang[2], G. Lin[3]

[1]Reproductive & Genetic Hospital of CITIC-Xiangya, science research department, Changsha- Hunan, China ;
[2]Reproductive & Genetic Hospital of CITIC-Xiangya, Reproductive Center, Changsha- Hunan, China ;
[3]Reproductive & Genetic Hospital of CITIC-Xiangya, president, Changsha- Hunan, China

Study question: Does blastocyst morphological parameters: blastocyst expansion degree(Expansion), inner cell mass (ICM), and trophectoderm (TE) grades affect live birth and singleton birthweight in single blastocyst transfer cyles?

Summary answer: The effects of blastocyst morphological parameters on live birth and singleton birthweight are different between biopsied blastocysts cycles and non-biopsied blastocysts cycles.

What is known already: It has been known that blastocysts with highest scores for three blastocyst morphological parameters achieve highest pregnancy rates, however, very few studies have comparatively analysed the effect of individual parameters on live birth and singleton birthweight about single blastocyst transfer cycles.

Study design, size, duration: This retrospective study involved all single blastocyst transfers cycles and their live birth outcome and singleton birthweight during the period from January 2014 to August 2019 at a tertiary care center.

Participants/materials, setting, methods: A total of 28515 single blastocyst transfer cycles were available for analysis and were divided into four groups: biopsied blastocysts cycles (BBC), thawed blastocysts cycles(TBC), blastocysts from thawed cleavage embryos cycles(BTCEC) and fresh blastocysts cycles(FBC). The primary outcome were live birth and singleton birthweight. Multiple logistics regression and linear regression analyses were respectively performed to investigate the effect of blastocyst morphological parameters on live birth and birthweight after adjusting potential confounders.

Main results and the role of chance: While analyzing the effect on live birth, we found that live birth of grade B ICM were lower than grade A ICM , live birth of grade C TE were lower than grade A TE and Expansion doesn't matter. Those result were same in three kinds of non-biopsied cycles. While all three parameters were statistically independently significant in biopsied blastocysts cycles.

While analyzing the effect on singleton birthweight, only Expansion was found to be statistically significant in biopsied blastocysts cycles, and birthweight of Expansion grade 5 was lower than Expansion grade 6(P=0.005),with a mean difference of 57g(3375.12±527.91 versus 3318.42±510.33). Limitations, reasons for caution: Most blastocysts with poor grade, especially ICM grade C, were not transferred, then the effect of poor grade such as ICM grade C were still unknown.

Wider implications of the findings: The study identified the association between blastocyst morphological parameters and live rate and compared the relative importance of three parameters in different kind of cycles through large size comparative analysis, which would help selecting high-quality embryos for transfer.

Trial registration number: not applicable

P-148 Effect of additional laser assisted drilling (LAD) during trophectoderm (TE) biopsy on mosaicism rate

Z.Q. Tee[1], C.W. Chan[2], A.Y.X. Lim[1], C.S.S. Lee[3]

[1]IVF Nexus Sdn Bhd, IVF Laboratory, Petaling Jaya, Malaysia ;
[2]Alpha IVF & Women's Specialists, IVF Laboratory, Petaling Jaya, Malaysia ;
[3]Alpha IVF & Women's Specialists, Clinical, Petaling Jaya, Malaysia

Study question: Does applying additional LAD during TE biopsy cause higher mosaicism rate in blastocysts?

Summary answer: Applying LAD during TE biopsy to create additional zona opening will produce more mosaic blastocysts.

What is known already: In Alpha IVF, laser assisted hatching (LAH) was done on day3 after ICSI for all pre-implantation genetic testing for aneuploidy (PGT-A) cycles. TE biopsy techniques used were laser+pulling (L+P), laser+flicking (L+F) and flicking only (F). At the time of biopsy, an extra step of creating additinonal artificial opening by LAD may be required when (a) blastocyst has very little herniated cells; (b) inner cell mass (ICM) is at the hatching point or biopsy site. Our internal study showed that biopsy using different techniques (L+P, L+F and F) does not affect mosaicism rate.

Study design, size, duration: This prospective study was designed to evaluate the effect of additional LAD during TE biopsy on the mosaicism rate. This study was conducted between 11th March–19th August 2019. Four hundred forty-three (443) patients had undergone oocyte retrieval and blastocyst culture after intracytoplasmic injection (ICSI) was done. A total of 824 hatching blastocyst (BG5) and fully hatched blastocyst (BG6) with at least a Grade A or Grade B TE (Gardner's grading) were included in this study.

Participants/materials, setting, methods: LAH was done on day3 post-ICSI while biopsy was done on day5 and/or day6 for PGT-A. Laser pulse length used during LAH and biopsy was fixed at 400ms. The biopsied blastocysts were classified into 3 groups: (A) BG6 (n=79), (B) BG5 without additional LAD during biopsy (n=713) and (C) BG5 with additional LAD (n=32). The number of biopsied cells ranged from 5-10 cells. Biopsied cells were tested using Next Generation Sequencing (Ion Torrent, USA).

Main results and the role of chance: The mosaicism rates for Group A, B and C were 19.0% (15/79), 23.4% (167/713) and 39.5% (15/38) respectively. Mosaicism rates of Group A and B were comparable (p=0.4807), whilst Group C had significant higher mosaicism rate compared to Group A and B (p=0.0238 and p=0.0319 respectively). The mean age of Group A, B and C were 31.1, 31.4 and 27.1 respectively. The mean age between these 3 groups were not statistically significant (A vs B, p=0.0713; A vs C, p=0.06727; and B vs C, p=0.4408).

Limitations, reasons for caution: Additional LAD during TE biopsy maybe be a confounding variable which affects the mosaicism rate. Moreover, the increase in mosaicism rate could be due to other unknown factors. A larger sample size is needed to confirm the results.

Wider implications of the findings: Based on our study, additional LAD during TE biopsy is not recommended as this may increase mosaicism rate. Biopsy should be done when the blastocyst has more herniated cell or when the ICM leaves the hatching point/biopsy site.

Trial registration number: not applicable

P-149 Calcium ionophores as an aid to surgically retrieved sperms in male factor infertility for increasing cumulative live birth rate

A. Sahu[1], S. Singh[1], A.C. Varghese[2], R. Ashraf[2], N. Majiyd[1], S. Singh[1], R. Basheer[1], M.C. Ashraf[1]

[1]CRAFT Hospital- INDIA, Reproductive Medicine, Kodungallur, India ;
[2]CRAFT Hospital- India, Embryology, Kodungallur, India

Study question: Does the addition of calcium ionophores for **artificial oocyte activation(AOA)** help in improving **Cumulative Live Birth Rate** in **surgically retrieved sperms** for male factor infertility?

Summary answer: AOA **significantly improved cumulative live birth rate** in Micro-TESE (**M-TESE**), TESA for non- azoospermia (**TESTICULAR**) and Non-Obstructive Azoospermia(**NOA**)-**TESA** but not in Obstructive Azoospermia (OA)-TESA.

What is known already: The main cause of Total Fertilization Failure after ICSI is thought to be due to oocyte activation deficiency (OAD) because of oocyte-related or sperm-related factors. Studies have shown that artificial oocyte activation (AOA) is helpful in these situations, but is **most effective in couples**

who have clear sperm-related OAD. Oocyte activation, by Phospholipase-C- Zeta **(PLCζ)** present in the sperm, leads to series of events resulting in calcium oscillation, oocyte activation and fertilization. AOA increases the free intracellular calcium thereby mimicking physiologic cell signaling mechanisms that result in oocyte activation and fertilization.

Study design, size, duration: This is a retrospective cohort study done in an academic private ART center, in which patient's records were analyzed, from January 2016 to December 2019 (total 4 years' duration) and all ICSI cycles with surgically retrieved sperms were included (n= 365). Study subjects were divided into 4 groups- M-TESE (n=143), NOA-TESA (n=38), OA-TESA (n=62) and TESTICULAR (n=92). Subdivision was done into cases if AOA was done and control were with conventional ICSI without AOA.

Participants/materials, setting, methods: Method- Immediately after ICSI, in case group (AOA), all metaphase II oocytes were treated with calcium ionophore (GM508- CultActive) for 15 minutes, then thoroughly washed and incubated under standard conditions.

Primary outcome measured was **cumulative live birth rate**(CLBR) and Secondary outcomes were **fertilization rate** (Fert. rate), **Cleavage rate**, **clinical pregnancy rate** (CPR) and **miscarriage rate** (MA). Statistical analysis was performed with Chi-square and Mann-Whitney- U test, with significance at P<0.05. Institutional committee clearance was obtained.

Main results and the role of chance: The **CLBR** was **significantly higher** with **AOA- M-TESE** (55.8% vs 33.3%, *p*- 0.008), **AOA-NOA-TESA** (55.55% vs 15%, *p*- 0.027) and **AOA-TESTICULAR** (62.9% vs 32.3%, *p*- 0.006) group. Fert. rate was significantly higher with AOA-M-TESE (81 ± 0.84 vs 64 ± 0.97, *p*- 0.001), AOA-NOA-TESA (86 ± 0.76 vs 64 ± 0.13, *p*- 0.001) and AOA-TESTICULAR (72 ± 0.12 vs 57 ± 0.11, *p*- 0.001). Cleavage rate, CPR also showed similar significant differences while MA was comparable. However, **significant differences were not observed** in any of the outcome measured in **OA-TESA group between cases and controls** - CBLR (51.6% vs 41.9%, *p*- 0.611), Fert. rate (0.77±0.14 vs 0.75±0.11, *p*- 0.539), CPR and MA, *p*- value > 0.05.

It may be hypothesized that surgically retrieved sperms in cases of NOA or non- azoospermia where TESTICULAR sperms are taken have reduced or absent capacity to cause Calcium oscillations due to deficient or inadequate PLC or there may be some chromatin level abnormalities in these sperms, leading to lesser fertilization and lesser good quality embryos in control group in which AOA was not done.

Limitations, reasons for caution: This study is retrospective in nature. Sibling oocytes were not compared. The study neither looked at obstetrics complication nor the neonatal outcomes. Further studies are required for long term impact on children born from AOA cycles.

Wider implications of the findings: To our knowledge, this is the **first study in the literature** evaluating the efficacy of calcium ionophores for NOA (M-TESE, TESA), OA (TESA) and TESTICULAR sperms. Further research is needed for use of calcium ionophores in cases of unexplained infertility and recurrent implantation failure.

Trial registration number: NOT APPLICABLE

P-150 Does trophectoderm biopsy performed on different blastocyst stages affect the clinical outcome?

S.H. Tan[1], A.Q.Y. Chan[1], A.Y.X. Lim[1], M.W. Lim[1]

[1]IVF Nexus, IVF laboratory, Petaling Jaya, Malaysia

Study question: The objective of this study is to evaluate the effect of trophectoderm (TE) biopsy on different blastocyst stages and its clinical outcome.

Summary answer: Our results showed that TE biopsy significantly reduced the clinical outcome of fully hatched blastocyst. What is known already: TE biopsy is a method widely practiced to harvest cells to determine the chromosomal constitution of a blastocyst, ensuring higher implantation and healthy pregnancies. The effect on clinical outcome after transferring blastocysts biopsied at different blastocysts stages has not been extensively studied.

Study design, size, duration: This retrospective study was conducted from January 2017 until July 2019 at Alpha IVF & Women's Specialists. Following laser assisted hatching on day 3, TE biopsy was performed on unhatched, hatching and fully hatched day-5 blastocysts. A total of 1,020 single euploid blastocysts transfer (SBT) were performed. The average maternal age was 31.7. Implantation rates (IR) were evaluated for all stages of hatching (Unhatched: BG3 & 4; hatching: BG5; fully hatched: BG6).

Participants/materials, setting, methods: Laser assisted hatching (Hamilton Thorne Bioscience, USA) was performed on day-3 and subsequently cultured to blastocyst-stage. Different hatching stages were observed using embryoscope time-lapse system (Vitrolife, Sweden) and were recorded. Day-5 blastocysts with at least BG3BB grade (Gardner's System) were selected for TE biopsy and the biopsied cells were sent for preimplantation genetic testing for aneuploidy (PGT-A) using Next-Generation Sequencing (Life Technologies, USA). All blastocysts were vitrified and warmed using the Cryotec Method (Cryotech, Japan). Main results and the role of chance: All 1,020 blastocysts survived post-warmed (post-warm survival rate= 100%) and were transferred in frozen transfer cycles. TE biopsy performed on unhatched blastocysts showed a comparable IR to hatching blastocysts (60.0% [15/25] and 65.2% [627/961]). While fully hatched blastocysts (44.12% [15/34]) show a significantly lower IR when compared to hatching blastocysts (65.2% [627/961]), no significant difference was seen when comparing unhatched blastocysts to fully hatched blastocysts (60.0% [15/25] and 44.12% [15/34]; p= 0.2949).

Limitations, reasons for caution: The sample size was comparatively smaller in the unhatched and fully hatched group than the hatching group. Further studies with a larger sample size is recommended to ascertain the clinical outcome. Since this is a retrospective study and biopsy was done by different embryologists, the biopsy technique was not controlled. Wider implications of the findings: To achieve higher clinical pregnancy, it is recommended to perform TE biopsy before the blastocysts is fully hatched.

Trial registration number: Not applicable

P-151 Correlation between the first euploid frozen-thawed blastocyst embryo transfer (FBT) and the subsequent euploid FBT outcome originating from the same cohort of oocytes

R. Abalı[1], F.K. Boynukalın[2], M. Gültomruk[3], Z. Yarkiner[4], M. Bahçeci[2]

[1]Bahceci Health Group- Uskudar University, IVF Unit, Istanbul, Turkey ;
[2]Bahceci Health Group, IVF Unit, Istanbul, Turkey ;
[3]Bahceci Health Group, Research and Development, Istanbul, Turkey ;
[4]Cyprus Science University, Statistics, Lefkoşe, Cyprus

Study question: Does the outcome of the first euploid frozen-thawed blastocyst embryo transfer affect the subsequent euploid FBT originating from the same cohort of oocytes?

Summary answer: The clinical pregnancy rate and ongoing pregnancy rate of the subsequent FBT are higher if a clinical pregnancy was attained in the first euploid FBT.

What is known already: Numerous factors including patient, cycle and embryological characteristics affect the outcome of an IVF treatment cycle. There is no data available whether the outcome of euploid FBT has an impact on the outcome of the subsequent euploid FBT of embryos originating from the same cohort of retrieved oocytes.

Study design, size, duration: The study enrolled cycles preimplantation genetic test for aneuploidy (PGT-A) performed between January 2016 and July 2019 at the Bahceci Fulya IVF Center. A total of 1051 patients with single euploid FBT were evaluated and resulted live birth (n=589, live birth rate (LBR): 56%(589/1051)), miscarriage (n=100, miscarriage rate (MR): 14.5% (100/689)) and no clinical pregnancy (n=362, 34,4%, (362/1051)). 159 FBT after the first single euploid FBT originating from the same cohort of oocytes were analyzed.

Participants/materials, setting, methods: Second euploid FBT cycle after first FBT with a clinical pregnancy were compared to frozen-thawed cycles after a without a pregnancy. Logistic regression analysis was utilized to adjust for potential confounders including female age, body mass index, embryo quality, day of embryo frozen, number previous failed attempt, number of previous miscarriage, endometrial thickness, outcome of the first euploid FBT.

Main results and the role of chance: The pregnancy outcome from the first euploid FBT in the study group was resulted live birth (25.1%, (40/159)), miscarriage (15.7%, (25/159)) and no clinical pregnancy (59.1%, (94/159). The pregnancy outcome of the subsequent euploid embryo transfer from the same oocyte cohort was clinical pregnancy rate (CPR): (67.3%, (107/159) ongoing pregnancy rate (OPR) (52.2% (83/159) and MR (22.4%, (24/107)). The CPR in the subsequent euploid FBT was 80% (52/65) among patients who achieved a clinical pregnancy in the first euploid FBT and 58.5% (55/94) of those who did not

(p=0.0045). The OPR in the subsequent euploid FBT was 64.6% (42/65) among patients who achieved a clinical pregnancy in first euploid FBT and 43.6% (41/94) of those who did not (p=0.009). On a multivariate regression analysis, clinical pregnancy in the first euploid FBT was a significant independent predictor for a pregnancy in the subsequent FBT transfer (p=0.003).
Limitations, reasons for caution: The limitation of the study is in the retrospective nature of the study. As the PGT-A strategy significantly decreases number of transferable embryos, the sample size of the study is limited.
Wider implications of the findings: Identifying predictive factors for the success of euploid FBT is important. These can help physicians while counseling patients regarding the outcome of the previous euploid FBT.
Trial registration number: NA

P-152 Morphokinetic and maternal profiles of embryos derived from centrally granulated oocytes vary with their ability to implant

C. Moutier[1], A. Bartolacci[1], D. Turchi[1], M. Lain[1], D. Pignataro[1], M.R. Mignin. Renzini[1], J. Buratini[1], M. Da. Canto[1]

[1]Biogenesi Reproductive Medicine Center, Istituti Clinici Zucchi, Monza, Italy

Study question: Does oocyte central granularity (CG) impact embryo morphokinetics and does this change with embryo implantation ability and maternal profile?
Summary answer: Oocyte CG slows fertilization and cleavage morphokinetics in overall derived embryos, but not in those capable to implant, an ability associated with lower maternal age.
What is known already: Oocyte morphology is easily accessible after pre-ICSI oocyte denudation, but the implications of morphological alterations for oocyte developmental competence are not entirely known. The presence of a centrally located granular area in the ooplasm was previously associated with alterations in the actin cytoskeleton and meiotic spindle, both potentially affecting meiosis completion, fertilization dynamics and embryo mitotic divisions. In fact, we have recently reported lower fertilization rates and delayed pronuclei fading and first cleavage associated with the presence of CG in oocytes subjected to ICSI.
Study design, size, duration: Retrospective analysis including 1378 control ICSI cycles providing only morphologically normal oocytes (1225 patients) and 220 CG cycles (201 patients) providing normal and CG oocytes, from July 2014 to March 2020. Morphokinetic parameters were compared between embryos from control and CG oocytes, as well as among embryos from control oocytes reaching implantation (C-I) and embryos from CG oocytes achieving (CG-I) or not (CG-NI) implantation. Maternal profiles were compared between CG-I and CG-NI.
Participants/materials, setting, methods: Oocytes were recovered from patients after controlled ovarian stimulation and ovum pick-up. Following ICSI, embryo culture was performed in a time-lapse incubator with annotation of time of pronuclei fading (tPNf) and cleavage times t2, t3, t4, t5 and t8. Morphokinetic data were retrospectively coupled with implantation outcomes of single transfers and of double transfers achieving double or no implantation. Differences were assessed with Chi-square and Kruskal Wallis tests.
Main results and the role of chance: Patients providing CG oocytes (n=201) presented higher maternal age (37.4 ± 4.4 vs. 36.7 ± 4.3; p=0.005), higher basal FSH (8.52 ± 3.7 vs. 7.62 ± 2.8 IU/L; p=0.002) and lower AMH levels (2.2 ± 2.2 vs. 2.9 ± 3.1 ng/mL; p<0.001) compared to control patients (n=1225). Morphokinetic parameters from tPNf to t4 were faster in embryos derived from oocytes with normal morphology (control; n=6947) compared to embryos derived from CG oocytes (n=382; tPNf: 24.0 ± 3.8 vs. 24.6 ± 3.6; t2: 27.0 ± 4.3 vs. 27.6 ± 4.1; t3: 37.0 ± 5.7 vs. 37.4 ± 5.7; t4: 39.4 ± 6.4 vs. 40.1 ± 6.2 hours; p<0.05). In addition, CG-NI (n=103) embryos were slower than CG-I (n=13) and C-I (n=226) embryos for tPNf, t2, t3, t4 and t8 (p<0.05), while CG-I did not differ from C-I embryos (p>0.05; tPNf: 22.4 ± 2.6 vs. 22.0 ± 2.5; t2: 24.9 ± 2.7 vs. 24.6 ± 2.8; t3: 36.0 ± 3.5 vs. 35.4 ± 3.0; t4: 36.7 ± 3.5 vs. 36.7 ± 3.6 hours, for C-I and CG-I, respectively). Finally, patients providing CG-I embryos (n=10) were younger than those providing CG-NI embryos (n=65; 31.3 ± 4.6 vs. 38.0 ± 3.9; p<0.05).
Limitations, reasons for caution: Our study is subjected to the intrinsic limitations of a retrospective analysis, the results presented could have been affected by variables that are uncontrolled for. Other studies are necessary to assess the impact of CG on clinical outcomes.
Wider implications of the findings: The findings indicate that early developmental morphokinetics and maternal age constitute valid parameters for the decision of whether to transfer CG-derived embryos, as well as for the transfer prognosis.
Trial registration number: not applicable

P-153 Comparison outcome of vitrified human embryos stored in vapor phase liquid nitrogen (LN2) and direct LN2

E.A. Park[1], K.Y. Kang[1], J.H. Lee[1], J.Y. Lee[1], H.S. Kim[1], H.S. Choi[1], G.Y. Song[1], E.H. Moon[1], M.Y. Shiin[1], Y.J. Hur[2], E.J. Yu[2], R. Kim[2], M.K. Koong[2], K.A. Lee[3], M.J. Kim[2]

[1]CHA Fertility Center Seoul Station, Fertility laboratory, Seoul, Korea- South ;
[2]CHA Fertility Center Seoul Station, Department of Obstetrics and Gynecology, Seoul, Korea- South ;
[3]CHA University, Department of Biomedical Science- College of Life Science, Seoul, Korea- South

Study question: Is vapor cryopreserved LN2 storage beneficial for clinical outcomes of vitrified human embryos that are frozen compared to vitrified human embryos having direct contact with LN2.
Summary answer: There are no significant differences compared to clinical outcomes of human embryos stored in LN2 vapor and direct store in LN2.
What is known already: There has been concerned about potential cross-contamination and biohazard issues of embryos for long term storage using direct LN2. This study aimed to compare clinical outcomes of human embryos transfer between vapor phase and liquid LN2.
Study design, size, duration: The embryo has undergone vitrification for long term storage with vapor or direct contact in LN2. After the thawing of the embryo, we checked on the survival rates. We transferred only one or two embryos per patient and kept analyzing the implantation and pregnancy rates
Participants/materials, setting, methods: This retrospective study was carried out from January 2018 to December 2019 with 3272cycles 4713embryos; vitrified for long term storage in vapor phase or direct contact with LN2. We compared the clinical outcomes of frozen embryo transfer cycles using vitrified for long term storage in vapor phase and direct contact with LN2. Clinical outcomes monitored were embryo survival, subsequent implantation and pregnancy after single or double embryo transfer
Main results and the role of chance: A total of 4713 fertilized human embryos are vitrified and then stored in LN2 vapor (n=2520 cycles) or direct contact LN2 (n=752 cycles). The study showed that the blastocyst stored in vapor able to retain full development. Survival was 97.8% (vapor) and 97.6% (direct contact LN2), and the vapor storage of human embryos had no significant difference in survival rates after a long term storage. For single blastocyst transfer, pregnancy and implantation rates were 51.5%, 52.4% in vapor, 54.6%, 54.9% in direct LN2; respectively (p=NS). In double blastocyst transfer, the pregnancy and implantation rates were 61.8%, 42.0% in vapor and 64.7%, 44.5% in direct LN2; respectively (p=NS). There were also no significant differences between two groups.
Limitations, reasons for caution: The study showed that the blastocyst stored in vapor can retain full development. A vapor storage system thus is safe and effective for long term vapor storage of vitrified human embryos.Within the limits of this study, there was no detection of an adverse effect of vapor storage.
Wider implications of the findings: Vapor storage systems thus represent a useful alternative for safe and effective long-term storage of vitrified human embryos that can avoid cross contamination chances from having direct contact with LN2.
Trial registration number: not applicable

P-154 The role of the X Chromosome in early human embryo metabolism

A. Groff[1], A. Korkidakis[2], D. Sakkas[3], D. Page[1]

[1]Whitehead Institute for Biomedical Research, Cambridge, U.S.A. ;
[2]Beth Israel Deaconess Medical Center, Reproductive Endocrinology and Infertility, Boston, U.S.A. ;
[3]Boston IVF, Waltham, U.S.A.

Study question: What role does the X chromosome play in early embryo metabolism? Does X chromosome copy number contribute to sex differences in early embryonic metabolism?

Summary answer: Chromosome X contains several metabolism-related genes that are expressed prior to X-inactivation, suggesting that their dosage plays a role in sex-biased regulation of embryo metabolism.
What is known already: Published reports indicate that sex differences in preimplantation embryo metabolism exist across mammalian species, including humans. Two observations supporting this are that male embryos reach blastocyst stage earlier than their female counterparts, and that glucose uptake and processing is thought to be higher in female compared to male embryos. It has been hypothesized that these differences reflect the location of the metabolism gene *G6PD*, the rate limiting enzyme in the Pentose Phosphate Pathway, on Chromosome X.
Study design, size, duration: This study is a reanalysis of publicly available RNA-seq data, including 1176 single cells from 59 blastocysts (24 E5, 18 E6, 17 E7) published in one study (Petropoulos et al 2016).
Participants/materials, setting, methods: Cells were subjected to a digital karyotype inference algorithm and aneuploid samples were removed from the dataset. Sex differential gene expression analyses (DE) were then performed in euploid trophectoderm cells (TE; 233 XY from 16 embryos and 180 XX cells from 12 embryos). Cell numbers from ICM were too sparse to compare.
Main results and the role of chance: Analysis of XX and XY TE revealed 618 significantly differentially expressed genes (DEGs; 507 upregulated in XX cells, and 111 upregulated in XY cells). These genes are spread across autosomes and sex chromosomes. Interestingly, *G6PD* is not significantly more highly expressed in XX cells.

Gene Ontology (GO) analysis of the XX-biased DEGs revealed a transcriptional sex bias in metabolism-related GO categories, including "mitochondrial ATP synthesis coupled electron transport", and "respiratory chain complex I".

Gene-level assessment revealed that the drivers of these enrichments are spread across the genome, but 28/64 reside on Chromosome X (hypergeometric p-value = 5.984473e-27), including *NDUFA1*, *NDUFB11*, and *COX7B* (components of the electron transport chain), and *SLC25A5* (an ATP/ADP transporter involved in maintaining mitochondrial membrane potential). This indicates a direct role for multiple X-linked genes in sex-biased regulation of embryo metabolism.

Metabolic genes that are not sex-biased are distributed across the genome, with no significant enrichment on Chromosome X (76/266, hypergeometric p-value=0.607). Together, these data indicate that GO metabolic term X enrichment is a feature of sex-biased expression and not due to an accumulation of metabolism-related genes on the X.
Limitations, reasons for caution: This analysis draws on publicly available data, and thus we are unable to perform orthogonal validation of karyotype calls. Additionally, while the initial dataset is large, the quality-filtered dataset (euploid XX and XY TE) is small, and single cell data is infamously variable. Further data collection is required.
Wider implications of the findings: Our analysis of sex-biased gene expression in early human embryos suggests a more important role for the X chromosome in modulating sex biases in early embryo metabolism than previously recognized. This study provides insight into the mechanisms underlying the development of metabolic sex differences throughout the lifespan.
Trial registration number: NA

P-155 Oocyte recovery 39 hours (from 39h to 41h) after administration of follicular maturation trigger does not affect clinical results

K. Michitaka[1], H. Kitasaka[1], N. Fukunaga[1], Y. Asada[1]

[1]Asada Ladies Clinic, Asada Institute for Reproductive Medicine, Aichi, Japan

Study question: What is the clinical outcome of oocytes recovered after 39 hours from ovulation inducing drug administration?
Summary answer: Oocytes obtained after 39 hours from follicular maturation triggering are equally viable to those obtained at the standard time of 36 hrs.
What is known already: In the clinical setting of ART, ovum pick-up (OPU) is generally performed around 36 hours after the administration of ovulation inducing drugs (OID). However, there are cases where OPU cannot be performed at this time often due to long operating lists. As the time elapsed between the administration of ovulation inducing drugs and OPU becomes longer, there is a concern about time-related oocyte aging. Nevertheless, there are few reports of clinical results of OPU after 36 hours from OID.
Study design, size, duration: We conducted a review of 1187 cycles and 1951 patients in which OPU and embryo transfer was performed in 2017-2018. All cycles underwent a 'freeze-all' of embryos and the transfer cycle was in the thawed embryo transfer cycle for all cases.
Participants/materials, setting, methods: The time from the administration of OID to the end of OPU was divided into 36h group and over 39h group and the MII and normal fertilization rate of oocytes obtained from OPU after ovarian stimulation were compared. After confirmation of fertilization, the D3 good-quality embryo and the D5 and 6 good-quality blastocyst rates of embryos that continued to be cultured and the pregnancy and miscarriage rates of cleavage-stage embryos and blastocyst transfers were compared.
Main results and the role of chance: The MII rate in the 36h and >39h groups was 78.1% vs. 80.0%, and the normal fertilization rate was 77.9% vs. 78.1% (ICSI) and 65.4% vs. 67.6% (Conventional-IVF). The D3 good-quality embryo rate (good-quality embryos are embryos with less than 5% fragmentation in 7-9 cells and compaction with more than 50% adhesion between split spheres) was 21.8% vs. 25.3%, the D5 good-quality blastocyst rate (at least 3BB according to Gardner classification) was 33.6% vs. 40.1%, and the D6 good-quality blastocyst rate was 31.1% vs. 37.5%, all of which were not significantly different. The pregnancy rate for cleavage-stage embryo transfer was 26.6% vs. 6.7%, and the miscarriage rate was 25.3% vs. 42.9%, both of which were not significantly different. The pregnancy rate for blastocyst transfer was 45.4% vs. 50.0%, and the miscarriage rate was 22.2% vs. 20.0%, both of which were not significantly different. (The significance difference test was a χ-square test)
Limitations, reasons for caution: The study was a retrospective study.
Wider implications of the findings: Even if OPU is conducted after 36h of the administration of OID, to the extreme range of 39h-41h, oocyte aging does not seem apparent and pregnancy outcomes are similar to the standard time interval of 36 hours.
Trial registration number: 'not applicable'

P-156 Automatic pronuclear detection based on deep learning technology has clinical utility

S. Takeda[1], N. Fukunaga[1], S. Sanami[2], Y. Tsuzuki[2], H. Kitasaka[1], S. Takeda[2], H. Watanabe[1], Y. Kida[1], F. Kondou[1], Y. Asada[1]

[1]Asada Ladies Clinic, Asada Institute for Reproductive Medicine, Aichi, Japan ; [2]Dai Nippon Printing Co., Ltd., Tokyo, Japan

Study question: Does the performance of an automatic pronuclear detection system based on deep learning technology have clinical utility?
Summary answer: Output results for 2PN detection using the automatic system powered by deep learning technology has clinical utility.
What is known already: In order to establish a more objective embryo evaluation system, we have been developing an automatic pronuclear detection system that utilizes deep learning technology based on Time- Lapse (TL) images. We have previously reported that the accuracy of pronuclei detection was improved by introducing an analysis method using 11 slices in the Z axis. In this study, we evaluated the potential clinical practicality of the automatic pronuclear detection system.
Study design, size, duration: Embryos clinically evaluated between May 2018 and December 2019 by embryologists were chosen for this study. We prepared for analysis TL videos of 995 embryos that had been evaluated as having 0, 1, 2, and 3PN.
Participants/materials, setting, methods: Part1:We compared the outputs of the automatic pronuclear detection system with these embryologists(three junior embryologists (1a), three intermediate embryologists (1b),and three senior embryologists (1c)) who had judged the pronuclei number from TL videos from 40 embryos each having 0,1,2,and 3PN.

Part2:The automatic pronuclear detection system determined the pronuclei number from the TL videos of 955 embryos scored as either 1,2,and 3PN,(different from those used in Part1),and the detection rate for 2PN was calculated.
Main results and the role of chance: Part1: The sensitivities for embryologist groups 1a),1b),1c) and the automatic pronuclear detection system were 80.0%,100%,100%,100% for 2PN, 60.0%,83.3%,86.7%,100% for 0PN, 46.7%,80.0%,86.7%,10.0% for 1PN, and 73.3%,96.7%,96.7%,10.0% for 3PN.

Part2: The precision for 2PN by the automatic pronuclear detection system was 99%.

Limitations, reasons for caution: In order to further improve the performance of the automatic pronuclear detection system, further adjustment of the algorithm and more training images will be utilised.

Wider implications of the findings: The detection of 2PN by the automatic pronuclear detection system was highly reliable, and the performance of the system was comparable to that of embryologists. These first results are reassuring and support the clinical use of the system as a further aid for embryologists, in routine laboratory practice.

Trial registration number: 'not applicable'

P-157 The pregnancy potential of embryos cryopreserved and thawed twice: A case-control study

J. Seikkula[1], M. Hallamaa[2,3], S. Willman[4], H. Ollila[5], V. Jokimaa[2,]

[1]*Central Finland Central Hospital, Obstetrics and Gynecology, Jyväskylä, Finland ;*
[2]*Turku University Hospital, Obstetrics and Gynecology, Turku, Finland ;*
[3]*University of Turku, Obstetrics and Gynecology, Turku, Finland ;*
[4]*Ovumia Fertinova, Fertility laboratory, Jyväskylä, Finland ;*
[5]*Turku University Hospital, Turku Clinical Research Centre, Turku, Finland*

Study question: What are the pregnancy and perinatal outcomes of twice-cryopreserved embryos compared to once-cryopreserved embryos?

Summary answer: Transfers of twice-cryopreserved embryos result in similar live birth rates (LBR) and perinatal outcomes compared to transfers of once-cryopreserved embryos.

What is known already: Repeated cryopreservation of viable surplus embryos in frozen embryo transfer (FET) cycles is a potential method to increase the cumulative pregnancy rate and reduce the risks related to multiple pregnancies. Currently, evidence on the safety and success of repeated cryopreservation is limited. Existing data from a few studies indicate that the vitrification of previously slow-frozen or vitrified embryos does not negatively impact pregnancy outcome, and no long-term health consequences in neonates have been reported. However, due to the limited number of reported pregnancies and children, more studies are needed.

Study design, size, duration: This retrospective register-based case-control study included FETs (n=2834) performed at the University Hospital of Turku and the Central Hospital of Central Finland, Finland, between January 2012 and December 2019. The case group consisted of twice-cryopreserved FETs (n=89), and the control group consisted of once-cryopreserved FETs (n=304). The matching criteria were embryonic age at transfer and female age category of less or over 35 years.

Participants/materials, setting, methods: All the FETs in the case group and 86% in the control group were single-embryo transfers (p=<0.001). The first cryopreservation was performed by slow freezing or vitrification (cases 58% vs 42% and controls 40% vs 60%, p=0.002, respectively). The re-cryopreservation method was vitrification. Mixed effects logistic regression was used to analyse the pregnancy outcomes, and a linear mixed model was used to analyse neonatal weight, adjusting for gestational age, neonatal sex, parity and BMI.

Main results and the role of chance: The survival rate of the twice-cryopreserved embryos was 92.2 % (94/102), and 93.7% (89/95) of the planned FETs could be carried out. FET was performed with D3-4 embryos in 17 cases and 68 controls and with D5-6 embryos in 72 cases and 238 controls. The rates of live birth, clinical pregnancy and miscarriage in the case and the control groups were comparable (27.0% vs 31.9%, p=0.35; 31.4% vs 36.8%, p=0.35 and 4.5% vs. 3.9%, p=0.77, respectively). No difference was seen in the preterm delivery rate (cases 4.2% vs controls 10.3%, p=0.69). Twenty-five children were born in the case group and 100 in the control group. No differences in birth weights were detected between the groups (3730 g, upper and lower quartiles 3500 g and 4050 g, vs 3490g, upper and lower quartiles 3150 g and 3900 g, p=0.28), and, in the case group, all the newborns' birth weights were appropriate for gestational age. There were no congenital malformations among the newborns in the case group. In the control group, there was one pregnancy termination due to aneuploidy, one case of undescended testicles, one child with a hypoplastic aortic valve without stenosis and one child with craniosynostosis.

Limitations, reasons for caution: This study was retrospective, and the small sample size limits interpretation of the results. FET has been demonstrated to increase the risk for fetal macrosomia and gestational hypertension/pre-eclampsia. Whether repeated cryopreservation enhances these effects or influences neonatal health in the long term needs further investigation.

Wider implications of the findings: Acceptable LBR and neonatal outcomes may be expected after transfer of twice-cryopreserved embryos. Also, the survival rate is high. To avoid embryo wastage or transfer of multiple embryos, good quality surplus embryos from FET cycles may be considered for repeated cryopreservation by vitrification.

Trial registration number: not applicable

P-158 Assisted Hatching on D+3 in order to facilitate trophectoderm biopsy in blastocyst for PGT-A is not advisable in all patients

P. Belchin[1], Y. Cabello[2,3], M. Sanche. d. Burgos[1], J. Guerrero[2], M. D. Riva[1], A. Garcia-Enguidanos[4], E. Izquierdo[4], D. Ordonez[4]

[1]*Hospital Ruber Juan Bravo Quironsalud, Embryology, Madrid, Spain ;*
[2]*Overture Life, Embryology, Madrid, Spain ;*
[3]*Hospital Ruber Juan Bravo Quironsalud, Scientific, Madrid, Spain ;*
[4]*Hospital Ruber Juan Bravo Quironsalud, Gynaecology, Madrid, Spain*

Study question: Is it useful or beneficial to perform Assisted Hatching (AH) on D+3 previously to biopsy for PGT-A on blastocyst stage on D+5?

Summary answer: The routine use of AH on D+3 to facilitate the embryo biopsy on D+5 could negatively influence the development of the embryos to blastocyst stage.

What is known already: The blastocyst stage is the optimal stage for performing biopsies for PGT-A, which has been reported as a key factor determining the growing clinical application of this strategy worldwide. For trophectoderm (TE) biopsy, laser-assisted drilling is used to create a zona opening on D+3 or D+5 of development. The method of zona opening on D+3 allows some of the TE cells to herniate during blastocyst formation and expansion, which facilitates the biopsy process. However, this method may result in herniation of inner cell mass cells instead of TE or maybe could affect the development of the embryo to blastocyst stage.

Study design, size, duration: A total of 100 PGT-A cycles were performed in 2019 and 2020. In 78 of them laser-assisted drilling was used to create a zona opening on D+5 only in those embryos which arrived to blastocyst stage for TE biopsy (Group No-AH). In 22 cycles the same drilling was achieved on D+3 in all embryos, independently of their quality (Group AH). The average of embryos per cycle in each group was 5 and 4.3 respectively.

Participants/materials, setting, methods: A total of 100 PGT-A cycles coming from 65 patients were studied. The average of the age of the patients was 40.83 (SD 3.45) in the group No-AH vs 42.18 (SD 3.42) in the Group AH (p= 0.108), so the age was not a determining factor for the development of the embryos. We analyzed by 2 test differences between groups on fertilization rates, number of embryos, development to blastocyst stage, euploidy and pregnancy rates.

Main results and the role of chance: The fertilization rate was 74.79% (No-AH group) and 68.53% (AH group) with no significative statistical differences (p=0.12).

In the No-AH group, the TE biopsy was performed on D+5 in 63 cycles (81%). In the AH group, 41% of cycles didn't reach the blastocyst stage, obtaining statistical differences between groups (p=0.035). We found also significant differences in the number of cycles with biopsied blastocyst when we had 1 to 6 embryos/cycle on D+3 between groups (p=0.002), without obtaining any blastocyst to be diagnosed in 53% of the cycles in AH group vs 27% in No-AH group. When the number of embryos on D+3 per cycle was > 6, at least 1 embryo reached the blastocyst stage in both groups, although this number was higher in No-AH group. The rate of biopsied blastocysts was significantly higher in the No-AH group compared to the AH group (46.61 vs 34.69) with a p=0.031.

The rate of euploid embryos analyzed was 23.30% in the No-AH group compared to 29.41% in the AH group, although no significant differences were found (p=0.44) between groups.

In the No-AH group, a clinical pregnancy rate of 52.94% was obtained (n=34) vs 50% in the AH group (n=4) (p=0.91).

Limitations, reasons for caution: We have recently started to perform AH on D+3, so the number of cases is smaller than No-AH group. We use a time lapse incubator in all cases, so in the No-AH the culture dish is changed, disturbing the stable incubation environment, while in the other group it is not.

Wider implications of the findings: The use of AH on D+3 in order to facilitate the TE biopsy on D+5 could affect negatively the development of the embryos to blastocyst stage. Its routine use should be avoided based on laboratory workload, mainly if the patient has less than 7 embryos at D+3.
Trial registration number: Not applicable

P-159 Slow-growing embryos should be frozen on day 5

M.J. Zamora[1], I. Katsouni[1,2], D. Garcia[1], R. Vassena[1], A. Rodríguez[1]

[1]Eugin, Eugin, Barcelona, Spain ;
[2]UPF, Barcelona School of Management, Barcelona, Spain

Study question: What is the live birth rate after frozen embryo transfer (FET) of slow-growing embryos frozen on day 5 (D5) or on day 6 (D6)?
Summary answer: The live birth rate after single FET is significantly higher for slow-growing embryos frozen on D5 compared to those frozen on D6.
What is known already: Most data on the outcomes of blastocyst transfer stem from studies that evaluate fresh transfer from normal growing D5 blastocyst ET. However not all embryos will begin blastulation nor reach the fully expanded stage by D5; those are the slow-growing embryos. Studies that compare D5 to D6 embryos in FET cycles show contradictory results. Some have reported higher clinical pregnancy rates after D5 FET, while others have reported similar outcomes for D5 and D6 cryopreserved blastocyst transfers. There is a lack of evidence regarding the best approach for vitrifying embryos that exhibit a slow developmental kinetic.
Study design, size, duration: This retrospective cohort study included 821 single FET of slow-growing embryos frozen on D5 or D6, belonging to patients undergoing in vitro fertilization with donor oocytes between January 2011 and October 2019, in a single fertility center. The origin of blastocysts was either supernumerary embryos after fresh embryo transfer or blastocysts from freeze-all cycles. All embryos were transferred 2- 4h after thawing.
Participants/materials, setting, methods: We compared reproductive outcomes of slow-growing embryos frozen on D5 versus (n=442) slow-growing embryos frozen on D6 (n=379). D5 group consisted in embryos graded 0, 1, 2 of Gardner scale and frozen on D5. Similarly, D6 group consisted in embryos graded 3, 4, 5 of Gardner scale (blastocyst stage) and frozen on D6. Differences in pregnancy rates between study groups were compared using a Chi2 test. A p-value <0.05 was considered statistically significant.
Main results and the role of chance: Baseline characteristics were comparable between study groups. Overall, mean age of the woman was 42.3±5.4 years old; donor sperm was used in 25% of cycles, and it was frozen in 73.2% of cycles. Pregnancy rates were significantly higher when transferring slow D5 embryos compared to D6 for all the pregnancy outcomes analyzed: biochemical pregnancy rate was 27.7% vs 20.2%, p<0.016; clinical pregnancy rate was 17.5% vs 10.2%, p<0.004); ongoing pregnancy rate was: 15.7% vs 7.8% (p< 0.001); live birth rate was: 15.4% vs 7.5%, (p<0.001). These results suggest that when embryos exhibit a slow development behavior (not reaching full blastocysts at D5), waiting until D6 for blastulation and expansion does not improve clinical outcomes. Vitrification at D5 will should the preferred option in cases where the oocyte is assumed of high quality
Limitations, reasons for caution: The retrospective design of the study is its main limitation. Also, morphology as sole selection criterion for transfer. However, blastocyst morphology is a very good predictor of implantation and pregnancy, and a good indicator of the embryo's chromosomal status (higher euploidy rate in higher morphological quality blastocysts).
Wider implications of the findings: These results can help to the standardization of laboratory protocols. As the decision of vitrifying slow developing embryos on D5 or D6 is made by the laboratory team or by the gynaecologist in agreement with the patient, having an evidence based strategy simplifies patient counselling and decision making.
Trial registration number: not applicable

P-160 Sibling oocytes cultured in a time-lapse versus benchtop incubator: limited exposure of embryos outside the incubator improves outcomes

N. D. Munck[1], N. Nobrega[2], A. Abdala[1], A. El-Damen[1], A. Arnanz[1], A. Bayram[1], I. Elkhatib[1], B. Lawrenz[3], H.M. Fatemi[3]

[1]ART Fertility Clinics, IVF lab, Abu Dhabi, United Arab Emirates ;
[2]GCRM, IVF Lab, Glasgow, United Kingdom ;
[3]ART Fertility Clinics, IVF Clinic, Abu Dhabi, United Arab Emirates

Study question: Does the limited exposure of embryos outside the incubator, during evaluation and changeover, have an impact on the blastocyst development, blastocyst quality and euploid outcomes?
Summary answer: Exposure of embryos outside the incubator, negatively impacts the number, quality and euploidy rate of day 5 blastocysts.
What is known already: The laboratory environment with its culture conditions is one of the crucial elements of the delicate equation to a successful ART outcome. It has been shown that increased fluctuations in the culture conditions have a considerable impact on the number of blastocysts obtained and cycle outcomes. Compared to conventional benchtop incubators, Time Lapse Technology (TLT) incubators capture images of the embryo and allow morphologic and morphokinetic assessment without disturbance during incubation. Several studies have been published comparing the efficiency, safety and outcome performance between conventional and TLT incubators, however, none of them explored the euploid outcomes.
Study design, size, duration: An observational sibling oocyte study was performed at ART Fertility Clinics, Abu Dhabi between March 2018 and April 2020 and included data of 796 mature oocytes injected from 42 stimulation cycles. Sibling oocytes were randomly split between 2 different incubators: 12 oocytes were assigned to the twelve wells of the EmbryoscopeTM (ES) and the remaining oocytes were cultured in a conventional benchtop incubator, G185 K-System (KS).
Participants/materials, setting, methods: Embryos from patients with primary or secondary infertility, who underwent ovarian stimulation for ICSI and PGT-A through NGS on trophectoderm biopsies, were eligible. All patients had at least 16 fresh mature oocytes, randomly allocated to two different incubators after ICSI: 503 (63.2%) oocytes were cultured in ES and 293 (36.8%) in KS. The fertilization, cleavage, useable blastocyst and euploid rates, as well as embryo/blastocyst qualities were assessed to evaluate each incubator's performance.
Main results and the role of chance: The fertilization and cleavage rates were similar between incubators. Total useable blastocyst rate (64.8% *vs* 49.6%, *p*<0.001) was significantly higher for embryos cultured in ES, mainly due a higher percentage of blastocysts biopsied on day 5 in ES (67.8% *vs* 57.0%, *p*=0.037), with improved quality (p=0.008). There was no difference in the total euploid rate between ES and KS (59.9% *vs* 50.4%, *p*=0.314), but a significantly higher euploid rate was seen for blastocysts cultured in ES and biopsied on day 5 (63.5% *vs* 37.4%, *p*=0.001). Day 3 embryo quality and total biopsied blastocyst quality was not different between incubators. No difference was observed in the total useable blastocyst development from good (p=0.0832) and poor (p=0.112) quality day 3 cleavage stage embryos. However, when stratifying according to the day of blastocyst development, poor quality embryos on day 3 showed superior blastocyst formation on day 5 when cultured in ES (64.1% vs 39.1% for day 5 and 35.9% vs 60.9% for day 6, p=0.005). Accordingly, blastocyst formation from poor quality embryos on day 3, was shifted to day 6 for embryos cultured in KS. This difference in the day of blastocyst development was not observed for good quality cleavage stage embryos (p=0.917).
Limitations, reasons for caution: The current observational study needs confirmation in a prospective trial and should also include the implantation potential of the euploid blastocysts, which was not followed in the current study. A good prognosis population (≥16 mature oocytes) was studied and may not reflect the outcomes in patients with lower oocyte numbers.
Wider implications of the findings: This work builds evidence to the solid introduction of the TLT incubators to the clinical routine, as the reduced exposure of embryos outside the incubator – and hence decreased stress - improves the blastocyst development.

P-161 Is enough the staff in your lab?

C. Olmed. Illueca[1], E. Veiga[2], E. Ferrer[3], M. Fernández[4], A. Mauri[5], L. Sanche. Castro[6], N. Ortíz[7]

[1]Hospital General Universitario de Valencia, Unidad de Medicina Reproductiva, Valencia, Spain ;
[2]Complexo Hospitalario Universitario de Santiago de Compostela CHUS. Servicio Gallego de Salud SERGAS. Travesía da Choupana- s/n. 15706 Santiago de

Compostela- España., Laboratorio Central/Unidad de Reproducción Humana Asistida., Santiago de Compostela, ;
[3]Crea. Centro médico de reproducción asistida., Laboratorío de embriologia, Valencia, Spain ;
[4]Clinica Ergo, Laboratorio de embriología, Gijón- Asturias, Spain ;
[5]Procrear, laboratorio de embriología, Reus. Tarragona, Spain ;
[6]Hospital Universitario central de Asturias, Unidad de Reproducción Asistida, Oviedo, Spain ;
[7]Instituto Europeo de Fertilidad, Unidad de Reproducción asistida, Madrid, Spain

Study question: Must be all the activity made in *in vitro* fertilization (IVF) laboratories keep in mind to size its staff?
Summary answer: To create a staff calculator based on number of cycles carry on, assisted reproduction techniques, quality controls, administration management, weekend duties, labour regulations and holidays.
What is known already: In a bibliographic search about staff in human reproduction labs there is no mention about de number of embryologists recommended for every cycle done. Only that it will be according to the workload. Other guidelines establish that every embryologist could assume 150 IVF cycles/year. However, here is a downward tendency in the work that an embryologist can assume. Alikani established a maximum of 100 cycles/year for every embryologist (Alikani *et al,* 2014).
Study design, size, duration: Seven senior embryologists working in different IVF centres, three public and 4 privates, take part lead in this Multicentre study during 2019 and 2020. We made a survey to create a calculator for staff using the mean time spent in every lab by each embryologist of the centre to do any IVF procedure and measured three times each one.
Participants/materials, setting, methods: Different lab procedures and activities related with quality control, time spent to do them, and witnessing were included in the survey. For the calculations it was considered an embryologist with a full-time contract working 1744 hours / year according to current labour agreement in Spain.

The times included in the calculations for each task were those corresponding to the 95th percentile. For the calculation, the program used was Microsoft Office Excel.
Main results and the role of chance: In the IVF laboratory many gametes and embryos from different couples are manipulated daily. The maintenance of traceability could be affected by not having the right staff and lead to dramatic consequences for the patients and the centre.

Workload or overload caused by non-suitable staff number also affects the embryologist having a direct impact on his health.

The results of the survey carried out showed the time needed by embryologist to perform the different procedures necessary for an IVF treatment, being a classic IVF cycle (8.11 hours), also taking into account the time spent in managing documentation, preparing the cycle and databases. An ICSI with Time lapse needs 10.27 hours and an ICSI-PGD cycle 13.91 hours. To all off this, 1.81 hours should be added for every vitrification support needed and the time to control more than 200 critical steps, including equipment control and culture parameters.

The time spent in semen analysis (including managing documentation, cycle preparation and databases) or intrauterine insemination with a partner sperm was 2.7 hours. For donor sperm an additional hour for the management involved is required. The time required to perform and cryopreserve a testicular biopsy and seminal cryopreservation was 4 and 3.7 hours, respectively.
Limitations, reasons for caution: The study was made taking account of Spanish regulations, quality standards and recommendations and should be adapted to the foreigner's regulations**.** Wider implications of the findings: New advance staff calculator allows laboratories estimate minimum number of embryologist necessary for a particular public or private laboratory without compromise neither security nor success in their results. Nevertheless, we recommended a minimum of two qualified embryologists in every lab, whatever it was the workload.
Trial registration number: none

P-162 Laser-assisted collapse of blastocysts prior to vitrification improves clinical outcomes

J. Ten[1], J. Guerrero[1], A. Rodríguez-Arnedo[1], L. Martí[1], M. Herreros[1], N. Díaz[1], R. Sellers[1], M.C. Tió[1], A. Bernabeu[2], J. Llácer[2], R. Bernabeu[2]

[1]Instituto Bernabeu, Embriology Unit, Alicante, Spain ;
[2]Instituto Bernabeu, Reproductive Medicine Unit, Alicante, Spain

Study question: What is the effect of artificial laser-assisted collapse before vitrification on pregnancy and implantation rates after transfer of vitrified-warmed blastocysts?
Summary answer: The artificial shrinkage by laser-induced collapse before vitrification significantly increased the implantation and clinical pregnancy rates after single thawed embryo transfer.
What is known already: Freeze all, cycle segmentation and, in general, single embryo transfer (SET) strategies (for example trophectoderm biopsy-based aneuploidy testing) have targeted blastocysts vitrification as the best option for reproductive practice worldwide. Artificial shrinkage seems to be a pre-vitrification parameter associated with an increased embryo survival after warming and implantation rate. However, the available medical evidence shows controversial results with only a limited number of prospective studies assessing the subject.
Study design, size, duration: This prospective cohort study evaluated 394 women who underwent a frozen blastocyst transfer at Instituto Bernabeu between July and December 2020. All patients were prepared with substitutive cycle and received single blastocyst embryo transfers.
Participants/materials, setting, methods: Before embryo vitrification on day 5 of development, some expanded and/or early hatching blastocysts (A/B ASEBIR categories) were artificial laser-assisted collapsed. (n=83, study group). 311 embryos of the same quality and day of development were not collapsed (control group). We compared the embryo survival rate, clinical, implantation and miscarriage rates between groups. The statistical analysis was performed using SPSS (version 20.0).
Main results and the role of chance: The two groups were comparable in terms of maternal age (39.79 ± 3.83, control group; 40.21 ± 4.45, study group; p=0.341). Embryo survival rate resulted in 100% in both groups.

Regarding clinical outcomes, collapsed blastocysts significantly increased the positive pregnancy test and the clinical pregnancy and implantation rate compared to the control group, respectively (positive test: 69,9% vs 43,4%, p=0.000018, odds ratio (OR)= 3.02 [95% CI 1.80–5.08]; clinical pregnancy and implantation: 56,6% vs 35,4%, p=0.000041, OR= 2.39 [95% CI 1.46–3.90]). The miscarriage rate was not affected by the blastocyst collapse effect (23,6% in the control group vs 27,6% in the study group, p=0.593, OR= 1.23 [95% CI 0.57-2.68]).
Limitations, reasons for caution: This is a non-randomized controlled study. Additional RCTs are warranted to corroborate our findings.
Wider implications of the findings: Considering the large number of blastocyst vitrification cycles that are carried out worldwide, artificial laser-assisted collapse before vitrification has the potential to increase the clinical results in benefit of many patients.
Trial registration number: Not Applicable

P-163 The presence of trophectodermal vesicles on expanded ICSI-derived blastocysts is a good predictor of implantation

O. Pravdyuk[1], M. Gryshchenko[2], L. Shatalova[1], K. Borodai[1]

[1]Gryshchenko Clinic-IVF, Embryology laboratory, Kharkiv, Ukraine ;
[2]Gryshchenko Clinic-IVF, Reproductive endocrinology, Kharkiv, Ukraine

Study question: Is the implantation rate (IR) higher in blastocysts with trophectodermal vesicles (TVs) compared to blastocysts without TVs or euploid blastocysts with unknown spontaneous hatching status?
Summary answer: The blastocysts with TVs demonstrate significantly higher IR in comparison to blastocysts without TVs or euploid blastocysts with unknown spontaneous hatching status.
What is known already: After ICSI spontaneous hatching mainly occurs by trophectoderm cell herniation via a small slit in the zona pellucida. At the beginning of this process, TVs are formed on the outside of the zona pellucida. It was previously shown that the clinical pregnancy rate was similar after the transfer of expanded blastocysts and expanded blastocysts with TVs. But another study showed that transfer of blastocysts of more advanced hatching stages yields better pregnancy rates than expanded blastocyst transfer. It remains unclear whether there is an association between the presence of TVs and IR in the transfers of single vitrified blastocysts.

Study design, size, duration: This retrospective cohort study was conducted from October 2018 to November 2019 and included 477 transfers of a single vitrified blastocyst. Cases were divided into 3 groups. Group 1 included transfers of blastocysts without TVs and with assisted hatching (AH). Group 2 contained the transfers of blastocysts at TVs stage of spontaneous hatching and without AH. Group 3 consisted of transfers of the euploid blastocysts with AH performed and unknown spontaneous hatching status.
Participants/materials, setting, methods: The age of women was between 21 and 39. Embryo transfers following oocyte donation programs were excluded from the study. This study included only transfers of the ICSI-derived fully expanded blastocysts with top-graded inner cell mass and trophectoderm. AH was performed using laser Saturn 3. The primary outcome was the implantation rate. Statistical analysis was performed using Pearson's chi-square test and likelihood ratio test. Preimplantation genetic testing for aneuploidy (PGT-A) was performed by next-generation sequencing.
Main results and the role of chance: The number of cases in groups 1,2 and 3 was 133, 49, and 295, respectively. The average age in the groups was about 32.5 and did not differ between groups. The implantation rate in group 3 with PGT-A was 60% (177 out of 295), which was insignificantly higher compared to group 1 - 55% (73 out of 133) (p = 0.34). In group 2, the implantation rate was 76% (38 out of 49), which exceeded significantly the outcomes in groups 1 and 2 (p = 0.016). Thus the transfer of expanded blastocyst with TVs gives higher IR in comparison to expanded blastocyst. Therefore TVs could be utilized as a morphological marker for embryo selection. Furthermore, according to obtained results the presence of TVs on nontested blastocysts predicts implantation better than euploidy does in blastocysts with unknown spontaneous hatching status.
Limitations, reasons for caution: This is a retrospective nonrandomized study with its inherited limitations.
Wider implications of the findings: Based on the results of the study embryo selection practice could be optimized. To maximize the outcomes of PGT-A programs embryo culture and biopsy workflow could be modified to allow collecting data on spontaneous hatching and TVs presence before performing the biopsy.
Trial registration number: not applicable

P-164 Mulitcentre derived time lapse algorithms developed using 6228 transferred embryos with known birth outcome incorporating novel morphological and morphokinetic markers

R. Smith[1], B. Petersen[2], A. Barrie[3], S. Montgomery[4], S. Duffy[4], L. Best[5], S. Thirlby-Moore[6], A. Wachter[7], L. Kellam[8], A. Campbell[1]

[6]CARE Birmingham, Embryology, Birmingham, United Kingdom ;
[7]CARE Beacon, Embryology, Dublin, Ireland ;
[8]CARE Nottingham, Embryology, Nottingham, United Kingdom

Study question: Can incorporation of novel markers of morphology with known temporal events successfully rank embryos to enable prediction of propensity for live birth?
Summary answer: Incorporation of variables for trophectoderm and morula grading demonstrably enhanced the model to rank embryos in order of potential for live birth.
What is known already: Models built using morphokinetic markers of development are widely used to rank embryos within a cohort. Such models include defined temporal parameters which are closely related to morphological grade. However, morphological grading by an embryologist is subjective and is not strongly correlated to outcome. Combining with defined kinetic events has been suggested to improve prediction of outcome.
Study design, size, duration: Data from 6228 known live birth outcome embryos from 8 UK clinics between 2011 – 2018 were investigated using an exploratory approach to identify novel markers of development.
Participants/materials, setting, methods: Five significant variables were defined, a derivative of time to start of blastulation; a derivative of trophectoderm grade; a kinetic variable utilising t3, t4, t5 and t8; an interval variable of tB-tSB and a variable based on novel morula classification. To maximise the output, a proxy value was derived for missing datapoints. The model was built using logistical regression and validated using fivefold cross validation with the data split as 80% training and 20% test.
Main results and the role of chance: An algorithm was developed including the five significant variables identified with an AUC of 0.685 demonstrating reliable prediction of live birth. Without morphological variables, the AUC was 0.674 demonstrating the improvement in the prediction value by including the derivative of the trophectoderm and morula grade. This resulted in ten classes of algorithm scores, 1-10, giving a live birth rate from 2% to 46%, irrespective of patient variables, for chance of live birth.
Limitations, reasons for caution: Successful application of the algorithm is reliant on stringent quality assurance for maintenance of accurate annotation and grading, and may not be transferable between laboratories with different SOPs.
Wider implications of the findings: The addition of a trophectoderm and morula grade in combination with morphokinetic parameters, increases the predictive value of the algorithm in relation to live birth outcome. Using proxy values allows maximization of data for model generation, and allows the model to be applied when missing values are present.
Trial registration number: not applicable

P-165 Using Artificial Intelligence to Classify Embryo Shape: An International Perspective

Study question: Is a pre-trained machine learning algorithm able to accurately detect cellular arrangement in 4-cell embryos from a different continent?
Summary answer: Artificial Intelligence (AI) analysis of 4-cell embryo classification is transferable across clinics globally with 79% accuracy.
What is known already: Previous studies observing four-cell human embryo configurations have demonstrated that non-tetrahedral embryos (embryos in which cells make contact with fewer than 3 other cells) are associated with compromised blastulation and implantation potential. Previous research by this study group has indicated the efficacy of AI models in classification of tetrahedral and non-tetrahedral embryos with 87% accuracy, with a database comprising 2 clinics both from the same country (Brazil). This study aims to evaluate the transferability and robustness of this model on blind test data from a different country (France).
Study design, size, duration: The study was a retrospective cohort analysis in which 909 4-cell embryo images ("tetrahedral", n = 749; "non-tetrahedral", n = 160) were collected from 3 clinics (2 Brazilian, 1 French). All embryos were captured at the central focal plane using Embryoscope™ time-lapse incubators. The training data consisted solely of embryo images captured in Brazil (586 tetrahedral; 87 non-tetrahedral) and the test data consisted exclusively of embryo images captured in France (163 tetrahedral; 72 non-tetrahedral).
Participants/materials, setting, methods: The embryo images were labelled as either "tetrahedral" or "non-tetrahedral" at their respective clinics. Annotations were then validated by three operators. A ResNet-50 neural network model pretrained on ImageNet was fine-tuned on the training dataset to predict the correct annotation for each image. We used the cross entropy loss function and the RMSprop optimiser (lr = 1e-5). Simple data augmentations (flips and rotations) were used during the training process to help counteract class imbalances.

Main results and the role of chance: Our model was capable of classifying embryos in the blind French test set with 79% accuracy when trained with the Brazilian data. The model had sensitivity of 91% and 51% for tetrahedral and non-tetrahedral embryos respectively; precision was 81% and 73%; F1 score was 86% and 60%; and AUC was 0.61 and 0.64. This represents a 10% decrease in accuracy compared to when the model both trained and tested on different data from the same clinics.
Limitations, reasons for caution: Although strict inclusion and exclusion criteria were used, inter-operator variability may affect the pre-processing stage of the algorithm. Moreover, as only one focal plane was used, ambiguous cases were interpoloated and further annotated. Analysing embryos at multiple focal planes may prove crucial in improving the accuracy of the model.
Wider implications of the findings: Though the use of machine learning models in the analysis of embryo imagery has grown in recent years, there has been concern over their robustness and transferability. While previous results have demonstrated the utility of locally-trained models, our results highlight the potential for models to be implemented across different clinics.
Trial registration number: Not Applicable

P-166 Machine learning for automated cell segmentation in embryos

Study question: Is it possible to automate the process of detecting individual blastomeres within a 4-cell embryo?
Summary answer: Deep learning models are capable of identifying individual cells in single focal plane images of 4-cell embryos.
What is known already: As individual blastomeres within a 4-cell embryo maintain totipotency, their intercellular junctions are critical in maintaining and directing communication. These junctions are determined by the zygote's cleavage patterns, and can affect the overall embryo 'shape', which can be described as either 'tetrahedral' or 'planar'. Planar embryos carry significantly worse outcomes both in the short and long term, such as more compromised blastulation, clinical pregnancy and live birth rates. Therefore, more accurate identification of cell borders at the 4-cell stage may contribute to improved classification of cell shape and embryo visualisation.
Study design, size, duration: This was a retrospective cohort analysis of 222 single focal plane images from 3 clinics. Each image captured an embryo at the 4-cell stage and was taken using the Embryoscope™ time-lapse incubator at the central focal plane. Images from two of the clinics were split into training (n=161) and validation (n=17) sets. Images from the third clinic formed a blind testing set (n=44).
Participants/materials, setting, methods: Ground truth masks were manually created by two human operators using the VGG Image Annotator software. A MaskRCNN neural network model with a pre-trained ResNet-50 backbone was trained to segment individual blastomeres from training images. Data augmentation (flips, rotations, Gaussian noise, cropping, brightness changes and optical distortion) were used during the training process. The model's performance was evaluated using the IoU metric (a measure of overlap between model-predicted and human-annotated masks).
Main results and the role of chance: The model was evaluated on a blind test set of 44 images. The model had a mean IoU of 0.92 for individual cells (Standard Deviation (SD) = 0.05) with precision and sensitivity of 0.95 and 0.97 respectively.

The mean IoU for the entire embryo (in relation to all 4 blastomeres combined) was 0.92 (SD 0.02). Furthermore, the model was able to count the number of cells in the images with 70% accuracy, and deviating by no more than 1 cell in each error. The nature of these errors can be broken down into the detection of fragmentation as a cell (2 cases); the detection of two cells as one (1 case); the cell being directly under another cell (4 cases); and duplicate detection of the same cell (6 cases). This last issue could be resolved by rejecting detections with significant overlap.

Our results demonstrate that our model can be used across different clinics.
Limitations, reasons for caution: Inaccuracies in segmentation and cell counting sometimes occurred when a cell's borders were unclear or obscured (e.g. in a different focal plane). The inclusion of multiple focal planes will be key for improving performance. Moreover, as only one focal plane was used, ambiguous cases were annotated with a 'best guess'.
Wider implications of the findings: The creation of a model capable of detecting individual cells would be highly beneficial in the IVF industry. Aside from automating laborious processes for embryologists, it may also prove a useful tool for future research such as in identifying intercellular contact points or rendering three-dimensional embryo visualisations.
Trial registration number: N/A

P-167 Assuring quality in embryology decision making: blastocyst grading agreement assessed via a smartphone application

D. Morbeck[1], E. Hammond[1], A.M.F. Kit[2], C. Curchoe[3]

[1]Fertility Associates, Embryology, Auckland, New Zealand ;
[2]Sunfert International Fertility Centre, Embryology, Bangsar South, Malaysia ;
[3]Fertility Guidance Technologies, Development, San Francisco, U.S.A.

Study question: Given the subjectivity of blastocyst grading and the challenge of performing routine competency assessments, how consistently do embryologists grade blastocysts when using an easily accessible phone application?
Summary answer: Grading agreement was fair to moderate for inner cell mass (ICM) and trophectoderm (TE), evidence that a mobile application can be used for quality assurance.
What is known already: Embryologists routinely perform external quality assessments (EQA), though the utility of EQA for quality improvement is limited, and more active, user-friendly tools are needed to improve quality assurance in embryology. Blastocyst grading is one of the most important and subjective tasks in clinical embryology, important for both blastocyst ranking and decision to freeze. Inter-user agreement is only fair for ICM (kappa 0.349) and TE grade (kappa 0.397; Storr et al., 2017). Fair agreement has also been reported for decision to freeze for a cohort of blastocysts that exhibited borderline morphology (kappa 0.301; Hammond et al., 2020).
Study design, size, duration: A prospective study of blastocyst grading consistency using ARTCompass, a mobile phone application designed to assess clinical decision making of laboratory staff for andrology and embryology competency. Two assessments, each with 100 images of expanded blastocysts in three planes, were performed by 42 embryologists from 9 clinics in 2 countries between April to July 2020. Survey 1 assessed ICM grading and survey 2 assessed TE grading using the same set of images for consistency.
Participants/materials, setting, methods: Blastocysts were of proportionally mixed grades (ranging from grade A to X) using a modified Gardner system that included "X" for non-viable ICM/TE. Embryologists were advised to complete the tests individually in one sitting. The Fleiss kappa coefficient (k) measured inter-rater agreement among embryologists when assigning blastocyst grade. Kappa value interpretation is as follows <0.20: poor; 0.21–0.40: fair; 0.41–0.60: moderate; 0.61–0.80: good and 0.81–1.00: very good.
Main results and the role of chance: Overall, agreement for ICM and TE grades was moderate among embryologists (kappa 0.47, 0.52, respectively). ICM grade B and C had the lowest agreement (0.37, 0.39), while ICM grade X (no, or degenerate ICM), and TE grade A showed the highest agreement (0.68, 0.62). These results illustrate that embryologists had difficultly classifying ICM grade when it was of moderate to poor quality (grade b or c), likely due to subjectivity in grading size and compaction level, but were good at classifying ICM grade when there was no apparent ICM (grade x). For TE grade, embryologists consistently identified a top-quality TE (grade a), which is reassuring as TE grade is the primary morphological feature used for blastocyst ranking. In general, this QA platform offers ease of use and shows agreement values for

ICM and TE that are similar to other studies, suggesting that blastocyst grading with a mobile phone application is a viable option for quality assurance.
Limitations, reasons for caution: Only blastocyst grading was assessed, therefore additional competency assessments using a mobile device should be assessed for accuracy. Further studies are needed to determine if mobile applications can improve competency.
Wider implications of the findings: Ease of use by 42 embryologists indicates mobile applications may provide a user-friendly and accessible platform for QA. Since effective and efficient assessment of competency and KPIs is an ongoing challenge for laboratories, a mobile application is a novel and effective tool to monitor QA parameters in the IVF laboratory
Trial registration number: not applicable

P-168 RCT comparing the effect of Continuous (Single Step) embryo culture system versus a Sequential embryo culture system on the outcome of IVF/ICSI cycles

R. Singh[1], M. Singh[2]

[1]BHOPAL TEST TUBE BABY CENTRE, INFERTILITY, BHOPAL, India ; [2]BTTB Centre, Infertility, Bhopal, India

Study question: Is the outcome of IVF/ICSI cycles done with continuous (single step) embryo culture system different from that with sequential embryo culture system ?
Summary answer: Yes the outcome of IVF / ICSI cycles done with continuous (single step) embryo-culture system is better than that with sequential embryo-culture system .
What is known already: Embryo culture media are important factors in IVF, which can significantly influence the clinical outcome of IVF/ICSI cycles. However it is not clear which formulation is most optimal and whether sequential or continuous media (single step) should be favored. Sequential media complies with embryo demands based on developmental stage , taking into account metabolic changes embryos undergo in-vivo, while moving from the oviduct to the uterus. The embryos in the early cleavage stage prefer to use pyruvate to produce energy, whereas once development nears the blastocyst stage , the embryos start using glucose in the process of glycolysis .
Study design, size, duration: A prospective RCT was carried out at our centre between 2018-2019 and IVF-ICSI patients meeting inclusion criteria (at least six normal MII - Oocytes) were included in this study. The aim of study was to compare blastocyst formation rates after embryo-culture in two different culture media systems. 436 metaphase II Oocytes from 62 women were randomly and equally divided to be fertilized and cultured to the blastocyst stage in either sequential media or single-step media.
Participants/materials, setting, methods: In this prospective trial with sibling oocytes, 436 metaphase II oocytes from 62 women were randomly and equally divided to be fertilized and cultured to the blastocyst stage in either sequential media (n = 218 MII oocytes) or a single medium (n = 218 MII oocytes). In both groups, embryos were cultured in an interrupted fashion with media changes on day 3. Embryo transfer was performed on day 5.
Main results and the role of chance: Blastocyst formation rates on day 5 were significantly higher following culture in single step media 60.55 % (132 / 218) as compared to sequential media 34.86% (76 / 218) . The percentage of good quality blastocysts was also significantly higher in single step media. In conclusion, culture in single step media was associated with higher blastocyst formation rates compared to sequential media , suggesting that the single medium may provide better support to the developing embryo. The proportion of poor quality embryos was significantly higher in the sequential media group. Results indicate that embryo culture in continuous media could be as efficient as embryo culture in sequential media. A significant difference observed was the proportion of poor quality embryos on day 5 , which was significantly higher when the embryos were cultured in sequential media. Our results suggest that the type of embryo culture media can influence the quality of embryos both at the cleavage stage and blastocyst stage. The use of continuous embryo culture media does not seem to cause an adverse effect; in fact, their use can lower the workload in busy IVF labs and lower the stress that embryos are exposed to during handling.
Limitations, reasons for caution: Although single-step-medium for extended culture has practical advantages and blastocyst formation rates appear to be higher, there is insufficient evidence to recommend either sequential or single-step media as being superior for the embryo-culture to days 5/6. Further studies comparing these two media systems in well-designed trials should be performed.
Wider implications of the findings: When employing sequential media for embryo culture , it is necessary to transfer the embryos from one medium to another (cleavage stage medium to blastocyst stage medium) which increases stress related embryo damage . Therefore, single-step media is beneficial as the embryos can develop undisturbed till blastocyst stage.
Trial registration number: not applicable

P-169 Does increasing the time interval between Oocyte-Retrieval and Oocyte-Denudation improve the results in ICSI cycles ?

M. Singh[1], R. Singh[2]

[1]Bhopal Test Tube Baby Centre, Gynaecology and Obstetrics, Bhopal, India ; [2]BTTB Centre, Infertility, Bhopal, India

Study question: What should be the optimal time interval which elapses between oocyte retrieval and denudation followed by ICSI , for optimal results in ART cycles ?
Summary answer: Our study suggests that an optimum interval between oocyte retrieval and oocyte denudation followed by ICSI, leads to better results in ART cycles.
What is known already: It is widely accepted that the best timing for OPU is 34-39 hours after ovulation trigger. Some studies suggest that preincubation time before ICSI can be beneficial when it comes to fertilization and pregnancy rates while late ICSI (fertilization) may have negative results due to oocyte ageing. Other studies claim that there is no significant difference in ART results when ICSI is performed between 2-6 hours post Oocyte-Retrieval (OR) . Few studies state that 1-3 hours of COC-culture prior to denudation and oocyte injection is better as far as fertilization , embryo quality and improved oocyte cytoplasmic maturity is concerned.
Study design, size, duration: RCT of 234 ICSI cycles was carried out between 2017-2019. Patients were divided into two groups-: A- Early denudation with ICSI and B- Late denudation with ICSI.Both the groups were comparable in terms of female age, number of oocytes, day of transfer, number of embryos transferred and embryo quality. Fresh or frozen embryos were transferred , which were always derived from the same stimulation cycle. Exclusion criteria were : Severe male factor / TESA / PESA.
Participants/materials, setting, methods: 234 ICSI cycles with similar ovarian stimulation protocols were analyzed as per time range between triggering, OPU, denudation and ICSI. Patients were divided into two groups: A- Early denudation (1-2 hours after OPU) with ICSI (1-2 hours after denudation) and B- Late denudation (4-6 hours after Oocyte-Retrieval) with ICSI (1-2 hours after denudation).Primary outcomes were oocyte maturation and fertilization rates and secondary outcomes were clinical pregnancy rate and abortion rates.
Main results and the role of chance: In group B (Late denudation and ICSI), the mean fertilization rate was 67% and the Clinical Pregnancy rate was 46%. This was better than the mean fertilization rate of 56% and clinical pregnancy rate of 39% observed in group A (Early denudation and ICSI). However the difference was not statistically significant. Therefore, ideal maturation rates were observed when denudation (followed by ICSI) was delayed and done 4-6 hours after Oocyte-Retrieval. In ICSI cycles in ART , ovarian stimulation is used to induce the simultaneous growth of multiple follicles, followed by final maturation and ovulation triggering with exogenous hCG. or GnRH-Agonist or both. Generally, oocyte retrieval (OR) is performed 34 - 36h later. In addition, 2-4 hours in culture of the cumulus oocyte complexes (COC) prior to oocyte injection is believed beneficial for fertilization and embryo quality, probably due to improved oocyte cytoplasmic maturity. However, in large ART centers with high workloads, following such definite time intervals is frequently very difficult.
Limitations, reasons for caution: In large busy centers , maintaining meticulous time intervals is difficult . As our study numbers are small, larger multicentric trials are required in order to confirm our findings and to provide more robust data . This data cannot be applied to IVM, TESE / PESE and severe male-factor infertility.
Wider implications of the findings: To achieve a successful fertilization, both nuclear and cytoplasmic maturity are required. Our Study indicates that a

slight delay in denudation following Oocyte-Retrieval , will yield a higher number of good quality oocytes. A higher success rate can also be expected due to more number of embryos available for transfer.
Trial registration number: not applicable

P-170 The secretomy of embryo sex

M. Orteiro[1], M. Piccolomini[1], C. Garcia[1], I. Massaia[2], A. Alvarenga[1], E. L. Turco, D.V.M.[3], O. Duarte[4], L. Yamakami[5]

[1]Lab For Life, Embryology, São Paulo, Brazil ;
[2]Faculdade de Medicina da Santa casa de São Paulo, Clinica Médica, São Paulo, Brazil ;
[3]UNIFES/EmbrioLogica, Urologia, Sao Paulo, Brazil ;
[4]Lab For Life, Clinical, São Paulo, Brazil ;
[5]Vida Bem Vinda Clinic, Clinical, São Paulo, Brazil

Study question: Does the analysis of the metabolites of the embryonic culture medium can predict the sex of the embryo?
Summary answer: The presence and quantity of some metabolites in the culture medium can predict the sex of the human embryos.
What is known already: Advances in analytical techniques for metabolomics have brought the possibility of better tools for the characterization of molecules. Embryonic metabolism can be used as a good indicator of viability, regardless of the morphology of the blastocysts, since differences were observed in the metabolic activities between the days of embryo development and in the rates of live births.
Study design, size, duration: 16 patients had their embryos biopsied between the months of January to July 2019 in a human reproduction laboratory. All cases had PGT-A indication and after the biopsy, the embryos were frozen. The culture medium samples were individually prepared for metabolites extraction according to the Bligh and Dyer protocol. Controlled ovarian stimulation and dose adjustments according to the response of each patient. The metabolomics analysis was performed by mass spectrometry.
Participants/materials, setting, methods: Follicular puncture were performed 35 hours after r-hCG. The eggs were kept in individual culture until the blastocyst stage. The blastocysts biopsy was performed (20). After the culture medium was sent to the 337 metabolites analysis by mass spectrometry. 14 molecules with the highest score on the PLS-Da was submitted to the ROC curves showing the power of metabolic analysis to predict the sex of euploid embryos. Besides, we performed the functional enrichment analysis.
Main results and the role of chance: After the genetic analysis by PGT-a, we obtain 20 euploid embryos, being 12 female embryos and 08 male embryos. Comparing the quantitative target metabolomic analysis of the 337 metabolites in the embryo culture medium, we observed the Asymmetric dimethylarginine, FAD, Malic Acid, Serotonin, increased in female embryos and Adenosine monophosphate, L-Alanine, L-Arginine, Cysteamine, DL-Dopa, Flavin Mononucleotide, Methionine sulfone, Nicotinic acid, L-Tyrosine, Uracil in male embryos. Through the ROC curve, we can verify AUC = 0.937. This result suggests that the metabolomic analysis of the culture medium is valid to be used as a complement of PGT-A to know embryo sex diagnostic. The functional enrichment analysis shows the Asymmetric dimethylarginine and Malic Sulfone metabolism as the principal function alter by female embryos.
Limitations, reasons for caution: Small number of samples
Wider implications of the findings: Further studies are needed to validate these findings for the diagnostic of sex embryos
Trial registration number: N/A

P-171 Automated oocyte and zygote denudation using a novel microfluidic device supervised by a computer vision algorithm

J. Guerrer. Sánchez[1], Y. Cabello[1,2], G. Fernánde. Blanco[3], J. Fidalgo[3], I. Hernánde. Montilla[3], P. Carasa[3], L. Matthys[3], P. Belchin[2], J.A. Horcajadas[1], S. Munné[1,4]

[2]Hospital Ruber Juan Bravo Quironsalud, Embryology, Madrid, Spain ;
[3]Overture Life, Engineering, Madrid, Spain ;
[4]Yale University, Ob/Gyn, New Haven, U.S.A.

Study question: Is it possible to remove cumulus cells using a 16-well microfluidic device with automated flows to facilitate vitrification, ICSI, NI-PGT or non-invasive metabolomics analysis?
Summary answer: The designed automated system and protocol efficiently denude 16 samples simultaneously with a x10 lower shear stress than the manual process and without human intervention.
What is known already: Most processes involved in IVF such as insemination, washing, denudation, embryo culture and selection are still manually performed, labor-intensive and require highly skilled professionals. This leads to a significant variability in the clinical outcomes achieved by different embryologists and labs. The automation of these processes is a promising approach to reduce costs and improve the accessibility to assisted reproductive therapies. Although a simple procedure, standardization of cumulus oocyte complex (COCs) and zygotes denudation is key to facilitate ICSI, vitrification and to avoid DNA contamination for NI-embryo testing (PGT or metabolomics), while avoiding damage to the oocyte by excessive shear stress.
Study design, size, duration: A total of 160 cow COCs were used due to their size similarity with human COCs. Half were denuded 16-20 hours post-insemination and half pre-insemination for 5-10 minutes. COCs were classified as partially denuded if fertilization assessment, ICSI or vitrification was possible, and completely denuded if no cumulus cells remained. COCs controls were manually denuded (Stripper® capillary 145µm ID) to compare shear stress between procedures. This study was conducted during 2020 – 2021.
Participants/materials, setting, methods: We developed a customized microfluidic biochip that exerts a particular fluid motion while avoiding egg entrapment within microfluidic channels. The denudation efficacy was established by subjectively scoring images of bovine oocytes after generating a continuous "Push & Pull" fluid motion inside the biochip wells. A Computer Vision model was developed in parallel in order to optically assess denudation completion. The model used was a Pytorch implementation of Faster-RCNN with ImageNet pretrained weights
Main results and the role of chance: 96 bovine COCs were microfuidically handled post insemination achieving complete (56/96) or partial (40/96) removal of the cumulus cells on day 1, while for day 3 double denudation group, 89/96 (92.7%) were completely denuded while the rest remained partially denuded. In comparison, 80/80 (100%) of manually denuded cow COCs, achieved complete denudation (50% post-insemination group and 50% pre-insemination group). In addition, 48/64 (75%) cow COCs treated pre-insemination were partially denuded, enough to carry out ICSI after 5-10 min of treatment. The results here obtained indicate that media needs to flow through the device at a rate that can generate enough shear to strip off the cumulus-corona cells while avoiding emptying of the reservoirs containing the fertilization or culture medium. The shear stress of our design was calculated to be smaller than 4.4 Pa, about ten times lower than the one applied by the manual process (~44Pa). The deep learning algorithm was tested on 20 unseen human oocytes on day 1, with 10 true positives 9 true negatives, and 1 false negative (95% accuracy).
Limitations, reasons for caution: The success of the denudation procedure was dependent on the design of the biochip wells and the microfluidic protocol used. The accuracy of our findings is still limited because of the difficulty in manufacturing prototype biochips.
Wider implications of the findings: Complete denudation is key to avoid DNA contamination for NI-PGT or metabolomics analysis, while avoiding damage to the oocyte by excessive shear stress. Our device, which has the potential of scaling up and treat each oocyte individually, can improve automation and increase efficiency of current ART procedures
Trial registration number: NA

P-172 Data-independent acquisition-proteomics of human embryo-spent medium and identification of potential embryo biomarkers

M. Pathak[1], V. Venkatappa[1], S.S. Vasan[2], K. Prasad[3], C. Narayana[3], S. Adiga[4], S.R. Varsha[5], G. Sachdeva[6], P.B. Seshagiri[1]

[1]Indian Institute of Science, Molecular Reproduction and Development, Bangalore, India ;
[2]Blue Bliss Hospital, Andrology, Bangalore, India ;
[3]Manipal Ankur Andrology & Reproductive Services, Bangalore, India ;
[4]Kasturba Medical College, Department of Clinical Embryology, Manipal, India ;
[5]Advanced Fertility Centre, Bangalore, India ;
[6]National Institute of Research in Reproductive Health, Primate Biology, Mumbai, India

Study question: Can human embryo-derived protein(s) serve as viability biomarkers to predict pregnancy outcome, post embryo transfer?
Summary answer: The human embryo-spent medium proteome, using data-independent acquisition (DIA) approach, could identify novel biomarkers for use in elective embryo transfer.
What is known already: Morphological assessment is used for elective embryo transfer. To improve IVF outcomes and to avoid multiple gestations, embryo-viability assessment is required toward single embryo transfer. Embryo proteomics could provide a non-invasive approach to assess embryo viability. With the advent of DIA mode proteomics, a robust proteome of E-SM could be determined.
Study design, size, duration: This was a retrospective study performed between May and December, 2020 using ten E-SMs obtained from ten individual transferable-quality embryos. Frozen E-SMs, following post-thaw, were subjected to LC-MS-MS analysis. Identified proteome profiles were being potentially correlated to embryo quality scores and pregnancy outcomes in terms of live births.
Participants/materials, setting, methods: The E-SMs were processed for proteomic analysis and subjected to reduction, alkylation and trypsin digestion. Trypsin digested samples were desalted followed by LC-MS/MS using DIA method. Obtained results were searched against human peptide spectral library using Skyline. Differentially expressed proteins were identified by MSStat. Individual peptide peak area under the curve was normalized and analyzed using Student t-test. Fold change was calculated to identify differentially regulated proteins in blank and E-SM samples.
Main results and the role of chance: Using a high-resolution mass spectrometer and high throughput DIA method, we identified 5,502 peptides corresponding to 3,396 proteins from blank and E-SM samples, derived from five non-transferred embryos. We observed that 516 proteins were specific to E-SMs *vies-a-vies* those of embryo-free blank medium. Statistical analysis showed that 25 proteins were significantly present E-SMs *vs.* blank. Interestingly, we observed that 16 proteins were down regulated and 9 were up regulated in E-SMs *vs.* blank medium. Furthermore, E-SMs, from transferred embryos, contained 2,467 peptides corresponding to 1,741 proteins; of these, 1, 689 proteins were specific to E-SMs with 60 (58 down regulated and 2 up regulated) of them being significantly expressed in E-SMs *vis-à-vis* embryo-free blank medium. Considering the available met analysis published data, our study is the first to use DIA acquisition for high-throughput analysis of human embryo proteome and identification of biomarkers of embryo viability and for possible prediction of pregnancy outcome.
Limitations, reasons for caution: Proteins, other than HAS, detected in the blank medium could be because of non-purified HAS or undeclared proteins and DIA approach used. A large cohort study and meta-analysis using DIA mode are required to establish the embryo-proteome having predictive potential for embryo biological viability.
Wider implications of the findings: For the first time, using DIA mode, a global embryo proteome assessment could be made, establishing a novel embryo viability biomarkers. This, along with the morphological analysis, could be practiced for selection of transferable quality embryo(s)
Trial registration number: Not Applicable

P-173 Predicting implantation: comparative performance of two embryo selection algorithms and conventional morphological grading after frozen blastocyst transfer

S. Biswa. Shivhare[1], A. Price[2], S. Ingamells[2]

[1]Simply Fertility, The Fertility Partnership, Chelmsford, United Kingdom ; [2]Wessex Fertility, The Fertility Partnership, Southampton, United Kingdom

Study question: What is the predictive performance of iDAScore® compared with KIDScore™ D5 and conventional morphology grading for implantation after frozen blastocyst transfer?
Summary answer: iDAScore®, KIDScore™ D5 models and conventional morphology grading are all significantly associated with implantation after frozen blastocyst transfer. However, their predictive performance remains fair.
What is known already: Embryo selection algorithms (ESA) have been used in conjunction with conventional morphology grading (CMG) to rank embryo quality in an attempt to optimise embryo selection prior to transfer. Traditionally, ESA, such as the KIDScore™ D5 prediction model, have been based on predetermined morphokinetic parameters which vary according to the specific ESA used. Recently, algorithms based on artificial intelligence (AI) deep learning such as the iDAScore®, have been developed using raw time lapse image data of embryos with known implantation outcome. Embryo scores generated by both traditional and AI based ESA have been positively correlated with implantation potential in retrospective studies.
Study design, size, duration: This retrospective single centre study included data from 157 frozen embryo transfers carried out between January 2020 and January 2021 with embryos cultured in EmbryoScope+ time-lapse incubator. Embryos were selected for transfer using CMG. iDAScore® and KIDScore™ D5 were generated retrospectively for each embryo transferred. Sensitivity and specificity for implantation in addition to concordance was determined for all three embryo scoring systems and compared.
Participants/materials, setting, methods: Statistical analysis was performed with SPSS software. ROC curve analysis was performed to investigate the predictive performance of the three embryo selection methods for implantation. Chi-Square test was used to determine if there was a significant association between iDAScore®, KIDScore™ D5 and CMG with implantation. Spearman's correlation tested for correlation between iDAScore®, KIDScore™ D5 and CMG.
Main results and the role of chance: A statistically significant but limited predictive power was observed between iDAScore®, KIDScore™ D5 and CMG methods of embryo selection and implantation rate (AUC=0.675, 95% CI 0.59, 0.76; AUC=0.683, 95% CI 0.60, 0.77 and AUC=0.638, 95% CI 0.55, 0.73) respectively. Unsurprisingly, higher values for each of iDAScore®, KIDScore™ D5 and CMG were significantly associated with higher implantation (p=0.002, p<0.001, p=0.003) respectively. Interestingly, there was a significantly moderate correlation between iDAScore® and CMG rs (155)=0.581, p<0.001, while a significantly strong correlation between KIDScore™ D5 and CMG rs (155)=0.775, p<0.001 as well as between iDAScore® and KIDScore™ D5 rs (155)=0.799, p<0.001.
Limitations, reasons for caution: This is a retrospective single centre study with limited sample size, hence the results may be interpreted with caution. Further analysis involving a larger patient cohort must be carried out prior to implementing iDAScore® or KIDScore™ D5 as primary embryo selection methods.
Wider implications of the findings: The findings of this study support the potential application of iDAScore® and KIDScore™ D5 prediction models in automatic embryo selection, thereby minimising operator variability and time taken for embryo grading.
Trial registration number: Not Applicable

P-174 Globulin-rich protein supplements improve blastulation efficiency in culture and promote implantation in vitro

S. Ojosnegros[1], A. Seriola[1], E. Aroca[1], A. Godeau[1], D. Denkova[1], M. Casals[1]

[1]Institute for BioEngineering of Catalonia IBEC, Bioengineering in Reproductive Health, Barcelona, Spain

Study question: Can globulin-rich compared to albumin (HSA) supplements improve blastulation and support embryo development towards post implantation?
Summary answer: Yes, globulin supplements with clinical-grade quality increase blastulation efficiency by 20% (50% in older mothers) and support the transition of embryos towards post-implantation development.
What is known already: During embryonic development at the morula stage there is a metabolic transition towards glycolysis as demand from outsourced energy increases. Therefore as cleavage proceeds, the demand for nutrients in the embryo increases accordingly.

With few exceptions, HSA from human plasma or recombinant origin has been the main an only protein supplement used in almost all IVF-procedures. Globulin rich supplements are available but their use is not widespread and little is known about their efficiency in post-implantation development.
Study design, size, duration: We have cultured more than 600 mouse embryos in continuous media containing a protein supplement#1 (PS#1), from 1-cell up to blastocyst stage. At blastocyst stage embryos were replaced into fresh media containing protein supplement#2 (PS#2). The embryos were allowed to hatch naturally and then transferred into a proprietary matrix for further development and implantation for an additional 48h. Participants/materials,

setting, methods: The blastulation rate, measured for HSA-supplemented embryo cohort was compared with embryos cultured in PS#1. Hatching efficiency was reported for embryos cultured in transfer media including PS#2. Once embedded in the matrix, advanced label-free imaging techniques and custom algorithms to measure matrix implantation strength were used. Key molecular markers (i.e. OCT4, CDX2) for correct post-implantation lineage patterning were documented by conventional 3D confocal immunofluorescence imaging.

Main results and the role of chance: Embryos supplemented with PS#1 reached blastocyst with overall 21% higher efficiency than embryos supplemented by HSA. When separated by age cohorts, embryos obtained from older females (ex-colony breeders, >14 weeks old) reached blastocyst stage with 55% higher efficiency than the same type of embryos cultured in the presence of HSA. Embryos obtained from females at optimal reproductive age reached blastocyst stage 10% more efficiently under PS#1 supplementation than with HSA. Hatching efficiency was 45% higher for embryos cultured with PS#2 than embryos supplemented with HSA. For every variable tested (e.g. % of arrested or degenerated embryos) or condition implemented (e.g. mouse basal media, human basal media from different brands, etc.) PS#1 and PS#2 outperformed, without exception, the supplementation with HSA.

When embedded in the implantation matrix, the embryos cultured with PS#1 (cleavage) and transferred to PS#2 at blastocyst stage showed a remarkable implantation ability as measured by trophoblast outgrowth and matrix deformations. The embryos in PS#2 medium exerted stronger force into the matrix and also survived longer times than the embryos in HSA. PS#2 supported the transition of blastocyst towards post-implantation stages of development showing the correct lineage patterning of embryonic and extraembryonic molecular markers, including Oct4, CDx2, EOMES or GATA4.

Limitations, reasons for caution: This is a study based on an animal model. These observations need to be confirmed by ongoing experiments with human embryos.

Wider implications of the findings: This work constitutes a proof-of-concept for the use of globulin-rich supplements as higher performance substitute of albumin in the culture of IVF embryos, both as (i) a standard protein source for culture media and (ii) as a supplement for transfer media to capacitate the embryo for implantation.

Trial registration number: not applicable

P-175 Possible role of NAD+ metabolism in oocyte aging: insights from gene expression profiles in reproductive aged oocytes

G. D. Emidio[1], F. Konstantinidou[2], P.G. Artini[3], V. Gatta[2], C. Tatone[1]

[1]University of L'Aquila, Dept. of Life- Health and Environmental Science, L'Aquila, Italy ;
[2]"G.d'Annunzio" University, Department of Psychological- Health and Territorial Sciences- School of Medicine and Health Sciences-, Chieti, Italy ;
[3]University of Pisa, Department of Clinical and Experimental Medicine- Division of Obstetrics and Gynecology Oncology, Pisa, Italy

Study question: Does reproductive aging alter the expression of genes involved in NAD+ metabolism in the mammalian oocyte?

Summary answer: We found that aging alters the expression of thirty genes encoding for NAD+-producing and NAD+-consuming enzymes pathway in mouse MII oocytes.

What is known already: NAD, a multifunctional metabolite in living cells, is known to convert between its oxidized NAD+ and reduced NADH forms during nutrients breakdown; the intracellular NAD+/NADH redox state reflects cell ability in generating ATP energy. NAD+ is utilized by proteins that control gene expression, DNA repair, apoptosis, mitochondrial biogenesis (i.e. sirtuins). Raising NAD+ by inducing its biosynthesis leads to sirtuins activation, so directly linking the cellular redox state with signalling events. The NAD+ pool is set by a critical balance between NAD+ biosynthetic and NAD+ consuming pathways. NAD(P)H levels declined in aged oocytes and NAD+ precursors seem to counteract ovarian aging.

Study design, size, duration: Pools of 25 oocytes at MII stage were obtained from young (4–8 weeks) and reproductively aged (48–52 weeks) CD-1 mice and processed for the analysis of 41 genes participating in NAD+ biosynthetic and NAD+ consuming pathways NAD+ pathways. Each experiment was performed three times and data were subjected to bioinformatic analysis to unravel potential age-related effects on NAD metabolism.

Participants/materials, setting, methods: Mice were superovulated by intraperitoneal injection of PMSG followed by hCG 48h apart. MII oocytes were isolated by 0.3 mg/ml hyaluronidase. RNA was obtained from each sample by Arcturus PicoPure Kit, and reverse transcribed. Each cDNA was analysed in triplicate by employing a NAD Metabolism H41 Predesigned panel for use with SYBR® Green, containing 41 genes of the NAD pathway, 2 housekeeping genes and 6 control probes. Raw data were analysed by DataAssist software.

Main results and the role of chance: The comparison between aged and young oocytes were focused on genes showing an absolute fold change (FC) <0.7 or > 1.4, a present call in at least the 50% of experiments and a p-Value <0.05 (ANOVA). Excluding transcripts showing a concordant value < 80%, n.30 differentially expressed genes (DEGs) were found: n.26 transcripts down-expressed and n.4 genes up-regulated. Data obtained by Ingenuity Pathways Analysis (IPA) software (Ingenuity Systems) provide evidence that NAD+ biosynthesis in aged oocytes is severely compromised.

Limitations, reasons for caution: Our results on animal model must be taken with caution. Validation of NAD+ precursor or activators of NAD+ biosynthesis in vivo administration is required.

Wider implications of the findings: Present results demonstrate that aging affect oocyte genes involved in the regulation of NAD+ availability and supports the hypothesis that modulation of NAD+ metabolism may be an "anti-aging" strategy. Overall, these data laid the foundation for a central role of NAD+ metabolism in the maintenance of oocyte competenc

Trial registration number: not applicable

P-176 Effects of high non-esterified fatty acids exclusively during bovine in vitro fertilization on cell lineage allocation of blastocysts

A. Idriss[1], E. Okello[1], S. Roger[2], M. Velazquez[3]

[1]Translational And Clinical Research Institute- Newcastle University- Newcastle upon Tyne- UK., Medical School, Newcastle, United Kingdom ;
[2]Center for Cardiovascular and Metabolic Research- Hull York Medical School- University of Hull- Hull- UK. 3School of Natur, Hull York Medical Schoo, Hull, United Kingdom ;
[3]Newcastle University- Newcastle upon Tyne- UK., School of Natural and Environmental Sciences- Newcastle University- Newcastle upon Tyne- UK., Newcastle, United Kingdom

Study question: Are there effects of high non-esterified fatty acids exclusively during bovine in vitro fertilization on cell lineage allocation of blastocysts?

Summary answer: Under the conditions of the present study, high exposure to NEFA during bovine IVF significantly decreases embryo production and alters cell allocation of resultant blastocysts.

What is known already: Cattle models have shown that a high exposure to non-esterified fatty acids (NEFA) such as steric acid (SA), palmitic acid (PA]) and oleic acid (OA) during in vitro oocyte maturation and embryo development can disrupt both embryo formation and quality. However, the fertilization process per se have been less studied, which is needed to identify developmental stages were potential therapies could be develop to ameliorate NEFA toxicity during the periconceptional period

Study design, size, duration: Day-8 blastocysts were immunostained for CDX2, a transcription factor involved in trophectoderm differentiation, to examine cell allocation of blastocysts derived from oocytes fertilised under high NEFA levels. VF (19 h) was carried with different NEFA levels(4 replicates) representing physiological (Control-1[C1], 28μM SA, 23μM PA, 21μM OA) and pathophysiological (NEFA, 280μM SA, 230μM PA, 210μM OA) relevant concentrations. A second control (C2) group contained solvent. Blastocysts (C1; n=14, C2; n=12, NEFA; n=8)

Participants/materials, setting, methods: All blastocysts were examined by confocal microscopy and cell counting was done with the Imaris software. Data were analysed by ANOVA (mean±SEM) with percentage data arcsine transformed before analysis.

Main results and the role of chance: Blastocyst formation was decreased by high NEFA levels (C1=25.6±2.7%, C2=26.0±2.3%, NEFA=9.4±0.4%, P<0.001) which was associated with a decreased cleavage rate (C1=70.1±6.5%, C2=71.5±3.1%, NEFA=42.5±4.1%, P=0.006) and an increase in embryo degeneration (C1=47.6±3.5%, C2=47.7±5.8%, NEFA=63.0±4.9%, P=0.05). A lower total cell (TC) the number was observed in high NEFA-derived blastocyst (C1=125.2±6.6, C2=132.3±8.4, NEFA=67.3±5.6, P<0.001) associated with a

low cell number in both the trophectoderm (CDX2 positive cells, C1=90.2±5.9, C2=96.7±6.4, NEFA=41.3±4.1, P<0.001) and the inner cell mass (ICM, C1=35.0±2.4, C2=35.7±3.5, NEFA=26.0±2.2, P<0.001). Furthermore, high NEFA-derived blastocyst showed an increased allocation of cells towards the ICM (ICM/TC proportion, C1=28.2±1.7%, C2=26.9±1.8%, NEFA=39.1±2.2%, P<0.001)

Limitations, reasons for caution: It will be better if the number of blastocysts reached increases.

Wider implications of the findings: such research can be widely applied to the human model due to the similarities between both specie.

Trial registration number: Royal Embassy of Saudi Arabia Cultural Bureau

P-177 Seminal transferrin levels are linked to embryo utilization rates: a prospective observational study

G. Raad[1], M. Bazzi[1], V. Massaad[1], C. Afeiche[1], F. Nasser[1], F. Fakih[1], Y. Mourad[1], C. Fakih[1]

[1]Al Hadi Laboratory and Medical Center, ivf, Beirut, Lebanon

Study question: What is the impact of seminal transferrin level on intracytoplasmic sperm injection (ICSI) cycle outcomes?

Summary answer: Seminal transferrin levels were positively correlated with embryo utilization rates.

What is known already: Transferrin, a glycoprotein involved in iron transport throughout the body, is produced by various organs such as liver, central nervous system, and testicules. Particularly, Sertoli cells synthesize transferrin to regulate their phagocytotic activity and to ensure iron transportation to germ cells across the blood-testis barrier. In this context, studies have demonstrated the importance of transferrin and iron in spermatogenesis by detecting low levels of seminal transferrin in oligozoospermic men. However, the effects of low seminal transferrin levels on the functionality of spermatozoa and on their ability to maintain embryo development were neither fully investigated nor well understood.

Study design, size, duration: A prospective study was conducted at Al Hadi IVF center, Lebanon, from July 2019 until May 2020. It included 60 infertile couples who have undergone ICSI cycles. Couples were categorized into two groups based on basic semen parameters assessed according to the World Health Organization recommendations 2010: normozoospermia group (n=30 couples) and non-normozoospermia group (n= 30 couples). In this study, non-normozoospermia was defined as the presence of at least one abnormality in basic semen parameters.

Participants/materials, setting, methods: In this prospective study, the inclusion criteria were: couples where women had 38 years old or less at the time of ICSI, using fresh gametes, and using ejaculated semen. Moreover, women with premature ovarian failure, obese women, and ICSI cycles with embryo biopsy were excluded. Seminal levels of transferrin and iron were measured using Cobas 400 plus (Roche Diagnostics). Fertilization rates, embryo utilization rates, and live birth rates were calculated.

Main results and the role of chance: There were no statistically significant differences in the characteristics of the study population (maternal age, paternal age, maternal body mass index (BMI), paternal BMI, maternal and paternal tobacco intake, maternal and paternal alcohol consumption, number of collected oocytes and number of embryos transferred) (p>0.05) between normozoospermia and non-normozoospermia groups. A statistically significant difference was detected in seminal transferrin levels (mg/dl) (2(0-23) *vs.* 1(0-6), p<0.02) between the two groups. Interestingly, these transferrin levels were positively correlated with sperm concentration (R = 0.29; p=0.03). In parallel, no statistically significant difference was observed between groups concerning seminal iron levels (µg/dl) (51(21.1-100.8) *vs.* 48.6 (11-85.7); p=0.33). Furthermore, there was no statistically significant difference in the fertilization rates (%) between the two groups (74.2 *vs.* 74.8; p=0.95). Of particular interest, a statistically significant positive correlation was detected between seminal transferrin levels and embryo utilization rates (R=0.33; p=0.013). In contrast, the live birth rates (%) were not different between groups (54.54 *vs.* 58.3; p=0.77) and were not correlated with seminal transferrin levels (R=-0.3; p=0.16).

Limitations, reasons for caution: A prospective study with a larger sample size is required to confirm the effects of seminal transferrin levels on assisted reproductive technology outcomes.

Wider implications of the findings: Deciphering the molecular mechanism by which transferrin level may influence spermatozoa quality and subsequently embryo development will be of paramount importance. Moreover, understanding the reasons behind the altered seminal transferrin level and testing several strategies to restore it, may enhance spermatozoa quality and increase pregnancy chances.

Trial registration number: Not applicable

P-178 Mural granulosa cells of the human follicles indirectly show death molecular signals not depending on different ovarian stimulation protocols

G. Ruvolo[1], F. Geraci[2], M.C. Roccheri[3], R. Alessandro[4], L. Bosco[4]

[1]Centro di Biologia della Riproduzione, Centro di Biologia della Riproduzione, Palermo, Italy ;
[2]Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF, Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF- University of Palermo, Palermo, Italy ;
[3]Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF, Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF, Palermo, Italy ;
[4]Department of Biomedicine- Neuroscience and Advanced Diagnostics Bi.N.D- Section of Biology and Genetics, Department of Biomedicine- Neuroscience and Advanced Diagnostics Bi.N.D- Section of Biology and Genetics- University of Palermo, Palermo, Italy

Study question: Could the expression of the anti-apoptotic molecules AKT, p-Akt and ERK1/2 in Mural Granulosa Cells (MGC) be considered as marker of oocyte quality?

Summary answer: MGCs activate cell death pathways in analyzed follicles and it is not influenced by different stimulation protocols and it is not correlated to oocyte competence.

What is known already: It has been previously demonstrated that apoptosis rate of mural granulosa or cumulus cells (CC) were correlated with follicular oocyte number, age, embryo numbers in IVF/ICSI and also clinical pregnancy. Moreover, our previous data demonstrated that in selected patients, who received recombinant LH associated with recombinant FSH (rFSH), the DNA fragmentation in cumulus cells was significantly lower and pregnancy rate was higher, compared to patients treated with rFSH alone. However, to date little is known about the differences between MGC and CC regarding death/survival pathways and whether the two cell types respond in the same way.

Study design, size, duration: Molecular study on MGCs to investigate the role of the surviving/apoptotic molecules AKT, p-Akt and ERK1/2 and their relationship with the administration of exogenous r-LH combined with r-FSH administration in ovarian stimulation comparing with r-FSH alone. We analyzed also the oocyte competence, for each follicle, according to the embryo development during *in vitro* culture and the pregnancy outcome. We included fifty-three normo-responder women undergoing ICSI in two years.

Participants/materials, setting, methods: Patients were divided into two groups: 1) 34 women were stimulated with r-FSH and used as control group, 2) 19 women were stimulated with r-FSH combined with r-LH. Mural granulosa cells isolated singularly from 255 MII oocytes of the 53 patients were used for the study. The study was conducted in public university laboratory. MGCs obtained from each single follicle were suspended in medium, without serum. For immunoreaction anti-AKT, p-AKT, ERK1/2 antibodies were used.

Main results and the role of chance: Out of 255 MII oocytes collected, 197 were fertilized and the derived embryos had the following evolution: 117 transferred, 57 vitrified and 23 arrested during *in vitro* culture. 58 oocytes were not analyzed because of failed fertilization or because of their immature condition (GV or MI).

In the MGCs isolated from the follicle of each oocyte generating an embryo, the expression AKT, pAKT and ERK1/2 was analyzed and associated with embryo quality and pregnancy outcomes.

Immunoblot analysis on granulose cells showed no statistically significant differences in protein level in MGCs isolated from oocytes that have generated transferred embryos (blastocyst at day 5 or 6) comparing with embryos who arrested during *in vitro* culture. No differences were found also in MGCs collected from the follicles derived from r-FSH ovarian stimulation compared to r-FSH+r-LH. Moreover, no difference was highlighted even between protein level and pregnancy outcomes. The results seem to demonstrate that the MGCs primarily have an endocrine function and support the growth of the follicle, and

finally follow a specific death pathway. This condition is not influenced by different ovarian stimulation protocol, in contrast with CC, and is not correlated to oocyte competence, embryo quality and clinical outcomes.
Limitations, reasons for caution: Only a limited number of patients have been observed.
Wider implications of the findings: Our current and past results suggest that the evaluation of cumulus cells and mural granulosa cells in the same follicle show different expression of molecules involved in the apoptotic pathway and therefore they cannot be used, as molecular markers, in the same way, to assess the competence of oocytes.
Trial registration number: not applicable

P-179 Timing of blastocyst observation on day 5: effect on the assessment to predict live birth, and the incorporation into a blastocyst selection model

Y. Liu[1], K. Ong[2], I. Korman[2], R. Turner[3], M. Leyden[4], D. Zander-Fox[5], L. Rombauts[6]

[1]Monash IVF Group, Queensland- Science, Southport, Australia ;
[2]Monash IVF Gold Coast, Medical, Southport, Australia ;
[3]Monash IVF Auchenflower, Medical, Auchenflower, Australia ;
[4]Monash IVF Rockhampton, Medical, Rockhampton, Australia ;
[5]Monash IVF Group, Victoria- Science, Richmond, Australia ;
[6]Monash IVF Group, Medical, Richmond, Australia

Study question: Does variation in day 5 observation timing confound embryo-morphology-based live birth prediction, and is it possible to develop a robust comprehensive numerical prediction model.
Summary answer: Day 5 observation timing confounds embryo-morphology-based live birth prediction. A robust comprehensive numerical prediction model can be developed after considering a number of contributing variables.
What is known already: Embryo development is a dynamic process, and therefore the widely used static observations potentially lead to biased prediction of live birth outcomes. So far, little is known in regard to potential confounding impact of day 5 assessment timing on the static-morphology-based live birth prediction. In addition, the inter-observer variation in morphology-based embryo assessment requires a more robust system to improve consistency of selection.
Study design, size, duration: This retrospective multi-center cohort study included 8866 autologous oocyte *in vitro* fertilisation treatment cycles performed at 14 associated clinics within the same network during 2012-2018. Only fresh cycles with single day 5 embryo transfers were included for analysis with all pregnancies followed up until birth. Repeat cycles of same patients were excluded to avoid clustering effect in statistical analysis.
Participants/materials, setting, methods: Dataset was randomly split into two subsets at 60:40 ratio, with one (n=5274) used for regression analysis and model development and the other (n=3592) used for model testing. Multiple logistic regression was performed to evaluate live birth predicting power of several potential contributors, expressed by odds ratio (OR) and 95% confidence interval (CI). A comprehensive prediction model was subsequently developed based on calculated weights of contributing factors, then tested via receiver operating characteristics (ROC) analysis.
Main results and the role of chance: The timings of day 5 observation of 8866 included embryos, measured by hours post insemination (HPI), distributed in a bell shape ranging from 112.0 to 120.0 h (mean±SD 115.7±1.7 h). After taking into account female age at egg collection (grouped as <30 yr, 30-34 yr, 35-39 yr, 40-44 yr, and 45 yr or older), whether or not the first egg collection, number of eggs collected, embryo developmental stage (grouped as pre-blastocyst, early blastocyst, expanding blastocyst, expanded blastocyst, and hatching/hatched blastocyst) and morphology score(A/B/C/D); multivariate logistic regression analysis showed significant association (OR 1.096, 95% CI 1.020-1.177, P=0.012) between HPI groups (112-113.9 h, 114-115.9 h, 116-117.9 , and 118-120 h) and subsequent live birth outcomes. A comprehensive numerical scoring system was developed based on the statistically significant predictors including female age (OR 1.465, 95% CI 1.364-1.574, P=0.000), embryo developmental stage (OR 1.341, 95% CI 1.244-1.445, P=0.000), morphology score (OR 1.520, 95% CI 1.392-1.661, P=0.000) and HPI (OR mentioned above); with a formula of Score=(Female_age_group/5)*1.465+(Developmental_stage/5)*1.341+(Morpho_Score/4)*1.520+(HPI_Group/4)*1.096. ROC analysis showed statistically significant predictive power of the resulting model as expressed by area under the ROC curve using both the development (0.690, 0.675-0.704, P=0.000) and testing (0.685, 0.667-0.703, P=0.000) subsets.
Limitations, reasons for caution: The retrospective design does not allow for controlling of unknown confounders. HPI was based on static observations in this study so future time-lapse study may bring more insights with more accurate observation and measurement.
Wider implications of the findings: The varying HPIs at day 5 observation were alarming as this could confound live birth prediction using embryology parameters. It is important to standardise the timing of embryo observations. The inclusion of HPI into a comprehensive numerical scoring system for live birth prediction may potentially improve its robustness
Trial registration number: not applicable

P-180 Bisphenols are present in culture media used for ART and cell culture

C. Vignault[1], A. Togola[2], A. Desmarchais[3], O. Téteau[3], V. Maillard[3], S. Bristeau[2], A. Binet[4], F. Guérif[1], S. Elis[3]

[1]CHRU de Tours, Médecine et Biologie de la Reproduction, Tours, France ;
[2]Bureau de Recherches Géologiques et Minières, Chemistry, Orléans, France ;
[3]INRAE, Physiologie de la Reproduction et du Comportement, Nouzilly, France ;
[4]CHRU de Tours, Chirurgie pédiatrique, Tours, France

Study question: Do plastic laboratory consumables and cell culture media used in human ART contain bisphenols?
Summary answer: Human embryo development media contained bisphenols close to the nanomolar concentration range while no release of bisphenols by plastic consumables was detected under routine conditions.
What is known already: The deleterious effect of the endocrine disruptor bisphenol A (BPA) on female fertility raised concerns regarding ART outcome. BPA was detected neither in media nor in the majority of plastic consumables used in ART, however it might have already been replaced by its structural analogs, including bisphenol S (BPS).
Study design, size, duration: Seventeen plastic consumables and 18 cell culture and ART media were assessed for the presence of bisphenols.
Participants/materials, setting, methods: Ten different bisphenols (bisphenol A, S, AF, AP, B, C, E, F, P, and Z) were measured using an isotopic dilution according to an on-line solid phase extraction / liquid chromatography/mass spectrometry method.
Main results and the role of chance: While all the plastic consumables of this study did contain bisphenols, none of them did release bisphenols under routine conditions. Moreover, 16 of the 18 cell culture and ART media assessed contained bisphenols, including 8 among the 10 media used in human ART. Five human ART media exhibited bisphenol concentrations higher than 0.8 nM and reached up to 3.2 nM (799 ng/L).
Limitations, reasons for caution: Further studies are required to investigate a greater number of ART media to identify less potentially harmful ones, in terms of bisphenol content.
Wider implications of the findings: As BPS has already been reported to impair oocyte quality at nanomolar concentrations, its presence in ART media, at a similar concentration range, could contribute to a decrease in the ART success rate. Thus far, there has been no regulation of these compounds in the ART context.
Trial registration number: Not applicable

P-181 Morphine regulates BMP4 growth factor and is involved in in-vitro early embryo development and PGCs formation

I. Muñoa1, M. Araolaza-Lasa1, I. Urizar-Arenaza1, M. Gianzo Citores1, N. Subiran Ciudad[1]

[1]University of the Basque Country, Physiology in the Faculty of Medicine and Dentistry, Leioa, Spain

Study question: To elucidate if morphine can alter embryo development.
Summary answer: Chronic morphine treatment regulates BMP4 growth factor, in terms of gene expression and H3K27me3 enrichment and promotes *in-vitro* blastocysts development and PGC formation.
What is known already: BMP4 is a member of the bone morphogenetic protein family, which acts mainly through SMAD dependent pathway, to play an important role in early embryo development. Indeed, BMP4 enhances

pluripotency in mouse embryonic stem cells (mESCs) and, specifically, is involved in blastocysts formation and primordial germ cells (PGCs) generation. Although, external morphine influence has been previously reported on the early embryo development, focus on implantation and uterus function, there is a big concern in understanding how environmental factors can cause stable epigenetic changes, which could be maintained during development and lead to health problems.

Study design, size, duration: First, OCT4-reported mESCs were chronically treated with morphine during 24h, 10-5mM. After morphine removal, mESCs were collected for RNA-seq and H3K27me3 ChIP-seq study. To elucidate the role of morphine in early embryo development, two cell- embryos stage were chronically treated with morphine for 24h and *in-vitro* cultured up to the blastocyst stage in the absence of morphine. Furthermore, after morphine treatment mESCs were differentiated to PGCs, to elucidate the role of morphine in PGC differentiation.

Participants/materials, setting, methods: Transcriptomic analyses and H3K27me3 genome wide distribution were carried out by RNA-Sequencing and Chip-Sequencing respectively. Validations were performed by RNA-RT-qPCR and Chip-RT-qPCR.

Main results and the role of chance: Dynamic transcriptional analyses identified a total of 932 differentially expressed genes (DEGs) after morphine treatment on mESCs, providing strong evidence of a transcriptional epigenetic effect induced by morphine. High-throughput screening approaches showed up *Bmp4* as one of the main morphine targets on mESCs. Morphine caused an up-regulation of *Bmp4* gene expression together with a decrease of H3K27me3 enrichment at promoter level. However, no significant differences were observed on gene expression and H3K27me3 enrichment on BMP4 signaling pathway components (such as *Smad1, Smad4, Smad5, Smad7, Prdm1* and *Prmd14*) after morphine treatment. On the other hand, the *Bmp4* gene expression was also up-regulated in *in-vitro* morphine treated blastocyst and *in-vitro* morphine treated PGCs. These results were consistent with the increase in blastocyst rate and PGC transformation rate observed after morphine chronic treatment.

Limitations, reasons for caution: To perform the *in-vitro* analysis. Further studies are needed to describe the whole signaling pathways underlying BMP4 epigenetic regulation after morphine treatment.

Wider implications of the findings: Our findings confirmed that mESCs and two-cell embryos are able to memorize morphine exposure and promote both blastocyst development and PGCs formation through potentially BMP4 epigenetic regulation. These results provide insights understanding how environmental factors can cause epigenetic changes during the embryo development, leading to alterations and producing health problems/diseases

Trial registration number: not applicable

P-182 The mechanism of mouse embryo hatching and the impact of laser drilling the zona pellucida: an RNA sequencing study

Y. Liu[1], C. Jones[1], K. Coward[1]

[1]University of Oxford, Nuffield Department of Women's & Reproductive Health, Oxford, United Kingdom

Study question: What is the mechanism of embryo hatching? Will laser-assisted zona pellucida (ZP) drilling alter the embryonic transcriptome?

Summary answer: Hatching is an ATP-dependent process. Hatching is also associated with Rho-mediated signaling. Laser-assisted ZP drilling might cause alternation in embryo metabolism.

What is known already: Embryo hatching is a vital process for early embryo development and implantation. Animal data suggests that hatching is the result of multiple factors, such as mechanical pressure, protease activation, and the regulation of maternal secretions. However, little is known about the regulatory signaling mechanisms and the molecules involved. In addition, despite the extensive use of laser-assisted ZP drilling in the clinic, the safety profile of this technique at molecular level is very sparse. The impact of this technique on the embryonic transcriptome has not been studied systematically.

Study design, size, duration: Eighty mouse embryos were randomly divided into a laser ZP drilling group (n=40) and an untreated group (n=40). After treatment, embryos were cultured *in vitro* for two days. Then, hatching blastocyst (n=8) and pre-hatching blastocyst (n=8) from the untreated group, and the hatching blastocyst from the treatment group (n=8) were processed for RNA sequencing (RNA-seq).

Participants/materials, setting, methods: Cryopreserved 8-cell stage mouse embryos (B6C3F1 × B6D2F1) were thawed, and a laser was used to drill the embryo ZP in the treatment group. Next, the treated and untreated embryos were individually cultured *in vitro* to the E4.5 blastocyst stage. The resulting blastocysts were lysed individually and used for subsequent cDNA library preparation and RNA-seq. Following data quality control and alignment, the RNA-seq data were processed for differentially expressed gene analysis and downstream functional analysis.

Main results and the role of chance: According to the RNA-seq data, 275 differentially expressed genes (DEGs) (230 up-regulated and 45 down-regulated, adjusted $P<0.05$) were identified when comparing hatching and pre-hatching blastocysts in the control groups. Analysis suggested that the trophectoderm is the primary cell type involved in hatching, and revealed the potential molecules causing increased blastocyst hydrostatic pressure (*Aqp3* and *Cldn4*). Functional enrichment analysis suggested that ATP metabolism and protein synthesis were activated in hatching blastocysts. DEGs were found to be significantly enriched in several gene ontology terms, particularly in terms of the organization of the cytoskeleton and actin polymerisation ($P<0.0001$). Furthermore, according to QIAGEN ingenuity pathway analysis results, Rho signaling was implicated in blastocyst hatching (*Actb, Arpc2, Cfl1, Myl6, Pfn1, Rnd3, Septin9,* z-score=2.65, $P<0.0001$). Moreover, the potential role of hormones (estrogen (z-score=2.24) and prolactin (z-score=2.4)) and growth factors (AGT (z-score=2.41) and FGF2 (z-score=2.213)) were implicated in the hatching process as indicated by the upstream regulator analysis. By comparing the transcriptome between laser-treated and untreated hatching blastocysts, 47 DEGs were identified (adjusted $P<0.05$) following laser-assisted ZP drilling. These genes were enriched in metabolism-related pathways ($P<0.05$), including the lipid metabolism pathway (*Mvd, Mvk, Aacs, Gsk3a, Pik3c2a, Aldh9a1*) and the xenobiotic metabolism pathway (*Aldh18a1, Aldh9a1, Keap1,* and *Pik3c2a*).

Limitations, reasons for caution: Findings in mouse embryos may not be fully representative of human embryos. Furthermore, the mechanism of hatching revealed here might only reflect the hatching process of embryos *in vitro*. Further studies are now necessary to confirm these findings in different conditions and species to determine their clinical significance. Wider implications of the findings: Our study profiled the mouse embryo transcriptome during *in vitro* hatching, identified potential key genes and mechanisms for future study. In addition, for the first time, we revealed the impact of laser-assisted ZP drilling on the transcriptome, this may help us to assess and improve the existing technique.

Trial registration number: not applicable

P-183 Air quality oscillations inside the IVF laboratory do not affect clinical outcomes

J. Mass. Hernaez[1], V. Montalvo[1], A. Garcia-Faura[1], B. Marques[1], M. López-Teijón[1]

[1]Instituto Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Do air contaminant oscillations impair in vitro fertilization clinical results?

Summary answer: Oscillations of the main air contaminants (SO2, NO, NO2, O3, CO, PM10, C6H6) inside the IVF laboratory do not impair success rates.

What is known already: Pollution is a challenge that as humans we face around the world. Given the limited number of studies that demonstrate the effect of pollution into IVF treatments, the effect that air contaminants have on *in vitro* human gametes/embryos is not clear.

IVF laboratories are designed to limit the stress that gametes and embryos suffer during culture and manipulation. Controlling temperature, humidity, light, and filtering the air is essential to have a successful IVF program. However, HEPA and active carbon filters are not enough to ensure that gametes/embryos are not exposed to contaminants, exposing them to potentially harmful gases and particles.

Study design, size, duration: Prospective study comprising treatments throughout 2019, recording levels of the main air contaminants (SO2, NO, NO2, O3, CO, PM10, C6H6) every 10 minutes inside the IVF laboratory in order to assess the effect of these pollutants. We included egg donor cycles without PGT-A.

Participants/materials, setting, methods: A total of 724 egg donation treatments were included. Using uninterrupted culture (Global, CooperSurgical) in time lapse incubators (Embryoscope, Vitrolife). A mean concentration of

every pollutant during the 6 days of every treatment was calculated. We analyzed success rates such as fertilization rates, blastocyst rates, pregnancy rates, implantation rates, miscarriage rates, and live birth rates.
Main results and the role of chance: Our results show that no contaminant affects neither fertilization rates nor good quality blastocyst rates.

The only pollutants that have an association with pregnancy rates are NO and CO (p=0.014 y p=0.021) in both the univariate and the multivariate statistical analysis. Still, this association is week and could be explained due to the large data set. When analyzing further data we do not find any association between the dose of contaminants and implantation rates, miscarriage rates nor live birth rates (p>0.01) demonstrating that oscillations in levels of these contaminants do not affect clinical results.

Our results differ with the results from a previous study where they detected an effect of SO2 and O3 when analyzing frozen embryo transfer results. This might be explained because the levels of these gases were lower in our clinic and the pregnancy and live birth rates are higher.
Limitations, reasons for caution: Although we measured the levels of the contaminants inside the IVF laboratory, we did not measure the levels inside the incubators.
Wider implications of the findings: This results show that IVF success rates are not impaired by oscillations in air quality if the laboratory does use the necessary HEPA and active-carbon air filter systems.
Trial registration number: Not applicable

P-184 Assisted hatching does not improve live birth rates, a prospective double-blinded randomized study.

V. Montalvo[1], J. Masso[1], A. Garcia-Faura[1], B. Marques[1], M. Lopez-Teijon[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Does Assisted hatching (AH) improve success rates when applied to frozen embryo transfers?
Summary answer: AH does not improve implantation, ongoing pregnancy or live birth rates when applied to thawed embryos.
What is known already: Vitrification has been proven to be the most efficient technique to preserve human embryos. However, vitrification has some consequences for the embryos, zona pellucida (ZP) hardening being one of them. Multiple studies suggest the need to apply laser Assisted hatching or ZP thinning to thawed embryos in order to improve success rates. Still, there is not enough evidence to ensure the utility of AH, and considering the great variation in design between studies more evidence is needed.
Study design, size, duration: Study performed from October 2019 and January 2020. Disregarding embryos with natural Hatching and PGT-A. Embryos that, immediately after thawing, were completely expanded (trophectoderm in contact with ZP) were also excluded from the study. We applied a randomization to choose in which embryos we had to perform AH. Neither the gynecologist nor the embryologist performing the embryo transfer knew whether the embryo had AH performed or not.
Participants/materials, setting, methods: 353 frozen embryo transfers of one blastocist were considered for the study, 71 excluded for expansion after thawing, 65 excluded because of PGT-A, 103 in which we performed AH (AH+) and 114 without AH (AH-). In the AH+ group we performed laser-AH of 1/3 of the ZP, avoiding to damage the trophectoderm and performing the laser shots as far away to the ICM as possible. We used Chi-square testing to assess the effects of AH.
Main results and the role of chance: We assessed all relevant clinical data parameters. No statistical differences were found in egg age, maternal age, embryo quality, nor endometrial thickness between groups. Implantation and miscarriage rates were equivalent between AH+ group (40.9%; 20.5%) and AH- group (47.4%; 18.5%).

The main outcome of this study was live birth rates. No statistical differences were found between groups (AH-= 38.6%; AH+= 30.1%; p=03221) proving that making it easier to get out of the ZP does not affect success rates.

Analyzing the data from the excluded embryos we found no improvement on live birth rates when embryos were expanded just after thawing (38.0%; p=0.457). As expected, PGT-A embryos yielded higher live birth rates (52.3%; p<0,05)
Limitations, reasons for caution: Preliminary study with a small data set.
Wider implications of the findings: This study suggest that thawed embryos have the capacity to get out of the ZP regardless if AH was performed or not. Having no positive effects, AH seems to be unnecessary in this scenario.
Trial registration number: Not applicable

P-185 Overcoming a sudden COVID-19 lockdown and other similar unforeseen adverse events: Oocyte-sperm cryopreservation 4 hours after conventional in vitro insemination

C. Bisioli[1], M. Otegui[1], F. Migliora[1], R. Crowley[1]

[1]Meiosis Medicina Reproductiva, IVF Unit, Comodoro Rivadavia, Argentina

Study question: Can human oocytes be cyropreserved when they were previously inseminated while obtaining normal fertilization, embryo development and pregnancies?
Summary answer: Cryopreservation of recently inseminated human oocytes produces normal 2PN zygotes, viable embryos and ongoing pregnancies.
What is known already: Oocyte vitrification is a well-established technique in the infertility field supported by its effectiveness to freeze and thaw embryos at various stages of development. However, it is yet unknown whether cryopreservation performed in a period between conventional in vitro insemination and the appearance of pronuclei, affects any of the steps leading to fertilization, thereby arresting this process.
Study design, size, duration: Case report that includes 5 IVF cycles where cryopreservation and thawing were performed in a pre-zygote stage, 4 hours after the conventional insemination of oocytes. The rationale for this procedure was to comply with a government restriction to circulate and work in order to prevent the spread of the SARS-CoV-2 virus, unexpectedly 3 days ahead (effective on 03/19/2020). Participants/materials, setting, methods: Off-site embryologists cancelled all pending embryo transfers and returned home (2,000 km away) before the stay-home quarantine. Five couples were informed and consent was obtained on the urgent need to cryopreserve their already inseminated oocytes despite of the limited scientific information. We vitrified 28 oocyte-sperm pairs in vitrification devices containing 2 to 3 inseminated oocytes each.

Main results and the role of chance: Eight months later all non-essential activities, including non-urgent procedures in hospital facilities, were permitted again, allowing embryologists to travel and resume their postponed work. We thawed 19 of the so-called "pre-zygotes" corresponding to 4 of the 5 initial couples. Female ages were 29, 39, 38 and 37 years old. Our primary outcomes were detection of pronuclei and the occurrence of fertilization. The secondary outcome was pregnancy success. On day 1, we observed the presence of 2PN in 16 oocytes (84%). Only one patient with 2 oocytes failed to fertilize. We transferred 2 good-to-fair-grade cleaved embryos to each of the 3 patients, obtaining one pregnancy with a positive fetal heartbeat from the 39 years old patient. Two of the couples were also able to cryopreserve 2 and 1 surplus embryos on day 5, respectively.
Limitations, reasons for caution: Our strategy was used exclusively to overcome an unexpected adverse event while complying with State and County regulations on COVID-19. As a case report, a large sample size is needed to confirm and extend these results including the putative detrimental effects of arresting the fertilization process through vitrification.
Wider implications of the findings: Although cryopreservation implies to arrest of any stage of a development continuum, to the best of our knowledge, this is the first time that both fertilization and pregnancy were achieved after halting the fertilization process long before the appearance of pronuclei (at ~4 hours after insemination).
Trial registration number: not applicable

P-186 Volumetric imaging provides insight into the 3D ultrastructural organization of maturing human oocytes

Z. Trebichalská[1], J. Javůrek[2], D. Kyjovská[3], M. Tatíčková[1], S. Kloudová[3], P. Otevřel[3], A. Hampl[1], Z. Holubcova[1]

[1]Masaryk University- Faculty of Medicine, Department of Histology and Embryology, Brno, Czech Republic ;
[2]TESCAN ORSAY HOLDING- a.s, Applications - Life Science, Brno, Czech Republic ;
[3]Reprofit International, Clinic of Reproductive Medicine, Brno, Czech Republic

Study question: Is volume electron microscopy suitable for high-resolution oocyte imaging in three dimensions (3D)?
Summary answer: Focused Ion Bean Scanning Electron Microscopy (FIB-SEM) allows 3D visualization and quantitative analysis of ultrastructural features in the large human oocyte volume.
What is known already: Transmission electron microscopy (TEM) has been traditionally used to study the fine morphology of female gametes. However, 2D micrographs provide only limited information about the topology of subcellular structures. Volumetric studies are needed to elucidate the 3D organization of complex oocyte cytoplasm.
Study design, size, duration: An academic study conducted in collaboration with an IVF clinic. Advanced 3D - ultrastructural analysis was performed on 9 human oocytes representing 3 stages of maturation (3 germinal vesicle (GV), 3 metaphase I (MI), 3 metaphase (MII) oocytes) collected from February 2018 to November 2019.
Participants/materials, setting, methods: Spare IVF oocytes, donated by 9 young egg donors (22-29 years), were cultured in vitro until they reached a defined developmental stage. Each oocyte´s meiotic status was determined based on the presence/absence of a prophase nucleus, a polar body, and a non-invasively detectable MI/MII spindle. Following standard TEM preparation, individual oocyte-containing resin blocks were coated with a thin carbon layer[JJ1] , mounted on the microscope stage, and subjected to FIB-SEM imaging.
Main results and the role of chance: FIB-SEM tomography provided an unprecedented view of the oocyte´s intracellular morphology. Automated serial scanning of newly exposed sample surface generated large stacks (120-1294 slices) of ultrastructural images with 40-100 nm z-resolution. The tomographic reconstruction of acquired datasets revealed the spatial arrangement of inner oocytes´ structures. The imaging protocol was optimized to ensure sufficient image detail, minimal noisiness, and time-efficiency of large volume scanning. Comparison of oocytes fixed at different maturation stages confirmed previous TEM observations that the cortical region of GV oocytes is deprived of membraneous structures, and major organelle redistribution occurs during the MI phase. Semi-automated 3D image segmentation was employed to distinguish distinct organelle populations and evaluated their abundance. Subsequent quantitative analysis of volumetric data showed that the mitochondrion occupies ~ 5.27 % of MII oocyte volume. In conclusion, the volumetric imaging, followed by advanced image analysis, maximizes the amount of morphological data obtained from a single human oocyte.
Limitations, reasons for caution: The imaging procedure was pioneered on a small number of hormonally-primed oocytes, which failed to complete development in vivo. There is a trade-off between resolution, the size of the 3D volume, and imaging time. Block-face ion milling during FIB-SEM imaging inevitably results in sample destruction.
Wider implications of the findings: This proof-of-concept study opens up new possibilities to study the delicate architecture of scarce human oocytes. Enhancing our knowledge of the spatial organization of ooplasm is pivotal for developing experimental and therapeutical strategies involving oocyte microsurgery.
Trial registration number: not applicable

P-187 Multinucleation and reverse cleavage, sings of early embryo self-repair mechanisms

A. Munuer. Puigvert[1], V. Montalv. Pallès[1], J. Mass. Hernáez[1], A. García-Faura[1], B. Marquè. López-Teijón[1], M. López-Teijó. Pérez[1]
[1]Institut Marquès, Reproductive Medicine Service, Barcelona, Spain

Study question: Have multinucleation and reverse cleavage any effect on embryo development and clinical outcomes on IVF treatments?
Summary answer: Embryos capable of repairing dysmorphisms and developing up to blastocyst stage keep intact their ability to become healthy babies.
What is known already: Time-lapse systems allow IVF laboratories to perform in-depth analysis of embryo development using the continuous monitoring tool. Some events that are impossible to detect with conventional morphologic evaluation, such as reverse cleavage or multinucleation, can be detected using time-lapse. Even though the low scientific evidence, the presence of these events is considered a negative factor when the embryo quality assessment is performed. However, it has been described the possibility that embryos have self-repair intrinsic methods.
Study design, size, duration: Retrospective study including data from 3,577 cycles with 21,274 embryos cultured until blastocyst stage using one-step culture media in time-lapse incubators (Embryoscope, Vitrolife) up to day 5/6 between 2014 and 2019.
Participants/materials, setting, methods: Three embryo groups were considered: Control group, embryos without multinucleation or reverse cleavage (CG; n=16,897); Multinucleation group, embryos with at least one blastomere multinucleated on D+2/3 (MNC; n=3,879) and Reverse Cleavage group, embryos undergoing complete fusion of two blastomeres on D+2/3 (RC; n=498). Single embryo transfer was performed on blastocyst stage. Clinical outcome rates were compared between groups and analyzed by Chi-square test.
Main results and the role of chance: As published by other groups, the 2.3% of our embryos showed at least one reverse cleavage event and we observed multinucleation in the 18.2% of the embryos. Blastocyst rate of dysmorphism groups was significantly lower ($p<0.05$) than Control group (MNC=20.0%; RC=27.7%; CG=58.0%). Once transferred, MNC and RC evolutive embryos showed significantly lower pregnancy (MNC=47.9%; RC=46.8%; CG=60.8%; $p<0.05$) and clinical pregnancy rates (MNC=39.4%; RC=40.4% CG=50.6%; $p<0.05$) than the Control group ($p<0.05$). However, during the post-implantational development the negative effect of dysmorphisms disappears, reaching values of live birth rate comparable to the Control group (MNC=28.3%; RC=31.9% CG=33.8%; p=0.17). These results prove the importance of blastocyst culture and the inherent capability of the embryos to overcome some abnormal dynamics as multinucleation and reverse cleavage. Thus, these embryos showing the poor-prognosis events can be considered for transfer or vitrify.
Limitations, reasons for caution: There is a wide difference on sample size between groups despite the fact that the statistical analysis considers that into account. There are some ongoing pregnancies in all groups.
Wider implications of the findings: When analyzing the development of embryos undergoing reverse cleavage and multinucleation, we hypothesize that these embryos could be showing a self-correction mechanism for some type of error detected. Embryos capable of repairing and developing up to blastocyst stage keep intact their ability to become healthy babies.
Trial registration number: not applicable

P-188 Ambient light intensity and wavelength in the IVF laboratory does not affect life birth rates

A. Farrera. Ayestaran[1], V. Montalvo[1], J. Masso[1], A. Garcia-Faura[1], B. Marques[1], M. Lopez-Teijon[1]
[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Do different wavelengths and intensities in ambient lighting affect clinical outcomes?
Summary answer: Variations on ambient lighting intensity and wavelength do not affect life birth rates.
What is known already: Light is one of the factors to consider when designing an IVF laboratory. Most IVF clinics work under reduced illumination, trying to mimic uterine conditions as much as possible. Nevertheless, it has been described that 95% of the light that affects an embryo comes from the microscope, not ambient lighting.

It is well accepted that exposure to extreme lighting conditions affects embryos through photo-oxidation and the creation of reactive oxygen species. Still, there is no study that documents the effect of different wavelengths on human embryos.
Study design, size, duration: Prospective study performed between january 2019 and february 2020. Every 60 days we changed ambient illumination conditions using the LED lighting installed throughout the IVF laboratory. Six different groups were created: Cyan (470nm), Green (550nm), Yellow (600nm), Orange (625nm), intense white (WH), and low intensity white (WL) as control group.
Participants/materials, setting, methods: A total of 572 egg donation cicles with 355 fresh single embryo transfers were included in the study. In all cycles ICSI and Time-lapse culture was performed (*Embryoscope*, Vitrolife). PGT and testicular biopsy/aspiration treatments were excluded. Eggs and embryos were exposed to ambient illumination during pick-up, denudation, ICSI, and embryo transfer procedures.
Main results and the role of chance: Light exposure during embryo/gamete manipulation is inevitable. Hence, we analyzed parameters linked to the success

of an IVF cycle to assess the effect of different lighting conditions concluding that neither light color nor intensity affect IVF success rates.

No differences were found between groups regarding maternal age, age of the recipient, diagnostic, or number of eggs received (p>0.05). Fertilization rates were similar between groups (C= 77.04%; G= 73.72%; Y= 75.64%; O= 78.1%; WL=76.4%; WH=75.2%; p=0.216) as well as good quality blastocyst rates (C= 57.35%; G= 57.37%; Y= 62.30%; O= 59.75%; WL=63.28%; WH=60.55%; p=0.234). Regarding clinical outcomes both implantation and miscarriage rates were found to be equal between groups (C= 61.67%; G= 52.89%; Y= 55.10%; O= 66.18%; WL=66.00%; WH=53.55%; p=0.194, and C= 24.32%; G= 19.15%; Y= 11.11%; O= 24.44%; WL=15.15%; WH=8.11%; p=0.301). The main outcome for this study was live birth rates and no differences were found (C= 51.85%; G= 50.00%; Y= 52.17%; O= 53.97%; WL=57.14%; WH=50.75%; p=0.168).

Limitations, reasons for caution: We must take into account that embryos were cultured inside a time-lapse incubator, diminishing the effect of ambient light.

Wider implications of the findings: This study demonstrates that, with advances in culture technology, neither light intensity nor light wavelength affecting gametes/embryos during manipulation influence clinical outcomes.

Trial registration number: Not applicable

P-189 The transcriptional profile of arrested cleavage stage human embryos

M. Pérez[1], F. Domínguez[2], A. Quiñonero[2], D. Beltrán[3], D. Arantza[3], A. Mercader[3], Á. Martín[1], A. Pellicer[4], M.J. D. lo. Santos[3]

[1]IVIRMA-Valencia, Research, Valencia, Spain ;
[2]IVI Foundation, Research, Valencia, Spain ;
[3]IVIRMA-Valencia, IVF laboratory, Valencia, Spain ;
[4]IVIRMA-Rome, Gynecology, Rome, Italy

Study question: What are the molecular pathways overactivated in arrested cleavage stage human embryos?

Summary answer: There is an upregulation of mitochondrial activity and cellular stress-related pathways in arrested cleavage embryos, which is in agreement with the "quiet hypothesis".

What is known already: mtDNA content decreases during embryo development, however there is a high increase in mtDNA content in arrested cleavage embryos that may correspond to a response to intrinsic or extrinsic factor creating stress. This reasoning would be in agreement with stablished hypothesis showing that a basal metabolism with a moderate-low energy consumption is actually a sign of embryo health, so a viable embryo does not need to use an extra energy to accommodate to the environment (Leese, 2012). The study of the transcriptional profile during human embryo development will give further information about key molecular process involved in in-vitro embryonic competence.

Study design, size, duration: A prospective cohort study was performed with 11 MII oocytes (average age= 22,9 years), 10 non-arrested cleavage embryos (average age= 29,9 years), 5 arrested cleavage embryos (average age= 38,8 years) and 8 blastocysts (average age= 39,1 years). All specimens were warmed and sampled in PCR tubes with 2 µl of suitable reaction buffer for the RNA sequencing protocol.

Participants/materials, setting, methods: Specimens were analyzed by single-cell RNA sequencing (scRNA-seq). Correlation studies, principal component and differential expression analysis were performed with DESeq2 package. Differential gene expression analyses were done using the parametric Wald test, with Benjamini-Hochberg multiple test correction (padj). Finally, Fgsea algorithm was used for enrichment analysis on Kyoto Encyclopedia of Genes and Genomes (KEGG) pathways and Gene ontology (GO) terms.

Main results and the role of chance: We do not observe mitochondria-related activity pathways significantly (P>.05) deregulated between MII oocytes and non-arrested cleavage embryos considering GO and KEGG categories.

When comparing non-arrested cleavage embryos versus blastocysts, we observe several ATP production/consumption and cristae formation-related pathways significantly (P<.05) upregulated in blastocysts compared to non-arrested cleavage embryos considering GO and KEGG categories. This change in activity coincides with the metabolic activation event that occurs in the blastocyst stage.

However, when we analyze arrested cleavage embryos versus non-arrested cleavage embryos, we observe several ATP production related-pathways and mitochondria-related apoptosis pathways significantly (P<.05) upregulated in arrested cleavage embryos compared to non-arrested cleavage embryos considering GO categories. With KEGG categories, we notice a significant (P<.05) upregulation of oxidative phosphorylation in arrested cleavage embryos. On the other hand, when we analyze the differences between arrested cleavage embryos and blastocysts, taking into account the differences related to the change of embryo stage, we do not observe ATP production or consumption-related pathways significantly (P>.05) deregulated considering GO and KEGG categories. Then, human arrested embryos in parallel with the increase in mtDNA content, display an upregulation of mitochondrial activity and cellular stress which is in line with the expected overactive metabolism of non-viable embryos.

Limitations, reasons for caution: All analyzed blastocyst were aneuploid, so we are unable to determine what the results would be with euploid blastocysts. Also, although age can it be ruled out, no differences were observed between mean age from cleavage stage embryos (arrested and non-arrested ones) and blastocyst.

Wider implications of the findings: This study evidences the relation between extreme mtDNA content increase and the identification of the pathways involved in active metabolism and apoptosis in arrested cleavage stage human embryos.

Trial registration number: Not applicable

P-190 Can pregnancy be predicted according to mean infrared attenuated total reflectance (MIR-ATR) spectrometry of incubation medium of embryos in IVF?: A proof of concept

N. Aslih[1], E. Shalom-Paz[1], D. Molenik[2], B.Z. Dekel[2]

[1]Hillel Yaffe Medical Center, IVF unit, Hadera, Israel ;
[2]Ruppin Academic Center, Dept. Of Electrical & Computer Engineering, Emek Hefer, Israel

Study question: Can MIR-ATR spectrometry of embryo incubation medium be used to predict embryo quality and IVF treatment results.

Summary answer: MIR-ATR spectrometry is able to distinguish between good and poor embryo quality and may improve the prediction of pregnancy based on better embryo selection.

What is known already: Infra Red (IR) spectra enable to determine if certain chemical functional components are present in a molecule. Attenuated total reflection (ATR) spectroscopy is a well established, simple and rapid technique for objective classification of biological samples. ATR spectrometry was investigated and confirmed to serve as an additional diagnostic tool in oral and gynecologic cancer. Currently, embryo quality is assessed based on morphokinetics parameters from Time-laps incubator and/or final embryo's grading

Study design, size, duration: Culture media of 227 embryos on cleavage stage and blastocyst stage were collected and analysed between January 1st, 2018 and December 31st 2020.

Participants/materials, setting, methods: The incubation medium liquid of embryos cultured in Time-lapse incubator were collected after transferring the embryos to their final destination. Infra-Red (IR) absorbance spectra was measured. Nominal resolution was 4 cm-1, wavenumber range was from 600 cm-1 to 5000 cm-1 and each absorbance spectrum was normalized to the height of amide I band at ~1650cm-1. Machine learning techniques utilized to build discrimination models for the absorbance data. Results were correlated with clinical and pregnancy results.

Main results and the role of chance: This preliminary study demonstrates that ATR spectrometry differs in media of : Day 3 embryos compared to day 5 embryos, top quality compared to poor quality embryos and implanting embryos comparing to non-implanting embryos. We found that MIR-ATR spectrometry might predict pregnancy in accuracy rates of 85%. MIR-ATR spectrometry of incubation medium can be used as an additional tool for selection of embryos for transfer.

Limitations, reasons for caution: Additional study and collection of larger number of culture Media is requested to validate MIR-ATR spectrometry as an additional tool in clinical set up in IVF units and laboratories.

Wider implications of the findings: MIR-ATR spectrometry can be used in the future as an additional tool for selection of embryos and prediction of cycles outcomes.

Trial registration number: NCT03317418

P-191 Time-lapse videography reveals morphometric and morphokinetic differences in the pronuclei of male and female human zygotes

L.S. Orevich[1], K. Watson[1], K. Ong[2], I. Korman[2], R. Turner[3], Y. Liu[1,4,5,6]

[1]Monash IVF Gold Coast, Embryology, Southport, Australia ;
[2]Monash IVF Gold Coast, Medical, Southport, Australia ;
[3]Monash IVF Auchenflower, Medical, Auchenflower, Australia ;
[4]Edith Cowan University, School of Medical and Health Sciences, Joondalup, Australia ;
[5]Monash IVF Auchenflower, Embryology, Auchenflower, Australia ;
[6]University of Western Australia, School of Human Sciences, Crawley, Australia

Study question: Do morphometric and morphokinetic profiles of pronuclei (PN) following intracytoplasmic sperm injection (ICSI) vary between male and female human zygotes?
Summary answer: Male and female zygotes displayed different PN morphometrics and morphokinetics. Additionally, variations were identified between sperm-originated (SPN) and oocyte-originated (OPN) pronuclei.
What is known already: Previous studies have investigated the use of PN-associated parameters via static observations as indicators of zygote viability, including size equality or juxtaposition. However, recent clinical application of time-lapse videography (TLV) provides a novel opportunity to assess these pronuclear events with greater accuracy and precision of morphometric and morphokinetic measurement. A number of recent TLV studies have also investigated potential live birth prediction by such PN associated measures, however whether or not there are gender associated differences in such measures which could in turn confound live birth prediction is unknown. Study design, size, duration: This retrospective cohort study included 94 consecutive autologous single day 5 transfer cycles (either fresh or frozen) performed between January 2019 and March 2020. Only ICSI cycles (maternal age <40 years) leading to a singleton live birth (43 males and 51 females) were included for analysis. All oocytes were placed in the EmbryoScope incubator for culture immediately post sperm injection with all annotation performed retrospectively by one embryologist (L-SO).
Participants/materials, setting, methods: Timings included 2nd polar body extrusion (tPb2), SPN(tSPNa)/OPN(tOPNa) appearance (differentiated by proximity to Pb2) and PN fading (tPNF). Morphometrics were evaluated at 8 (stage 1), 4 (stage 2) and 0 hour before PNF (stage 3), measuring PN area (um2), PN juxtaposition, and nucleolus precursor body (NPB) arrangement. Means ± standard deviation were compared using student t test or logistic regression as odds ratio (OR) and 95% confidence interval (CI), and proportional data by chi-squared analysis.
Main results and the role of chance: Logistic regression indicated that male zygotes had longer time intervals of tPb2_tSPNa than female zygotes (4.8±1.5 vs 4.2±1.0 h, OR=1.442, 95% CI 1.009-2.061, p=0.044), but not tPb2_tOPNa (4.7±1.8 vs 4.5±1.3 h, OR=1.224, 95% CI 0.868-1.728, p=0.250) and tPb2_tPNF (19.9±2.8 vs 19.1±2.3 h, OR=1.136, 95% CI 0.957-1.347, p=0.144). SPN increased in size from stage 1 through 2 to 3 (435.3±70.2, 506.7±77.3, and 556.3±86.4 um2, p=0.000) and OPN did similarly (399.0±59.4, 464.3±65.2, and 513.8±63.5 um2, p=0.000), with SPN being significantly larger than OPN at each stage (p<0.05 respectively). However, relative size difference between SPN and OPN was similar between male and female zygotes at 3 stages (33.6±61.7 vs 38.6±50.8 um2, p=0.664; 38.5±53.1 vs 45.7±71.9 um2, p=0.585; 38.4±77.4 vs 45.8±63.9 um2, p=0.615; respectively). More male than female zygotes reached central PN juxtaposition at stage 1 (77% vs 51%, p=0.010), stage 2 (98% vs 86%, p=0.048) and stage 3 (98% vs 86%, p=0.048). Furthermore, more OPN showed aligned NPBs than in SPN at stage 1 (45% vs 29%, p=0.023), but similar proportions at stage 2 (64% vs 50%, p=0.056) and stage 3 (76% vs 72%, p=0.618). There were no gender associated differences detected in NPB alignment in either SPN or OPN (p>0.05 respectively).
Limitations, reasons for caution: The retrospective design does not allow for control of unknown confounders. Sample size is considered relatively small. PN area measurement may not truly represent volume as PN may not be perfectly spherical. Findings were based on women <40 years old so may not apply to older population.
Wider implications of the findings: These findings augment and extend previous studies investigating PN parameters via static observations. The reported variations between male and female embryos may confound live birth prediction when using pronuclei morphometrics and morphokinetics. Larger scaled studies are warranted to verify these findings.
Trial registration number: Not applicable

P-192 Efficacy of postponement of intracytoplasmic sperm injection timing after spindle visualization for Metaphase I oocytes

N. Hisa[1], H. Ito[1], R. Kotake[1], S. Akimoto[1], Y. Suzuki[1], Y. Takahashi[1], C. Igarashi[1], S. Ono[2], H. Harada[2], M. Nakata[2], T. Abe[2]

[1]Shinjuku ART Cinic, IVF lab, Tokyo, Japan ;
[2]Shinjuku ART Clinic, Department of Gynecology, Tokyo, Japan

Study question: Does postponement of intracytoplasmic sperm injection (ICSI) timing after spindle visualization for Metaphase I (MI) oocytes improve developmental outcomes of embryos?
Summary answer: Postponement of ICSI timing after spindle visualization for MI oocytes improves blastocyst utility rates.
What is known already: Immature oocytes are generally considered poor developmental outcomes. Meanwhile, the timing of ICSI adjusted by using spindle visualization can improve clinically utilized embryos and live birth rates, but these outcomes remain inferior to those of mature oocytes. In in vitro maturation culture, nuclear maturation is thought to occur before the completion of cytoplasmic maturation, and in immature oocytes, synchronization of nuclear and cytoplasmic maturation may be insufficient for ICSI immediately after spindle visualization.
Study design, size, duration: Data for this retrospective cohort study were obtained 672 oocytes retrieved under mild stimulation cycles using letrozole, in patients aged younger than 39 years between April 2017 and October 2020. Written informed consent was obtained from all patients. This study was approved by the institutional review board.
Participants/materials, setting, methods: As a control group, 464 Metaphase Ⅱ oocytes that underwent ICSI immediately after visualization of the spindle were used. In group A, 103 MI oocytes underwent ICSI immediately after the first polar body release and spindle visualization, and in group B, 105 oocytes underwent ICSI 2-3 hours after spindle visualization. The primary outcomes were fertilization rates, degeneration, cleavage, embryo blastocyst formation, and utility rates. Outcomes were compared among the three groups.
Main results and the role of chance: The baseline fertilization rates of each group (control, A, B) were 82.3% (382/464), 73.8% (76/103), and 83.8% (88/105), respectively. The rate was significantly lower in group A than in the control group (P<0.05), and also tended to be lower in group A than in group B, although the difference was not significant. There was no significant difference in abnormal fertilization rates, oocyte degeneration rates, cleavage rates, and blastocyst formation rates among the three groups. [control, A, B: abnormal fertilization rate: 4.3% (20/464), 8.7% (9/103), 4.8% (5/105); oocyte degeneration rates: 3.0% (14/464), 1.9% (2/103), 3.8% (4/105); cleavage rates: 95.6% (307/321), 93.8% (61/65), 98.7% (74/75); blastocyst formation rates: 58.6% (177/302), 51.7% (31/60), 55.4% (41/74), respectively]. The blastocyst utility rates of control group and group B were significantly higher than in group A [41.7% (126/302), 45.9% (34/74), 26.7% (16/60), respectively] (P<0.05). There were no significantly different outcomes between the control group and group B.
Limitations, reasons for caution: The optimal timing of ICSI for MI oocyte cannot be determined by the presence or absence of spindles. In addition, the postponement duration we set was based on reports which reported on final oocyte maturation, and further investigation is needed to establish the optimal ICSI timing for MI oocytes.
Wider implications of the findings: In MI oocytes, postponement of ICSI timing after spindle visualization is essential for synchronization of the nucleus and cytoplasmic maturation.
Trial registration number: none

P-193 First cleavage division perpendicular to the pronuclear axis adversely affects the clinical outcome in human embryos

M. Nakaoka[1], K. Yumoto[1], T. Shimura[1], Y. Mio[1]

[1]Mio Fertility Clinic, Reproductive Centre, Yonago, Japan

Study question: Does the direction of formation for the first cleavage plane relative to the pronuclear axis affect clinical outcome?
Summary answer: A first cleavage division perpendicular to the pronuclear axis adversely affects the rate of embryo utilization for transfer or cryopreservation and the pregnancy outcome.
What is known already: It remains unclear how the first cleavage plane is determined in human embryos. By using time-lapse monitoring, our previous study (presented in ESHRE 2019) suggested that both the axis and locations of male and female pronuclei are involved in determining the first embryonic cleavage plane. Furthermore, by using immunofluorescence analysis, it was also revealed that most analyzed zygotes showed two pericentrin signals aligned around the interface between the male and female pronuclei. Our findings suggest that the pronuclear axis strongly influences the positions of the centrosomes, which become mitotic spindle poles and define the first cleavage plane. Study design, size, duration: From January 2015 to December 2017, time-lapse imaging (EmbryoScope®) of 3397 intracytoplasmic sperm injection (ICSI) oocytes was conducted. Of those, the relationship between the pronuclear axis and the first cleavage plane was analyzed in 607 normally fertilized embryos that cleaved to two cells and were obtained in 2015. Furthermore, of 3397 ICSI oocytes, 749 transferred embryos were classified based on the first cleavage patterns relative to the pronuclear axis, and the pregnancy rate was examined.
Participants/materials, setting, methods: A straight line connecting the centers of the pronuclei was defined as the 2PN axis. Based on the direction of the first cleavage relative to the 2PN axis, embryos were classified into three groups: parallel, perpendicular and intermediate. Fresh embryos were transferred on Day 2/3 (fresh-ET). Frozen and thawed embryos were transferred on Day 2/3 or Day 5 (F/T-ET). Clinical pregnancy was defined as confirmed gestational sac in the uterine cavity.
Main results and the role of chance: Of 607 analyzed embryos, 506 produced suitable images and were assigned to one of three groups: parallel (84.4%, n=427), perpendicular (9.7%, n=49) and intermediate (5.9%, n=30). Embryos that formed a cleavage furrow parallel to the 2PN axis were significantly more frequent than others (perpendicular, intermediate) (P <0.001). The embryo utilization rate for transfer or cryopreservation was significantly lower in the perpendicular group than in the parallel group (30.7% vs. 69.3%, P <0.01). Furthermore, of 749 transferred embryos, 504 assigned to the parallel and perpendicular groups were selected (n=470 and n=34, respectively), and the pregnancy outcome was analyzed. The mean maternal age was not significantly different between groups. The pregnancy rate of embryos was 24.2% (n=45/186) from fresh-ET and 39.4% (n=112/284) from F/T-ET in the parallel group, and 0% (n=0/14) from fresh-ET and 15.0% (n=3/20) from F/T-ET in the perpendicular group. Regardless of the types of embryo transfer (fresh or F/T), the pregnancy rate was significantly lower in the perpendicular group than in the parallel group (P <0.01). In addition, one of three patients who became pregnant from the transfer of an embryo in the perpendicular group had a miscarriage.
Limitations, reasons for caution: Since only ICSI embryos were analyzed in this study, the influence of fertilization methods on subsequent development could not be investigated. Further studies including preimplantation genetic testing for aneuploidy may help determine the reasons why pregnancy rates differ between groups.
Wider implications of the findings: We suggest that the 2PN axis is essential for determining the first cleavage plane because it seems to be involved in positioning the mitotic spindle poles. The direction of the first cleavage plane relative to the 2PN axis can be an important indicator for predicting embryo development and pregnancy outcome
Trial registration number: none

P-194 Impact of cryopreservation duration on pregnancy outcomes of vitrified-warmed blastocysts transfer using an open-device system

Q. Zheng[1], H. Zhang[1], S. Xu[1], F. Xu[1], F. Xiong[1], M. Mo[1], Y. Zeng[1]

[1]Shenzhen Zhongshan Urology Hospital, Fertility Center, Shenzhen, China

Study question: Is there a negative effect of long-term cryopreservation upon pregnancy outcomes after transfer of vitrified-warmed blastocysts stored in an open-device system?
Summary answer: Prolonged cryopreservation of vitrified blastocysts up to 24 months increased the incidences of clinical pregnancy, ongoing pregnancy, and live birth, while decreased early miscarriage rate.
What is known already: Vitrification is adopted as the dominant approach for cryopreservation of human oocytes and embryos. However, little is known about the potential effect of prolonged storage after vitrification on the genomic integrity and metabolism of embryos. Several studies have sought to decipher the effect of cryopreservation duration on IVF pregnancy outcomes, but few were confined to vitrification and the results were inconsistent.
Study design, size, duration: This retrospective study included 6722 patients undergoing their first vitrified-warmed blastocyst transfer (VBT) cycles from January 2015 to June 2019 in a single fertility center in South China. The study was approved by the hospital's Ethics Committee.
Participants/materials, setting, methods: A total of 6722 eligible patients were divided into five groups according to the storage duration after vitrification: Group I: 0-3 months; Group II: 3-6 months; Group III: 6-12 months; Group IV: 12-24 months; Group V: 24-36 months. The IVF pregnancy outcomes were compared between groups. Multivariate logistic regression was conducted to evaluate the independent effect of storage duration on pregnancy outcomes.
Main results and the role of chance: The odds of clinical pregnancy outcomes were similar from Group I to 4. However, the chance of clinical pregnancy (Group I as reference; Group 2: adjusted odds ratio (aOR)= 1.04, 95% CI 0.93-1.17; Group 3: aOR = 1.02, 95% CI 0.84-1.25; Group 4: aOR = 0.93, 95% CI 0.66-1.31; Group 5: aOR = 0.54, 95% CI 0.38-0.76) , ongoing pregnancy (Group 2: aOR=0.99, 95% CI 0.89-1.11; Group 3: aOR = 0.94, 95% CI 0.77-1.14; Group 4: aOR = 0.87, 95% CI 0.62-1.22; Group 5: aOR = 0.41, 95% CI 0.29-0.60), and live birth rate (Group 2: aOR=1.00, 95% CI 0.89-1.12; Group 3: aOR = 0.98, 95% CI 0.81-1.19; Group 4: aOR = 0.91, 95% CI 0.65-1.27; Group 5: aOR = 0.46, 95% CI 0.32-0.66) significantly decreased, while the early miscarriage rate (Group 2: aOR=1.11, 95% CI 0.92-1.35; Group 3: aOR =1.25, 95% CI 0.92-1.70; Group 4: aOR = 1.33, 95% CI 0.77-2.31; Group 5: aOR = 2.42, 95% CI 1.36-4.31) significantly increased as the storage duration increased up to 24-36 months.
Limitations, reasons for caution: The primary limitation of this study was its retrospective nature. Besides, as all these data come from a single IVF treatment center, the results should be confirmed by a larger multicenter study.
Wider implications of the findings: Our study provides more evidence about the negative impact of long-term storage of vitrified embryos on the clinical outcome. Clinicians should adapt FET strategies based on the embryo storage duration.
Trial registration number: not applicable

P-195 The influence of hormones and initial cell number on the size of self-assembled embryo-like structures

M. Niethammer[1], F. Knöspel[1], Z. Ban[1], M.R. Schneider[1]

[1]German Federal Institute for Risk Assessment BfR, German Centre for the Protection of Laboratory Animals Bf3R, Berlin, Germany

Study question: Do hormonal treatments and initial cell number influence the formation of embryo-like structures (ELS) during their development in regard to size?
Summary answer: The chosen initial cell number for ELS-assembly seems to influence the ELS size only until day 4, while hormones affect embryo size throughout their development.
What is known already: The initial cell number is an important parameter for the development of ELS, which might help to better understand how embryos regulate their size. Previous studies on differently sized natural murine embryos revealed that an initial difference in size at the early stage is compensated until E6.75. Normal-size embryos experience an increased mitotic activity before E6.75, whereas larger sized embryos show an increased apoptotic activity, indicating an important control point of cell turnover by adapting mitotic activity and cell survival. Embryo development is strongly dependent on appropriate β-estradiol and progesterone levels.
Study design, size, duration: The first set of experiments interrogated the influence of initial cell number (two conditions) on the size of formed ELS during the first 3 days (D1-3). The second set included two different hormonal treatments and the two conditions of initial cell number (the same as in the first experiments) generating four different groups. For each day one Aggrewell

(generating 1200 ELS/well) per condition was harvested. Experiments were repeated at least three times.
Participants/materials, setting, methods: ELS are generated by self-assembly in microwell-chamber plates combining embryonic stem cells, trophoblast stem cells and extraembryonic endoderm stem cells. Cells were cultured with and without addition of β-estradiol and progesterone, starting with different initial cell numbers (106 vs. 42 cells/ELS). ELS were harvested, stained, and at least 40 randomly picked ELS per condition were measured and statistically analyzed with Two-way ANOVA and Tukey's multiple comparison test. Results show the average area ± SD.
Main results and the role of chance: The results show a continuous increase in the size of ELS during the first three days of cultivation, with significant lower values (on D1-D3) when ELS were assembled from 42 initial cells (D1: 224.1±87.7 µm²; D3: 674.0± 84.4 µm²) compared to ELS formed with 106 initial cells (D1: 467.1±224.1 µm²; D3: 1275.0±348.0 µm²). Onward on the course of self-assembly, ELS with 42 initial cells were still smaller on D4 (1465.7±657.6 µm²) compared to ELS formed with 106 initial cells (2028.6±522.4 µm²). However, these differences could not be measured on D5 (106 initial cells: 1892.2±603.7 µm²; 42 initial cells: 1855±448.5 µm²), D6 (106 initial cells: 2143.3±622.1 µm²; 42 initial cells: 1788.4±585.5 µm²) and D7 (106 initial cells: 2146.7±628.1 µm²; 42 initial cells: 2319.5±778.8 µm²). Differences between the conditions with and without hormonal treatments (HT) could also be detected especially when ELS were generated with 42 cells: on D4 ELS with HT (1730.4±852.4 µm²) were significantly larger than without hormones (1201.2±462.9 µm²). In contrast, on D7 HT influenced the size of ELS distinctly depending on the initial cell number (42 cells: 1989.2±558.3 µm² with HT vs. 2649.7±999.4 µm² without HT; 106 cells: 2334.9±770.2µm² with HT vs. 1958.6±486.1 µm² without HT).
Limitations, reasons for caution: An even cell distribution is crucial for reproducible ELS-formation. Unfortunately, the used techniques for cell seeding led to an uneven distribution within the microwells. Moreover, different orientation of ELS during the size assessment might be an additional reason for the high variance of ELS size within one condition.
Wider implications of the findings: Even if the results seem to be in accordance with the observations made with natural embryos regarding compensation of size until E6.75, additional experiments need to be conducted. Further investigations should be carried out by testing different culture formats to obtain a more even cell distribution during the cultivation.
Trial registration number: Not Applicable

P-196 Bacterial influence on oocyte quality - the secret of a successful fertilization

M. Schenk[1], E. Voroshilina[2], M. Boldyreva2[3], M. Koranda[3], N. Reinschissler[1], G. Weiss[1]
[1]Das Kinderwunsch Institut Schenk GmbH, Research & Development, Dobl bei Graz, Austria ;
[2]Ural State Medical University, Research, Yekaterinburg, Russia C.I.S. ;
[3]DNA-Technology, Research, Moscow, Russia C.I.S.

Study question: Is there a difference in bacterial composition of follicular fluid between oocytes developing a good quality blastocyst and oocytes that fail fertilization?
Summary answer: Follicular fluids of oocytes failing fertilization show a different bacterial profile compared to follicular fluids of oocytes that were successfully fertilized.
What is known already: The presence of pathogens in the female reproductive tract has been intensively investigated. *Lactobacillus* species are mainly associated with a healthy genital tract and good prognosis for a successful pregnancy. Studies of the bacterial composition of follicular fluids have been mainly undertaken in women participating in reproductive medicine treatment because of the nature to obtain the specimen. In most studies follicular fluids have been pooled for analysis. Information on separately collected follicular fluids is still rare. We hypothesized that the composition of bacteria within follicular fluids is responsible for the success of the fertilization process.
Study design, size, duration: The study was designed and conducted at the Kinderwunsch Institut Schenk GmbH (Dobl, Austria) together with DNA-Technology. Follicular fluids from 46 patients undergoing IVF (*in vitro* fertilization) and ICSI (intracytoplasmic sperm injection) treatment were included and analyzed.
Participants/materials, setting, methods: Follicular fluids from 46 patients were collected separately. 2 follicular fluids from each patient were screened for common bacteria of the genital tract. One from an oocyte developing a good quality blastocyst and one displaying fertilization failures. Samples were analyzed for bacterial composition using the Femoflor16 (DNA-Technology).
Main results and the role of chance: Quantitative analysis revealed a higher total bacteria mass in follicles from oocytes that failed fertilization. Furthermore, *Lactobacillus* were not present in those follicles compared to good blastocyst follicles. In addition, *Chlamydia trachomatis* was found mainly in follicular fluid of not fertilized oocytes together with *Eubacterium*, *Gardnarella* and *Trichomonas species*. Interestingly, a trend of elevated levels of *Ureaplasma* species in follicular fluids of oocytes developing good quality blastocysts was observed.
Limitations, reasons for caution: Contamination of follicular fluids due to the procedure of oocyte pick up and follicular fluid retrieval cannot be completely excluded. Results should be confirmed with a higher sample size.
Wider implications of the findings: We assume that different bacterial compositions in follicular fluids are responsible for the destiny of the oocyte. It is tempting to speculate that bacterial analysis of follicular fluids may be beneficial to select to best oocytes in future IVF/ICSI treatments.
Trial registration number: not applicable

P-197 Two different strategies for embryo culture and selection: time-lapse with single-step medium and conventional incubator with sequential media. Are there differences in clinical results?

C. Alber. Rodriguez[1], M. Valera[1], L. Bori[1], F. Meseguer[1], L. Alegre[1], A. Galán[1], M. Meseguer[1]
[1]IVIRMA, Lab FIV, Valencia, Spain

Study question: Is there a significant difference in the clinical results of embryos cultured in time-lapse systems with single-step medium and conventional benchtop incubators with sequential media?
Summary answer: Embryos cultured in time-lapse systems and single-step media are more likely to achieve an ongoing pregnancy and have higher implantation rates than those cultured otherwise.
What is known already: One of the strategies for embryo culture in IVF consisted in conventional benchtop incubators combined with sequential culture media (CI-Seq). New generation time-lapse systems provide useful information on the morphokinetics of embryo development, but also a stable culture environment where embryos can develop undisturbed until blastocyst stage when paired with single-step culture media (TLS-SS). These features have the potential to improve embryo development and selection. Nonetheless, there is inconclusive evidence of whether this new culture strategy has a significant effect on clinical results of ICSI treatments. Studies on the matter are heterogeneous and reduced in both number and sample size.
Study design, size, duration: Unicentric retrospective cohort study. We compared the results of 11471 blastocyst transferences from 10276 ICSI treatments performed during 4 consecutive years, where embryos were cultured either on CI with sequential media (N=5255) or a TLS with single-step medium (N=5021). 3922 of the totals were fresh embryo transfers (ET) and 7549 frozen-thawed ET. We compared the implantation rate (IR) and ongoing pregnancy rate (OGPR) in both study groups, stratifying by ovum origin.
Participants/materials, setting, methods: Three models of TLS were used for embryo culture: EmbryoScope, EmbryoScope Plus (Vitrolife) and GERI (Genea Biomedx), as well as one CI (ASTEC). Sequential media: Cook, Origio, Vitrolife; Single-step media: Gems, Irvine, Life Global. Embryo scoring and selection was performed by ASEBIR criteria in the CI group, and by morphological and morphokinetic assessment for embryos cultured in TLS. Embryos were extracted from the CI only for media change. Statistical analysis: ANOVA tests and Logistic regressions.
Main results and the role of chance: A general Logistic Regression was performed, including egg origin, PGT-A and culture strategy to explain their impact in OGPR. Egg origin (OR=1,094 (95%CI: 1,015-1,179); *P*=0,019) and culture strategy (OR=1,141 (95%CI: 1,060-1,229); *P<0,001*) were statistically significant, which confirms the need for stratification due to the heterogeneity of the groups. The total IR in the TLS-SS group was 54,68±48,84%, significantly higher than that of CI-Seq (49,18±47,91 %; *P*<0,001). In ovum-donation treatments, a complete Logistic Regression for OGPR, with all typical confounding variables (age, BMI, n° oocytes, fresh/frozen transfer, number and day of ET)

resulted in an OR=1,187 (95%CI: 1,074-1,313; *P*=0,001) favoring culture in TL-SS. IR in these treatments were 61,98±47,68% in TL-SS vs 55,08±46,58% in CI-Seq (*P*<0,001) in fresh transfers and 51,48±48,91% in TL-SS vs 44,39±47,67% in CI-Seq (*P*<0,001) in frozen-thawed ET. In autologous treatments with PGT a similar regression yielded an OR=1,055 (95%CI: 0,889-1,252; *P*=0,542) for culture strategy. The IR of genetically tested ET was not significantly different: 53,08±49,49% for TL-SS, 50,90±49,07% for CI-Seq, *P*=0,246. In autologous procedures without PGT, culture strategy was not significant for OGPR (OR=0,998 (95%CI: 0,835-1,191), *P*=0,979) nor IR of fresh (49,75±48,91% TL-SS vs 44,23±47,36% CI-Seq; *P*=0,081) nor frozen-thawed transferences (50,77±48,33% TL-SS vs 50,67±47,33% CI-Seq; *P*=0,970).

Limitations, reasons for caution: After fertilization check, embryos were evaluated exclusively on D5/6. On D3, embryos cultured in CI were taken out only for a quick media change, but not for evaluation, and all handling was done in isolette cabins with controlled environmental conditions. Being a retrospective study, there is high variability in population.

Wider implications of the findings: A more homogenous prospective study, including comparison in life-birth rates, is necessary to extract final conclusions. However, our results suggest that the introduction of TLS and SS media in IVF laboratories might be a valid strategy to increase clinical results, especially in fresh embryo, thanks to an improved embryo selection.

Trial registration number: not applicable

P-198 Higher rate of direct uneven cleavage (DUC) embryos in women exhibiting high ovarian response

N. Schachte. . Safrai[1], G. Karavani[1], E. Esh. Broder[1], E. Levitase[2], T. Wainstock[3], I. Har-Vardi[2], A. Ben-Meir[1]

[1]Hebrew University-Hadassah Medical center, Department of Obstetrics and Gynecology, Jerusalem, Israel ;
[2]Soroka University Medical Center- Israel- Ben-Gurion University of the Nege, Fertility and IVF Unit Gyn/Obs, Beer-Sheva, Israel ;
[3]Ben-Gurion University of the Negev, Department of Public Health, Beer-Sheva, Israel

Study question: Does high ovarian response to controlled ovarian stimulation (COS) have a negative effect on oocyte quality?

Summary answer: High ovarian response is associated with reduced oocyte quality manifested as higher fraction of immature oocytes and higher rate of direct uneven cleavage (DUC) embryos.

What is known already: The literature regarding the effect of ovarian hyperstimulation on oocyte quality is limited and controversial. Results from several studies suggest that hyper response to controlled ovarian stimulation has a detrimental effect on oocyte and embryo quality, while others failed to confirm the existence of a direct toxic effect on oocyte and embryo quality. The association between temporal embryonal milestones and implantation rate has been previously demonstrated ,offering an additive tool by which oocyte quality, represented by embryo dynamics, can be evaluated. None of the aforementioned studies, however, used time lapse monitoring (TLM) system to evaluate oocyte and embryo quality.

Study design, size, duration: This study included a retrospective assessment of morphokinetic parameters performed by TLM from three university affiliated medical centers between January 2014 and December 2019. The developmental process and kinetics of 1863 embryos obtained from the study group, referred as the " high ovarian response" (HOR) group, was compared to 4907 embryos from the control group - the "normal ovarian response" (NOR) group.

Participants/materials, setting, methods: The study included patients younger than 38 years who underwent COS with consecutive aspiration of either more than 15 oocytes (the HOR group) or 6-15 oocytes (the NOR group). A comparison was made between the groups regarding morphokinetic parameters, including the rate of embryos manifesting direct uneven cleavage (DUC) at first cleavage (DUC-1), as well as implantation and pregnancy rates. Logistic regression was conducted to assess the association between patients' characteristics and implantation rate.

Main results and the role of chance: Oocyte maturation rate was significantly lower, and the DUC-1 embryos rate was significantly higher in the high ovarian response group compared to the normal ovarian response group (56.5% Vs 90.0%, p<0.001 and 16.2% Vs 12.0%, p=<0.001; respectively). Following the exclusion of DUC-1 embryos, embryos from the HOR and the NOR groups reached the consecutive morphokinetic milestones at a similar rate and demonstrated similar implantation and clinical pregnancy rates. In a multivariate analysis preformed, only maternal age was found to be predictive for implantation.

Limitations, reasons for caution: The groups were not homogenous in their basic characteristics. Important information regarding the maximal dose of GT obtained, previous IVF response and ovarian reserve testing was lacking

Wider implications of the findings: Higher oocyte quantity might have an effect on oocyte quality manifested as higher fraction of incompetent oocytes and higher rate of DUC-1 embryos. Once beyond the preliminary developmental stages, embryos from both groups reach the morphokinetic milestones at a similar rate and display similar implantation and pregnancy rates.

Trial registration number: not applicable

P-199 A case report to suggest that there must be other mutations than PATL2 or TUBB8 to cause oocyte maturation arrest

E. Molinari[1,2], M. Yang[3], J. Hu[1,2], L. Zhang[1,2], D.F. Albertini[1,3], D.H. Barad[4,5], N. Gleicher[3,4,5,6]

[1]Center for Human Reproduction, Embryology Lab, New York, U.S.A. ;
[2]Foundation for Reproductive Medicine, Embryology Lab, New York, U.S.A. ;
[3]Rockefeller University, Stem Cell Biology and Molecular Embryology Laboratory, New York, U.S.A. ;
[4]Center for Human Reproduction, Clinical Research, New York, U.S.A. ;
[5]Foundation for Reproductive Medicine, Clinical Research, New York, U.S.A. ;
[6]University of Vienna, Department of Obstetrics and Gynecology, Vienna, Austria

Study question: What causes our patient's repeated almost complete oocyte maturation arrest (OMA)?

Summary answer: Since we did not detect PATL2 and TUBB8 mutations, both known to cause OMA, this case was likely caused by mutations in HUS1 and ITGB3

What is known already: OMA has been associated with loss-of-function in key genes, such as PATL2 and TUBB8. Such patients have, however, uniformly have been unable to conceive with IVF

Study design, size, duration: We here report the case of repeatedly presenting patient between 2009 until 2020 (age 30 at 1st and 41 at last visit).

Participants/materials, setting, methods: The couple underwent 7 IVF treatments under several ovarian stimulation protocols at different gonadotropin dosages and in different preparations to try to recruit mature eggs. She conceived in her 2nd IVF cycle in 2009 and delivered uneventfully in 2010. She then conceived spontaneously and delivered a healthy boy in 2014. The couple since then has been attempting another pregnancy. Remarkably, in all IVF cycles all eggs but one arrested at prophase.

Main results and the role of chance: The female demonstrates abnormally high ovarian reserve for age (AMH=5.9 ng/mL in 2019) (mean, 10.6 oocytes). In all cycles, all but one retrieved were immature. In vitro maturation rate for the GV oocytes was 28%. Resultant M2s, however, demonstrated morphological abnormalities, such as giant polar bodies. *In vivo* M2s, in contrast, were always morphologically unremarkable, and their fertilization rate was 85%. Embryo morphology deteriorated appreciatively with advancing age. Sanger sequencing for TUBB8 and PATL2 genes were unremarkable. Whole genome sequencing of her and her sister (who had no fertility problems) revealed mutations of genes belonging to the integrin family (ITGB3) and DNA repair checkpoint (HUS1), both of which could be determinants in the observed maturation arrest.

Limitations, reasons for caution: A functional study, coupled with imaging of the discarded material, will likely offer further information regarding the mechanisms leading to OMA in this female.

Wider implications of the findings: This case report represents a new phenotype of female infertility, characterized by almost complete maturation arrest which, however, still offers opportunity for pregnancy. Further isolation of underlying mutation(s) may offer additional insights about checkpoints required for the transition of prophase to metaphase in human oocytes.

Trial registration number: NA

P-200 To transfer or to discard: A retrospective analysis of ploidy, implantation and birthweight outcomes of grade "C" blastocysts following preimplantation genetic testing for aneuploidy (PGT-A)

T. Ross[1]

[1]*Monash IVF, Embryology, Brisbane, Australia*

Study question: What's the ploidy status of grade "C" blastocysts and what are their implantation potential and birthweight outcomes when tested euploid?
Summary answer: Grade "C" blastocysts were less likely to be euploid compared to grades "A/B". Euploid "C"s led to reduced but reasonable implantation potential with similar birthweights.
What is known already: In contrast to grade "A" or "B", grade "C" blastocysts are generally considered borderline quality in most *in vitro* fertilization programs, with inconsistent policies between clinics. Little evidence has been reported regarding their euploidy rate, implantation potential, and birthweight outcomes.
Study design, size, duration: This retrospective cohort study included 426 consecutive autologous-oocyte patients undergoing PGT-A (biopsy at day 5/6) at two associated private clinics between January 2013 and August 2020. A total of 1418 resulting blastocysts (tested either euploid or aneuploid) were analysed. Implantation outcomes were assessed in a subset of 520 singly transferred euploid blastocysts. Birthweight outcomes were evaluated in 209 singleton newborns using a gestation-adjusted Z score taking into account gestational age and baby gender.
Participants/materials, setting, methods: Blastocysts were graded "A/B/C" according to a combination of inner cell mass and trophectoderm morphology. Endpoints included ploidy, implantation and birthweight outcomes. Multiple regression (logistic or linear) was performed to investigate relative prognosis of grade "C" blastocysts using different endpoints in reference to grade "A/B" blastocysts, expressed as either adjusted odds ratio (aOR) or coefficients (β) with 95% confidence intervals (CI). Maternal age and biopsy day (5/6) were included as potential confounders at regression analysis.
Main results and the role of chance: Grade "C" blastocysts (n=466) were associated with a lower euploidy rate in reference to either grade "A" (n=179, aOR=0.412, 95% CI: 0.278-0.611, P=0.000) or "B" blastocysts (n=773, aOR=0.535, 95% CI: 0.418-0.685, P=0.000). Euploid "C" grade blastocysts (n=128) led to significantly reduced chance to implant when compared to either grade "A" (n=90, aOR=0.387, 95% CI: 0.215-0.696, P=0.002) or "B" blastocysts (n=302, aOR=0.617, 95% CI: 0.404-0.944, P=0.026); although implantation rate was still considered at a reasonable level (44.5%) as opposed to grades "A" (66.7%) or "B" (57.6%). However, no significant difference was observed in the birthweight (g, mean ± standard deviation) following the transfer of a single euploid grade "C" blastocyst (n=42, 3310.8±704.1) in comparison to a single euploid grade "A" (n=48, 3367.8±519.3, P>0.05) or "B" blastocyst (n=119, 3284.5±535.5, P>0.05). Taking into account maternal age, biopsy day, gestational age and baby gender; further multiple linear regression analysis also showed similar results using either birthweight itself (C vs A, β=-52.395, 95% CI: -148.83–43.893, P=0.282; C vs B, β=-104.338, 95% CI: -272.653–63.977, P=0.223), or the gestation-adjusted Z score as an endpoint (C vs A, β=0.101, 95% CI: -0.001–0.164, P=0.052; C vs B, β=0.084, 95% CI: --0.073 – 0.241, P=0.290).
Limitations, reasons for caution: The retrospective design of this study does not allow control for unknown confounders. Inner cell mass or trophectoderm was not graded separately making it difficult to further break down the "C" grade blastocysts. Only blastocysts suitable for biopsy were included for analysis, so results may not extrapolate to untested blastocysts.
Wider implications of the findings: Grade "C" blastocysts may still hold its clinical value despite reduced euploidy rate. PGT-A may be considered as a potential approach to utilize grade "C" blastocysts more effectively, without affecting birthweight outcomes. This is also potentially useful in patient counselling.
Trial registration number: not applicable

P-201 The beneficial effects of ZP-free culture on cytoplasmic fragmentation in human embryos. : An innovative trial using 3PN zygotes

M. Sugishima[1], **K. Yumoto**[1], **T. Shimura**[1], **Y. Mio**[1]

[1]*Mio Fertility Clinic, Reproductive Centre, Yonago, Japan*

Study question: Is it possible to culture ZP-free embryos to eliminate perivitelline threads, which are known to be involved in generating cytoplasmic fragments at the first cleavage?
Summary answer: ZP-free culturing, an innovative system that decreases the amount of cytoplasmic fragments without disrupting the blastomeres, using incubators with time-lapse imaging.
What is known already: A study in 2017 observed perivitelline threads in more than 50% of cleavage-stage human embryos using time-lapse imaging, and the rate of cytoplasmic fragmentation (at the first cleavage) was significantly decreased in embryos without perivitelline threads ($P < 0.001$). While it has been proposed that perivitelline threads play an important role in crosslinking the cumulus cells and oocyte during maturation, the mechanism underlying such a role remains unclear. It is also unknown whether the threads still function in mature MII oocytes.
Study design, size, duration: A prospective study was conducted using 2,852 normal (2PN/2PB) embryos from c-IVF/ICSI and 113 abnormal (3PN) embryos obtained from c-IVF between 2017 and 2019. The zona pellucida (ZP) of 71 abnormal embryos was removed at the pronuclear stage ("ZP-free"), and the rest (n=42) were cultured as "ZP-intact". Normal and abnormal embryos were cultured for five days in bench-top incubators (MINC, COOK) and an incubator equipped with a time-lapse imaging system.
Participants/materials, setting, methods: Embryos used in this study were donated by 412 couples who underwent c-IVF cycles in our clinic between 2017 and 2019. For ZP removal, 3PN embryos were placed in 0.125M sucrose-containing HEPES media drops to reduce the ooplasm size. Then, ooplasms were completely separated from ZPs by a laser and pipetting. Embryo development and morphology of the three groups (normal, ZP-intact and ZP-free abnormal) were compared based on the degree of cytoplasmic fragmentation.
Main results and the role of chance: The first cleavage occurred in 97.8% (n=2,790/2,852) of 2PN/2PB, 83.3% (n=35/42) of ZP-intact 3PN and 97.2% (n=69/71) of ZP-free 3PN. Normal (2PN/2PB), ZP-intact and ZP-free 3PN embryos were classified into three groups based on the modified Veeck's criteria thus: <20% fragmented compared to the total volume of cytoplasm at the first cleavage (Grade 1 and 2, Good); 20-39% fragmented (Grade 3, Fair) and ≧40% fragmented (Grade 4, Poor). Of 69 cleaved ZP-free 3PN embryos, 68.1% (n=47) showed less than 20% fragments which was significantly higher than 2PN/2PB (43.7%, n=1,218/2,790) and ZP-intact 3PN (45.7%, n=16/35; $P < 0.05$). Furthermore, 24.6% (n=17/69) of ZP-free 3PN embryos showed 20-39% fragments which was significantly lower than 2PN/2PB (45.9%, n=1,281/2,790; $P < 0.05$). In addition, 50.7% of ZP-free 3PN embryos (n=36) developed to the morula stage after the third cleavage, and 29.6 % (n=21) formed blastocoel and became blastocysts. Thus, removing the ZP before the first cleavage did not adversely affect embryo development and decreased the cytoplasmic fragmentation.
Limitations, reasons for caution: Due to ethical and clinical limitations, we only examined abnormally fertilized embryos in this study. Moreover, since the relationship between the perivitelline threads and cytoplasmic fragments is unclear, we plan to conduct molecular biological analysis of the perivitelline threads in further studies.
Wider implications of the findings: This study revealed that ZP is not always necessary after the pronuclear stage because ZP-free embryos studied herein developed normally and maintained cell adhesion well. This innovative culture method might provide the breakthrough needed for patients to improve embryo quality who obtain embryos with severe fragmentation caused by perivitelline threads.
Trial registration number: not applicable

P-202 Past embryo viability is not always a good predictor of future pregnancy: dynamic viability suggests video has limited benefit over static images for AI assessment

Study question: Does embryo quality/viability change over time, suggesting the use of video for AI-based embryo quality assessment has limited benefit over single point-in-time images?

Summary answer: AI assessment of single static embryo images at multiple time-points indicates embryo viability is dynamic, and past viability is a limited predictor of future pregnancy.

What is known already: Artificial Intelligence (AI) has been applied to the problem of embryo quality (viability) assessment using either video or single static images. However, whether historical data within video provide an additional advantage over single static images of embryos (at the time of transfer) for assessing embryo viability is not known. This applies to both manual and AI-based embryo assessment. If embryo viability changes over time prior to transfer, then the implication is that the assessment of future pregnancy using historical embryo data from videos would provide limited additional value over single static images taken immediately prior to transfer.

Study design, size, duration: Retrospective dataset of single embryo images taken at up-to three time-points prior to transfer: Early Day 5, Late Day 5 (8 hours later), and Early Day 6 (16 hours later), with corresponding fetal heartbeat (pregnancy) outcomes. The AI assessed the viability of each embryo at its available timepoints. Viability prediction was compared with pregnancy outcome to assess viability predictiveness at each timepoint prior to transfer, and assess the variability of viability over time.

Participants/materials, setting, methods: Single static images of 173 embryos were taken using time-lapse incubators from a single IVF clinic. 116 embryos were viable (led to a pregnancy) and 57 were non-viable (did not lead to a pregnancy). The AI was trained on thousands of Day 5 static embryo images taken from multiple IVF laboratories and countries, but was not trained on data from this clinic.

Main results and the role of chance: When embryos were assessed as viable by the AI immediately prior to transfer (no delay), the AI accuracy (sensitivity) in predicting pregnancy was 88.1% (59/67) for Early Day 5, 84.8% (28/33) for Late Day 5 and 87.5% (14/16) for Early Day 6. When the delay between AI assessment and transfer is 8 hours, 16 hours and 24 hours, the the accuracy drops to 66.7% (22/33), 31.3% (5/16) and 12.5% (2/16), respectively.

These results indicate that the viability of the embryo is dynamic, and therefore time series analysis, i.e. using video, may not be well suited for embryo viability assessment because past viability is not necessarily a good predictor of future viability or pregnancy outcome. The viability of the embryo immediately prior to transfer, from a single static image, is a reliable predictor of viability. This is consistent with the current clinical practice of using Gardner score end-point assessment for embryo quality.

Results also suggest significant benefits from using time-lapse with AI, where AI continually assesses embryo viability over time using static images. The time point at which the embryo should be transferred to maximize pregnancy outcome is when the embryo has the greatest AI viability score.

Limitations, reasons for caution: Although evidence suggests past embryo viability is a limited predictor of future pregnancy, a side-by-side comparison of video versus single static image AI assessment would further verify that the historical or change in embryo development or viability has minimal impact on embryo viability assessment at the time prior to transfer.

Wider implications of the findings: Time-lapse and AI can beneficially change the way embryos are assessed. Continual AI monitoring of embryos enables optimization of which embryo to transfer and when, to ultimately improve pregnancy outcomes for patients. The findings also suggest that static end-point AI assessment is sufficient for predicting embryo implantation potential.

Trial registration number: not applicable

P-203 Applying artificial intelligence for ploidy prediction: The concentration of IL-6 in spent culture medium, blastocyst morphological grade and embryo morphokinetics as variables under consideration

B. Aparici. Ruiz[1], L. Bori[1], E. Paya[1], M.A. Valera[1], A. Quiñonero[2], F. Dominguez[2], M. Meseguer[1]

[1]IVIRMA Valencia, FIV Laboratory, Valencia, Spain ;
[2]IVI Foundation, Research Department, Valencia, Spain

Study question: Would it be possible to predict embryo ploidy by taking into account conventional morphological and morphokinetic parameters together with IL-6 concentration in spent culture medium?

Summary answer: Our artificial neural network (ANN) trained with blastocyst morphology, embryo morphokinetics and IL-6 concentration distinguished between euploid/aneuploid embryos in 65% of the testing dataset.

What is known already: The analysis of spent embryo culture media represents the protein and metabolic state of the embryo and could be a non-invasive method of obtaining information about embryo quality. The impact of the presence/absence of several proteins in embryo culture samples over clinical results has been widely studied. The IL-6 is one of the most mentioned protein for its effect on embryo development, implantation and likelihood of achieving a live birth. In this initial attempt, we examined the predictive value for euploidy of a model that took into account the concentration of IL-6 in the spent culture medium.

Study design, size, duration: This prospective study included 319 embryos with PGT-A results. Out of the total, 127 were euploid and 192 aneuploid embryos. Concentration of IL-6 in spent embryo culture media (collected on the day of trophectoderm biopsy-fifth/sixth day of development), morphokinetic parameters (division time to 2 cells-t2; to 3 cells-t3, to 4 cells-t4; to 5 cells-t5 and time of blastocyst formation-tB) and blastocyst morphological grade (according to ASEBIR criteria) were considered to predict the embryo ploidy.

Participants/materials, setting, methods: Embryos were cultured in EmbryoScope. The chromosome analysis was performed using next-generation sequence technology. The concentration of IL-6 was measured in 20µL of spent embryo culture media with ELISA kits. Morphokinetic parameters were automatically annotated and the blastocyst morphology was evaluated by senior embryologists based on blastocele expansion, inner cell mass and trophectoderm quality. All the embryos were divided into 70% for training, 15% for validating and 15% for testing our ANN model with MatLab®.

Main results and the role of chance: The general description for the euploid embryo population was the following: 2% of the embryos were graded as A, 71% were graded as B and 28% were graded as C; the means and standard deviations were 25.32±2.97 hours (h) for t2, 35.33±5.15h for t3, 37.30±5.43h for t4, 48.24±6.62h for t5 and 103.93±12.8h for tB; and the average of IL-6 concentration was 1.51±0.70 pg/ml. The general description for the aneuploid embryo population was the following: 1% of the embryos were graded as A, 48% were graded as B and 51% were graded as C; the means and standard deviations were 26.13±3.51h for t2, 36.70±4.29h for t3, 38.20±4.24h for t4, 49.86±6.89h for t5 and 107.10±8.29h for tB; and the average of IL-6 concentration was 1.47±0.71 pg/ml. Our ANN model showed a higher general success rate as we increased the variables considered in the final prediction of euploid embryos. The accuracy, sensitivity and specificity for the testing dataset were: 0.60, 0.12 and 0.87 with morphokinetic parameters; 0.63, 0.24 and 0.93 with morphokinetics and IL-6 concentration; and 0.65, 0.16 and 0.96 with morphokinetics, IL-6 concentration and blastocyst morphological grade.

Limitations, reasons for caution: The low sensitivity and high specificity achieved in our models indicated that they were more capable of detecting aneuploid than euploid embryos. As this was a preliminary study, the small number of embryos included in the test (n=48) was also a limitation.

Wider implications of the findings: The results showed that our model tended to classify the embryos as aneuploid. More euploid embryos would be necessary to train our model and achieve better results in the prediction of chromosomally normal embryos. Further studies with large number of embryos and additional variables could improve the non-invasive ploidy prediction.

Trial registration number: not applicable

P-204 Dynamics of cavitation as a potential non-invasive predictor of mammalian blastocyst quality

E. Kosyl[1], A. Ajduk[1]

[1]University of Warsaw- Institute of Developmental Biology and Biomedical Sciences, Department of Embryology, Warsaw, Poland

Study question: We wished to investigate whether dynamics of cavity formation can be used in embryo quality assessment.

Summary answer: Dynamics of mouse embryo cavitation reflects to certain extent blastocysts' developmental capabilities. It can be potentially used as a biomarker of mammalian embryo quality.

What is known already: During cavity expansion blastocyst pulsates, i.e. changes its volume in an oscillatory way. Recent studies performed on a mouse model have shown, that dynamics of cavitation, biomechanical properties of the

trophectoderm (TE) and embryo size are intertwined. Presence or absence of blastocyst contractions has been linked to particular parameters related to positive outcome of the in vitro fertilization procedures, but the data on influence of contractions on human embryos' developmental capabilities is often contradictory. Moreover, mostly in those studies only strong contractions (leading to a high volume loss) have been taken into consideration.

Study design, size, duration: We tested how postovulatory (in vitro or in vivo) or maternal aging of mouse oocytes affects dynamics of cavity formation and expansion in the resulting embryos (n=27, n=26 and n=30, respectively). Furthermore, we also analyzed almost 100 mouse blastocysts in order to correlate dynamics of their cavitation with their ability to form correct outgrowths (in vitro model of implantation).

Participants/materials, setting, methods: Mouse oocytes subjected to postovulatory (either in vivo or in vitro) or maternal aging were fertilized in vitro. Dynamics of cavity formation and expansion was assessed by time-lapse imaging; equatorial images were taken every 10 minutes. Blastocyst area was measured over time and compared to the outcome from control embryos. In another set of experiments, after the filming mouse blastocysts were cultured for additional 4 days to test their ability to form outgrowths.

Main results and the role of chance: We noticed, that mouse embryos which represent limited developmental potential (obtained from either postovulatory or maternally aged oocytes) and blastocysts developed from freshly fertilized young females' oocytes differ in terms of some parameters related to dynamics of cavitation, e.g. time of the initiation of cavity formation, frequency of contractions or mean loss of blastocyst's area during contraction. We observed that embryos obtained from oocytes subjected to maternal or postovulatory aging have distinct dynamics of cavitation. Moreover, we noticed slightly different effect on particular parameters related to cavitation between in vivo and in vitro version of postovulatory ageing. We also showed that blastocysts, which are unable to create proper outgrowths (i.e. too small or without epiblast cells), differ from embryos that differentiate into correct outgrowths in terms of certain parameters of cavitation dynamics. Our data indicates, that dynamics of cavity formation and expansion might be related to developmental potential of mouse embryo.

Limitations, reasons for caution: Further studies with extended group size and testing embryos' ability to implant in vivo are required to confirm our results. Moreover, we examined dynamics of cavitation only in a mouse model, so additional studies performed on other mammalian species are needed.

Wider implications of the findings: Our data proves, that dynamics of embryo cavitation reflects, to certain extent, developmental capabilities of mouse blastocysts. Therefore, it is possible that it can be a biomarker of embryo quality (in combination with parameters provided by other methods or solely) of other mammalian species, including humans.

[5]CHA fertility seoul center seoul sequare 3floor, Reproductive and Molecular Medicine., Seoul, Korea- South

Study question: What is primary factor of bioenergetics product activity between microtubule instability and the functional activity of mitochondria in embryo?

Summary answer: The actin cytoskeleton instability is presumably the primary cause for the bioenergenesis of mitochondrial function to the preimplantation embryo development.

What is known already: Mitochondria are cellular organelles dynamically moving and morphological changes. It provides for homeostatic energy to the cell. The dynamic property of the mitochondria is associated with the microtubule network in the cell. However, the stability of the microtubule was clearly identified for preimplantation embryo development.

Study design, size, duration: This study is designed to assess the ATP productivity of the mitochondria, and specifically to observe what its primary factor is in terms of providing microtubule stability in mammalian cells. Additionally, we investigated the relationship between blastocyst formation and actin cytoskeleton stabilization by EpD with 2-cell mice.

Participants/materials, setting, methods: We prepared the microtubule stability regulation model with the HEK293 cell line by using the microtubule stabilizer as an Epothilone D (EpD). Then we analyzed the metabolic activity of the cells through oxidative phosphorylation (OXP) ratios analysis. Also, we performed confocal live imaging to observe mitochondria morphology depending on the cells' microtubule. Next, we treated EpD to 2-cell culture media for the analysis of blastocyst development ratios.

Main results and the role of chance: EpD significantly increased fusion form. Also, EpD enhance bioenergy ratios like OXP in the mitochondria and functional activity related marker, like mTOR compared with the control. These results suggest that microtubule stabilization enhances mitochondrial metabolism by increasing oxygen consumption. Also, EpD in 2-cell culture media led to a significant increase in the speed of development and 50% higher hatched out blastocyst formation ratios compared to the control group.

Limitations, reasons for caution: This study had limited animal experiments. For the next study, we are planning with an aim to improve the quality and development ratios of human embryos by EpD.

Wider implications of the findings: Microtubule stabilizer has a possibility to recover the mitochondria's functional activity in the preimplantation embryo development. Mitochondrial functional activity along the actin cytoskeleton may play a pivotal role in determining the embryo quality and development ratios for archive pregnancy.

Trial registration number: non-clinical trials

P-206 Does oocyte vitrifcation affect morphokinetics of subsequent embryo development?

S. Montgomery[1], K. Montgomery[2], D. Nash[2], A. Campbell[1]

[1]CARE Manchester, Embryology, Manchester, United Kingdom ;
[2]University of Aberystwyth, Equine Svience, Aberystwyth, United Kingdom

Study question: Are the morphokinetic profiles, as assessed using time-lapse technology, of human embryos developed from vitrified oocytes different to those from fresh oocytes.

Summary answer: Vitrification of oocytes does have an effect on early developmental morphokinetic profiles, but this is normalized by the time the embryo has reached blastocyst.

What is known already: Vitrification of oocytes is now commonplace, but little is known about the effect this may have on subsequent embryo development.

Study design, size, duration: This was a retrospective data analysis, from 8 fertility clinics in the UK between 2012 and 2019. Embryos from patients in the vitrified group (n=557) were matched to fresh patient controls (n=539). The matching was performed based on the following criteria: type of treatment, patient age, cause of infertility and number of embryos.

Participants/materials, setting, methods: The embryos in each group were compared for mean morphokinetics of key developmental stages in hours post insemination (hpi). Parameters compared included early cleavage divisions (t2-t8), time to start of compaction (tSC), time to morula (tM), time to start blastulation (tSB), time to full blastocyst (tB) and duration of compaction (tB-tSC). Treatment outcomes were compared between the two groups, including percentage of blastocyst formation, clinical pregnancy rate, implantation rate and live birth rate.

Main results and the role of chance: The results showed a significant delay across all early cleavage divisions as follows for vitrified and fresh oocytes respectively: 2-cell (28.14 vs 26.10 ($p<0.001$)), 3 cell (37.56 vs 35.37 ($p<0.001$)), 4 cell (40.58 vs 37.54 ($p<0.001$)), 5 cell (50.31 vs 47.14 ($p<0.001$)), 6 cell (53.99 vs 50.87 ($p<0.001$)), 7 cell (57.08 vs 54.48 ($p<0.001$)) and 8 cell (61.26 vs 58.91 ($p<0.01$)). In addition, tSC was also significantly delayed in the vitrified group (80.65 vs 76.36 ($p<0.001$)). However, the compaction stage was significantly shorter in the vitrified oocytes (19.02 vs 22.45 ($p<0.001$)). Therefore, there was no difference in the time that embryos derived from fresh and vitrified

oocytes reached the blastocyst stage (108.03 vs 107.78 (p>0.05)). No difference was found in clinical pregnancy, implantation or live birth rates but significantly fewer blastocyst developed from vitrified oocytes compared to fresh (36.09% vs 42.4% (p<0.05)).
Limitations, reasons for caution: Although this was a matched analysis, it was a retrospective in nature therefore is subject to confounders. However, it would be problematic to perform a prospective randomized controlled trial to address this study question given the need to randomize patients to elective freezing of oocytes prior to embryo creation.
Wider implications of the findings: Vitrification of oocytes may affect early developmental morphokinetic profiles, but any effect is normalized by the time the embryo has reached blastocyst. However, fewer blastocysts may develop following oocyte vitrification. This may have implications for oocyte donation banks and those patients choosing to cryopreserve oocytes.
Trial registration number: na

P-207 Heterogoneic cell division proven to occur in bovine zygotes

T. D. Coster[1,2], H. Masset[1], O. Tsuiko[1], K. Smits[2], A. Va. Soom[2], J. Vermeesch[1]

[1]KU Leuven, Department of Human Genetics, Leuven, Belgium ;
[2]Ghent University, Department of Reproduction- Obstetrics and Herd Health, Gent, Belgium

Study question: We hypothesize that the zygote can segregate parental genomes via a non-canonical pathway. We coined this heterogoneic cell division. Can we proof the existence of this new segregational pathway?
Summary answer: We confirmed the existence of this non-canonical segregation mechanism leading to mixoploidy and provide a catalogue of abnormal zygotic divisions.
What is known already: Embryos show a high degree of chromosomal instability leading to chromosomal mosaicism. Chromosomal aberrations affect the developmental potential. We developed haplarithmisis which determines the single-cell genome-wide haplotype and copy number and allows to deduce the parental and segregational origin. Analysis of cleavage-stage bovine embryos by haplarithmisis, discovered the presence of uniparental and biparental blastomere lineages in individual embryos. We hypothesized that whole genome segregations can occur via a non-canonical zygotic division, a process termed "heterogoneic" division. Abnormal zygotic division has been observed in bovine and human *in vitro* produced zygotes using time-lapse, but parental genome segregation has never been disclosed.
Study design, size, duration: We hypothesized that abnormal cytokinetics and spindle mechanics may underlie the segregation of parental genomes in a separate blastomere line. *In vitro* produced zygotes were monitored by time-lapse microscopy. Zygotes cleaving 3 or 4 cells were disaggregated, picked and analysed by haplarithmisis.
Participants/materials, setting, methods: Blastomeres from bovine *in vitro* produced zygotes cleaving directly into 3 or 4 blastomeres, identified by time-lapse monitoring, were tubed following zona removal and blastomere dissociation and whole-genome amplified. Samples were subsequently hybridized on Illumina Bovine HD BeadChip SNP arrays. Data was analyzed by haplarithmisis, using a the siCHILD-bovine algorithm, to infer the haplotypes and the copy number of the parental genomes. Blastomeres showing failed haplarithmisis plots were low-coverage whole-genome sequenced on a HiSeq4000 sequencer. Main results and the role of chance: We obtained 25 bovine embryos, comprising 82 blastomeres, derived from 12 families (12 cows and 2 bulls) that cleaved directly into 3 or 4 blastomeres. Sixteen, 7 and 2 out of 25 zygotes cleaved respectively in 3 cells, 4 cells and 3 cells and a fragment. In at least 20 embryos, more than one paternal haplotype was identified, showing that a polyspermic fertilization resulted in an abnormal division. All embryos contained a whole-genome abnormality in at least one blastomere, resulting in mixoploid (5), mixed diploid biparental and androgenetic (12), polyploid (4), mixed gynogenetic and androgenetic (2) and androgenetic (2) embryos. Twenty-one embryos had at least one blastomere containing a uniparental signature. Based on the blastomere haplotype profiles we classified the embryos in six segregation categories. In twelve blastomeres haplarithmisis failed. Massive parallel sequencing of the amplified DNA showed the presence of mitochondrial DNA, indicating the blastomere did not contain any genomic DNA. This observation confirms that heterogoneic cell division does occur via different non-canonical zygotic segregations, which result in a variety of chimeric and mixoploid embryos constitutions.
Limitations, reasons for caution: These findings apply to a small set of bovine *in vitro* produced abnormally cleaving embryos. Segregation patterns may be incomplete and their true *in vitro* and *in vivo* prevalence remains unknown. Based on the haplotypes the non-canonical divisions have been reconstructed. Those patterns can now be evaluated and tested.
Wider implications of the findings: This study shows that heterogoneic cell division occurs. We hypothesize this non-canonical division occurs frequently in both *in vitro* and *in vivo,* not only in cattle but also in man and hypothesize that persistence of such cell lines might explain the development of androgenetic tumorous outgrowths and mosaic uniparental individuals.
Trial registration number: not applicable

P-208 Oleic acid rescues altered autophagy induced by palmitic acid during mouse preimplantation development

Z. Leung[1], M. Calder[1,2], D. Betts[1,2,3], B. Ab. Rafea[2,4], A. Watson[1,2,3]

[1]Schulich School of Medicine and Dentistry, Physiology and Pharmacology, London, Canada ;
[2]Schulich School of Medicine and Dentistry, Obstetrics and Gynaecology, London, Canada ;
[3]Lawson Health Research Institute, Children's Health Research Institute CHRI, London, Canada ;
[4]London Health Sciences Centre, The Fertility Clinic, London, Canada

Study question: The aim of the study is to identify the autophagic profile and the effects of fatty acid treatments on autophagic activity in preimplantation mouse embryos.
Summary answer: Autophagic activity varies significantly in early stages of mouse preimplantation development; exposure to fatty acids alters the embryonic autophagy profile.
What is known already: Obesity is one of the top comorbidities for infertility, and obese individuals have elevated fatty acid levels. In serum, palmitic acid (PA) and oleic acid (OA) are the most abundant saturated and unsaturated fatty acids, respectively. We recently reported that PA impairs blastocyst development, affects mitochondrial reactive oxygen species, triacylglycerol levels, and endoplasmic reticulum stress pathways during mouse preimplantation development. Interestingly, the addition of OA counteracts those effects. Autophagy plays an essential role in embryo development, as knock-out of a key autophagy protein is embryonic lethal. Little is known about the autophagic profile in fatty acid treated mouse preimplantation embryos.
Study design, size, duration: Pools of 20 – 25 mouse embryos were collected from gonadotrophin super-ovulated and mated CD1 female mice. Two-cell stage embryos were treated with 100 μM PA and 250 μM OA, alone and in combination, and 1.5% bovine serum albumin media (control) within KSOMaa media for 18, 24, and 48 hours *in vitro*. The detection of various autophagic markers were evaluated by immunofluorescence microscopy and RT-qPCR.
Participants/materials, setting, methods: mRNA levels of autophagic markers were measured using RT-qPCR with the Taqman primers and Universal PCR Mix. Immunofluorescence staining of LC3 puncta (marker for autophagosome formation) was performed using LC3A/B polyclonal antibody (Invitrogen PA1-16931) and DAPI (4 ,6-Diamidino-2-phenylindole dihydrochloride) was used to stain for cell nuclei. Analysis of LC3 puncta was performed using ImageJ software. Images were acquired using an LSM 800 laser scanning confocal microscope. Data analysis was completed by GraphPad Prism software.
Main results and the role of chance: Mouse preimplantation embryos showed no change in mRNA levels of autophagic markers (*Bcln1, ATG3, ATG5, and LC3*) relative to the control group after 48-hours exposure of 100 μM PA and 250 μM OA treatments, alone and in combination.

The number of LC3 puncta was measured and analyzed as a reflection of autophagic activity in mouse preimplantation embryos. Under the fatty acid-free condition, the average number of LC3 puncta per blastomere was significantly decreased after 18 hours of development ($p < 0.005$). However, the average number of LC3 puncta per blastomere at 18, 24, and 48 hours were not significantly different from each other ($p = 0.2724$).

Following 100 μM PA and 250 μM OA treatments, alone and in combination, autophagic activity was impacted by the presence of fatty acids. Mouse

preimplantation embryos exposed to control and fatty acid treatment groups demonstrated no significant differences in LC3 puncta per blastomere at 18- and 24-hours treatment time ($p = 0.5381$; $p = 0.7829$). However, embryos exposed to 48 hours of PA treatment had a significantly greater number of LC3 puncta per blastomere than embryos exposed to 48 hours of OA and PA and OA combination treatments ($p < 0.05$).

Limitations, reasons for caution: Although LC3 puncta count (autophagosome formation) is impacted by fatty acid treatment, autophagic flux must be measured to fully investigate autophagic activity during mouse preimplantation development. These processes need to be measured in human embryos cultured *in vitro*.

Wider implications of the findings: Profiling autophagic activity in fatty acid treated mouse preimplantation embryos would guide future investigations on pharmacological modulation of autophagy as a therapeutic intervention for developmentally delayed embryos. With the information gained, we aim to develop strategies to assist overweight and obese patients with their fertility needs.

Trial registration number: not applicable

P-209 Artificial collapse of human expanded blastocysts protects the quality of embryos during vitrification/warming procedure

M. Karagianni[1], A. Papatheodorou[1], N. Christoforidis[2], A. Chatziparasidou[1]

[1]Embryolab, Embryology Lab, Thessaloniki, Greece ;
[2]Embryolab, Clinical department, Thessaloniki, Greece

Study question: Does artificial collapse of human blastocysts before vitrification affect the post warming quality of embryos and/or the reproductive outcome?

Summary answer: This study suggests that artificial collapse with laser pulse before vitrification significantly benefits blastocyst quality post-warming without improving reproductive outcome.

What is known already: The efficiency of vitrification of blastocysts can be influenced by various factors, such as the stage of the expansion and the quality of the embryos. Expanded blastocysts seem to be more sensitive and prone to cryo-injury during vitrification because of the large amount of blastocoelic fluid which may cause insufficient dehydration. Artificial collapse (AC) with micro-needles or with laser pulse can improve the vitrification procedure and protect the expanded blastocysts from cryoinjuries by reducing the fluid of the blastocoel.

Study design, size, duration: This prospective randomized study was performed at Embryolab Fertility Clinic, in Thessaloniki, Greece between July 2020 and November 2020 and included 94 ICSI treatments with no fresh embryo transfer. Patients with more than 4 blastocysts were randomized and allocated to the study (AC) group or control group. Randomization list was created by a computer-based program. The embryos were vitrified at the blastocyst stage and the best 1-2 embryos were transferred in a subsequent cycle.

Participants/materials, setting, methods: Patients were divided in two groups: AC group (n=46) where 1 or 2 best expanded blastocysts were artificially collapsed by a laser pulse before vitrification and control group (n=48) where the corresponding best expanded embryos remained untreated before vitrification. The embryos were graded according to Gardner's criteria and vitrified using open system. Quality of embryos, pregnancy rate and clinical pregnancy rate from the first warming cycle were the parameters that were analyzed using z-test.

Main results and the role of chance: The analyzed embryos were in total 171, 85 in the AC group and 86 in the control group. The day 5 embryos in each group were 6.89 (±3.41) and 6.50 (±3.38) and the number of embryos per embryo transfer was 1.85 (±0.36) and 1.79 (±0.41) respectively. Cryoinjury was determined as the presence of degenerated cell in ICM or TE. In the AC group cryo-injury was significantly lower than in the control group [31.11% with at least 1 embryo per embryo transfer and 52.08% respectively ($p=0.0356$), 6.67% with cryo-injury in both embryos and 14.58% respectively ($p<0.0001$), 8.89% with cryo-injury in ICM and 10.42% respectively ($p<0.0001$), 15.56% with cryo-injury in trophectoderm and 27.08% respectively ($p<0.0001$), and 6.67% with cryo-injury in both ICM and trophectoderm and 12.50% respectively ($p<0.0001$)]. Pregnancy rate (positive b-hcg) was not significantly different between the two groups (62.22% in AC group and 76.09% in control group, $p=0.1479$), nor was the clinical pregnancy rate (52.38% and 60.87% in AC and control group respectively, $p=0.4208$).

Limitations, reasons for caution: The number of cases included in this study was limited and the live birth rate was not yet available. More prospective randomized studies are needed in order to validate the benefit of artificial collapse before the vitrification procedure.

Wider implications of the findings: Laser artificial Collapse does not compromise expanded blastocyst quality, on the contrary it seems to reduce the amount of cryoinjury observed post warming. Whether it can improve the reproductive outcome, remains to be examined in larger scale studies.

Trial registration number: not applicable

P-210 Abnormal cleavage patterns during embryo preimplantation development and their effect on blastulation: an overview from IVF patients with multiple IVF cycles in a time-lapse incubator.

D. Cimadomo[1], F. Innocenti[1], D. Soscia[1], A. Giancani[1], R. Maggiulli[1], M. Stoppa[1], L. Dovere[1], L. Albricci[1], G. Fabozzi[1], E. Scepi[1], F. Chimienti[1], A. Capalbo[1], F.M. Ubaldi[1], L. Rienzi[1]

[1]GeneraLife IVF, Clinica Valle Giulia, Roma, Italy

Study question: How common abnormal cleavage patterns (ACP) are in IVF and what are their consequences on embryo developmental competence?

Summary answer: ACP might affect up to 25% of the 2PN-zygotes, independently from patients'/cycles' characteristics, and mostly cause embryo developmental arrest around the 4-to-8-cell transition.

What is known already: Since its implementation in IVF, time-lapse-microscopy (TLM) allowed the standardization of embryo culture within undisturbed incubators, but it has not improved embryo selection especially if blastocyst transfer is performed. Nevertheless, TLM holds the potential for boosting our knowledge of embryo preimplantation development. In particular, a continuous observation of embryo morpho-dynamics unveiled peculiar blastomere cleavage patterns previously unidentifiable with a static morphological assessment. These events are possibly associated with massive mitotic errors, affecting both chromosomes and cytoskeletal components, as well as downstream metabolic imbalances. Still, the causes of ACP and their consequences on embryo developmental/reproductive competence require further investigation.

Study design, size, duration: Observational study including 75 patients (age:38.6±3.7yr, FSH:8.8±3.6IU/l, AMH:1.7±1.3ng/ml; BMI:21.4±2.4) who conducted multiple IVF cycles (N=160; 8.7±5.0 cumulus-oocyte-complexes and 6.3±3.6 metaphase-II collected; 201±245 days between first and second cycles) in a time-lapse incubator between 2014-2020. All annotations were performed blindly by two operators and confirmed by a third in case of discordance. The outcomes were the blastulation rate after any ACP, their association between each other and with patients'/cycles' characteristics.

Participants/materials, setting, methods: We included only ICSI-cycles after ovarian-stimulation with blastocyst culture conducted in the Embryoscope. Overall, 981 metaphase-II were inseminated and 677 2PN-zygotes annotated. The ACP investigated were: (i)cytokinesis-failure, formation of cytoplasmic septa without cell division; (ii)Chaotic-cleavage, disordered and uneven cleavages; (iii) Direct-unequal-cleavage (DUC), cleavage of zygotes or single blastomeres directly into 3; (iv)Rapid-cleavage, t3-t2<5hr; (v)Reverse-cleavage, fusion of 2 blastomeres into 1; (vi)Fragmentation, presence of numerous non-nucleated fragments; (vii)Blastomeres' exclusion/extrusion, nucleated cells excluded/extruded from the morula.

Main results and the role of chance: Among the 2PN-zygotes, the prevalence of cytokinesis-failure was 5.9% (N=40/677), 15.7% for chaotic-cleavage (N=106/677), 18.6% for DUC (N=126/677), 4.1% for rapid-cleavage (N=28/677), 3.5% for reverse-cleavage (N=24/677) and 24.1% for fragmentation (N=163/677). Among the morulae, the prevalence of blastomere exclusion/extrusion was 27% (N=109/410;1.5±1.2 excluded/extruded cells,range:1-7). The risk for reverse-cleavage was higher among 2PN-zygotes facing failed-cytokinesis (N=8/40,20% versus N=16/637,2.5%, OR:9.7,95%CI:3.9-24.3,$p<0.01$). Fragmentation was instead higher among 2PN-zygotes undergoing chaotic cleavage (N=47/106,44.3% versus N=116/571,20.3%, OR:3.1,95%CI:2-4.8,$p<0.01$) or DUC (N=46/126,36.5% versus N=117/551,21.2%, OR:2.1,95%CI:1.4-3.2,$p<0.01$). Lastly, higher prevalence of blastomeres' exclusion/extrusion were reported among morulae obtained after chaotic-cleavage (N=17/29,58.6%

versus N=92/381,24.1%, OR:4.4,95%CI:2-9.7,p<0.01), DUC (N=26/37,70.3% versus N=83/373,22.3%, OR:8.3,95%CI:3.9-17.4,p<0.01) and in presence of fragmentation (N=79/195,75.2% versus N=30/305,9.8%, OR:27.8,95%CI:15.6-49.8,p<0.01); only a higher trend after rapid-/reverse-cleavage.

No predictive factor of ACP was identified among patients' and cycles' characteristics, except for higher risks of fragmentation (OR:2.6,95%CI:1.1-6.3,p=0.04) and blastomeres' exclusion/extrusion (OR:2.7,95%CI:1.1-7.2,p=0.04) among patients with previous experience with these events.

The viable-blastocyst rate per 2PN-zygote was 45.1% (N=305/677). It was lower in case of failed-cytokinesis (N=12/40,30% versus N=293/637,46%, OR:0.5,95%CI:0.25-0.99,p=0.05), chaotic cleavage (N=20/106,18.9% versus N=285/571,49.9%, OR:0.23,95%CI:0.14-0.39,p<0.01), DUC (N=27/126,21.4% versus N=278/551,50.5%, OR:0.27,95%CI:0.17-0.42,p<0.01), rapid-cleavage (N=6/22,21.4% versus N=299/649,46.1%, OR:0.32,95%CI:0.13-0.8,p=0.02), and reverse-cleavage (N=5/19,20.8% versus N=300/653,45.9%, OR:0.31, 95%CI:0.11-0.84,p=0.02). No difference was instead shown in case of fragmentation and/or blastomeres' exclusion/extrusion.

Limitations, reasons for caution: The patients included were poor-prognosis women undergoing ≥2 cycles. We are expanding the sample size to account for all cycles conducted in time-lapse incubators. Larger sample size will provide also statistical-power to investigate the effect of ACP on blastocysts' chromosomal and implantation competence, and more visualizations of rapid-/reverse-cleavage events.

Wider implications of the findings: After ACP,developmental-arrest mostly occurs around the 4-to-8-cell transition (50-70% versus ~30%), when embryonic-genome-activation takes place. Surviving embryos often fragment and/or exclude/extrude blastomeres at morulation, without further impact on blastulation-rates. Moreover, ACP seem independent from patients'/cycles' characteristics. These evidence incite future Research on the biological/genetic mechanisms triggering ACP and their consequences.

P-211 Double warming and double vitrification for euploid embryos does not affect implantation nor ongoing pregnancy rate

B. A. Hashimi[1]

[1]*London womens clinic, Embryology, London, United Kingdom*

Study question: Does exposure of embryos to double vitrification and double warming affect the chances of ongoing pregnancy for patients undergoing PGT-A and transfer euploid embryos?

Summary answer: Our analysis shows that there is no statistically significant difference in implantation or ongoing pregnancy rate between single or double vitrification/warming cycles.

What is known already: The use of PGT-A is increasing in the last years and progressively more patients opting in for this, in order to reduce time to pregnancy. Implantation failures prior to genetic testing or the incidence of no-result embryos post PGT-A are some of the scenarios that expose the embryos to multiple rounds of vitrification/warming cycles. The exact effect that such exposure has on embryos is still to be investigated and confirmed as to whether it affects the outcome (i.e. implantation/ongoing pregnancy rate) or the future health of the child.

Study design, size, duration: Our analysis is a retrospective observation study of data collected from 151 consecutive frozen euploid embryo transfers (FET). These were performed at a single centre between January-December 2020. Two groups were created for this study. The first group includes euploid embryos that were transferred post being exposed to single vitrification/warming (n=126). In the second group euploid embryos were exposed twice to vitrification/warming (n=25). Statistical analysis using chi-square test and statistical significance was calculated when p≤0.05.

Participants/materials, setting, methods: Blastocysts from 151 patients were split into two groups based on the number of vitrification/warming cycles that they underwent prior to FET. The first group includes embryos that were subjected to trophectoderm biopsy and were then vitrified (n= 126). The second group includes embryos that were initially vitrified without undergoing PGT-A analysis. Following implantation failures, their remaining embryos were warmed, biopsied and re-vitrified. Post PGT-A analysis euploid embryos were then re-warmed and transferred (n= 25).

Main results and the role of chance: For the first group (A), 450 blastocysts (day 5-7) were subjected to trophectoderm biopsy, where 5-cells taken, and embryos were then vitrified. Post PGT-A analysis 260 euploid embryos identified. From them 126 embryos transferred in frozen replacement cycles, where the mean embryo age for the group was 36.1±4.2. The grade of embryos transferred were of 4BC or better based on Gardner's grading system. The implantation and ongoing pregnancy rate for this group was 62%.

For the second group (B), 101 blastocysts (day 5-7) warmed, in order to undergo trophectoderm biopsy and were then re-vitrified. Post PGT-A analysis 49 euploid embryos identified. From them, 25 embryos transferred in frozen replacement cycles, where the mean maternal age for the group was 35.05±5.2. The grade of embryos transferred were of similar quality to group A. The implantation and ongoing pregnancy rate for this group was 64%.

Statistical analysis confirmed that there is no statistical difference between the groups (p=0.74).

In addition, 60% of patients (n=5) who had double vitrification, double biopsy and double warming have ongoing pregnancy.

In conclusion, for transferrable quality euploid blastocysts, double vitrification has comparable reproductive outcomes as in single vitrification, thereby supporting the efficacy of double vitrification/warming when necessary.

Limitations, reasons for caution: This study uses a small sample size of patients. The data are observational and were retrospectively analysed so unknown confounders could not be assessed. The addition of more cycles and further multivariate analysis, including the child's health is essential for confirmation of the findings. However, initial results are very reassuring.

Wider implications of the findings: Our study has implications for clinical practice and patient counselling. Especially in patients that they choose to undergo PGT-A with pre-vitrified embryos post implantation failures with non PGT-A tested embryos.

Trial registration number: N/A

P-212 Mitochondrial DNA content shows a significant association with timing of human embryo development and fertility diagnosis in euploid embryos

C. Hur[1], **V. Nanavaty**[1], **A. Chehab**[1], **M. Yao**[2], **N. Desai**[1]

[1]*Cleveland Clinic Foundation, Women's Health Institute, Beachwood, U.S.A. ;*
[2]*Cleveland Clinic Foundation, Quantitative Health Sciences, Cleveland, U.S.A.*

Study question: Does mitochondrial DNA content (mtDNA) correlate with clinical parameters and embryo morphokinetics using advanced time-lapse technology?

Summary answer: mtDNA correlated with embryo morphokinetics and the growth trajectory of euploid embryos. Maternal age, anti-mullerian hormone level and fertility diagnosis were significantly associated with mtDNA.

What is known already: With the push towards single embryo transfers, laboratories are working to improve embryo selection. In addition to conventional microscopy, preimplantation genetic testing and time-lapse microscopy have been utilized to aid in embryo selection. More recently, as mtDNA may represent the energy potential of an embryo, some data have supported the use of mtDNA as an additional tool. Limited studies have suggested that a lower amount of mtDNA is associated with higher rates of implantation and improved embryo quality.

Study design, size, duration: This is a retrospective chart review. All embryos that underwent preimplantation genetic testing for aneuploidy (PGT-A) between January to December of 2020 were studied.

Participants/materials, setting, methods: Women undergoing in vitro fertilization (IVF) with intracytoplasmic sperm injection undergoing PGT-A were studied. All patients were from a single academic institution. This study exclusively examined the characteristics of euploid embryos. Mitochondrial DNA content was expressed as a ratio of mtDNA:nDNA (MitoScore). Time-lapse imaging was utilized to evaluate embryo development every 15 minutes in 5-7 focal planes. Chi square test and Spearman correlation analysis were performed with a p-value of <0.05 considered significant.

Main results and the role of chance: A total of 494 embryos from 52 women who underwent 58 IVF cycles were cultured to blastocyst and 331 embryos were biopsied for PGT-A evaluation. Of these, 132 embryos were diagnosed as euploid. A moderate positive correlation was found between MitoScore and time to morula, time to blast and time to expanded blast (correlation value 0.54, 0.50 and 0.54, respectively; p<0.001). Consistent with this trend, day 5 blastocysts had a significantly lower MitoScore values than day 6

blastocysts (20.2 v. 29.2; p<0.001). When examining all biopsied euploid embryos, no significant association was found between MitoScore, blastocyst maturity, trophectoderm or inner cell mass scores.

Our data also demonstrated a positive correlation between MitoScore and maternal age (correlation factor 0.33; p<0.001). A negative association between MitoScore and serum anti-mullerian hormone levels (correlation factor -0.20; p<0.021) was also noted. Of particular interest was the significant association between fertility diagnosis and mitochondrial score (p<0.001).

Even amongst euploid embryos, mtDNA content varied widely, potentially reflecting differences in embryo potential and quality. Additionally, the significant difference in MitoScore between that day 5 and day 6 blastocysts may reflect a fundamental difference in cytoplasmic characteristics and requires further study.

Limitations, reasons for caution: Due to the study cohort of euploid embryos undergoing PGT-A, this study was biased for the selection of high grade embryos. This limited diversity in embryo quality may have masked other potential associations between mitochondrial content and blastocyst quality.

Wider implications of the findings: mtDNA may be additional tool aiding in embryo selection as IVF labs work to improve pregnancy rates while minimizing the risks of transferring multiple embryos. To our knowledge, this is the largest study assessing the relationship of mtDNA content of blastocysts and the timing of embryo development using time-lapse imaging.

Trial registration number: None

P-213 Comparative optical analysis of spindle reformation after oocyte vitrification with media containing differing basal formulations

U.S. Braun[1], L. Watson[2], M. VerMilyea[3]

[1]Ovation Fertility, Embryology, Bryan, U.S.A. ; [2]Fujifim Irvine Scientific, Research and Development, Austin- TX, U.S.A. ; [3]Ovation Fertility, Embryology, Austin- TX, U.S.A.

Study question: Do the base ingredients and total composition of vitrification media have an effect on meiotic spindle reformation in warmed donor oocytes?

Summary answer: Meiotic spindle reformation occurs more readily in donor oocytes vitrified and warmed with a contemporary culture media based vitrification formulation than in traditional vitrification media.

What is known already: Embryo culture trends continue towards more freeze-all cycles and oocyte preservation is becoming more prevalent across all age groups, thus vitrification continues to serve a pivotal role in today's laboratory; however, the formulation of vitrification media remains largely unchanged from the m199 or mHTF base composition of antiquated slow freeze media. Literature identifies temperature as a key determiner in spindle reformation. Our preliminary data utilizing a robust vitrification medium with a basal formulation specifically designed for human embryo growth demonstrates a pronounced positive effect on oocytes post-warm in regard to spindle recovery time.

Study design, size, duration: In a prospective study, 30 oocytes obtained from a diverse population of 10 oocyte donors donating to an egg bank were imaged prior to vitrification to identify the meiotic spindle using the Oosight Imaging System (Hamilton Thorne). Donor oocytes were then split between two vitrification media groups, Vitrification Kit NX (FujiFilm Irvine Scientific) and Vitrification Media (Kitazato USA). After warming, oocytes were again imaged at various time points and meiotic spindle retardance was noted.

Participants/materials, setting, methods: Oocytes from approved egg bank donors were imaged, vitrified and warmed using protocols recommended by the manufacturers. The oocyte donors were all cycled and retrieved in the same private IVF Clinic and Laboratory between October 2019 and February 2020. Temperature of media, culture dishes, incubators and work stations were all monitored and maintained. Retrieved oocytes were imaged prior to vitrification. Oocytes were imaged immediately upon warm, and at 1 and 3 hours post warm.

Main results and the role of chance: Oocyte survival was similar across the two media groups, with Vitrification Kit NX at 86.7% and Vitrification Media at 80.0% survival. 100% of the degenerated oocytes in Vitrification Kit NX did not display an initial meiotic spindle when imaged prior to vitrification as opposed to 67% of the degenerate oocytes in Vitrification Media. Upon warming, immediate imaging showed oocytes from Vitrification Kit NX displayed a spindle at a rate of 41.7%, while Vitrification Media allowed this in 0% of the oocytes. At 1-hour post warm, Vitrification Kit NX and Vitrification Media displayed meiotic spindles in 83.3% and 22.2% of oocytes, respectively. The final time point was imaged at 3-hours post warm and showed meiotic spindle reformation in 91.7% of Vitrification Kit NX oocytes and 66.7% of Vitrification Media oocytes. While none of the time points imaged show significance, there is a defined trend towards a faster rate of meiotic spindle recovery in vitrification media formulated with a more modern culture media base.

Limitations, reasons for caution: The preliminary findings of this study offer that the composition and formulation of the vitrification medium perhaps do have an effect on the reformation of the meiotic spindle post-warm; however, more information is needed and a larger population size must be examined prior to discerning any significance.

Wider implications of the findings: If, through further study and imaging, it is ascertained that meiotic spindle reformation is determined in part by the vitrification media composition, it could lead to potentially healthier warmed oocytes for the patient and less workload and scheduling stress on the embryologists due to shorter wait times prior to ICSI.

Trial registration number: not applicable

P-214 Effect of artificial activation of oocytes (AOA-ICSI) on the ploidy status of the resultant blastocysts. A sibling-oocytes pilot study

E. Seo. Pe. Yin[1]

[1]Kesuburan Sentosa Sdn Bhd IVF Bridge Fertility Center, Embryology Lab, Johor Bahru- Johor, Malaysia

Study question: Will artificial activation of oocytes alter the ploidy status of the resultant blastocysts? A sibling-oocytes pilot study
