Abstracts

35th Annual Meeting of the
European Society of
Human Reproduction and Embryology,
Vienna, Austria
24 to 26 June 2019

The abstracts are available on-line to all Human Reproduction/Update/Molecular Human Reproduction subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals.org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference.

The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers.

Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results.

The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers, but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

INVITED SESSION

SESSION 01: KEYNOTE SESSION

Monday 24 June 2019 Mozart 08:30 - 09:30

O-001 Human Reproduction keynote lecture - Pre- and early pregnancy diet is associated with fertility and health in pregnancy

O-002 Gene editing - past, present and future

B. Davies[1]

[1]*University of Oxford, Wellcome Centre for Human Genetics, Oxford, United Kingdom*

Abstract text Over the past two decades, enzymes capable of cleaving chromosomal DNA at specific sequences have been developed and refined, with, most recently, the CRISPR/Cas family of enzymes drawing considerable interest due to their high efficiency and ease of use. The discovery of these enzymes and their successful application in mammalian cells has led to the emergence of the new technique of gene editing, whereby specific DNA sequences can be mutated, removed or inserted at will. This exciting technology is already transforming biomedical preclinical research and significant progress is being made in its therapeutic application for disease correction in somatic tissues and stem cells. These gene editing tools have been shown to function efficiently in the early embryo, and a number of proof-of-concept studies have demonstrated that the technology can be used for the correction of genetic mutations in the human embryo. Considerable ethical concerns surround the use of these technologies for germline editing and the need for an informed societal debate on the implications of these new technologies is acute. However, there exists a large knowledge gap in the understanding of scientists, clinicians, patient groups and the general public concerning the feasibility and associated risks of the new technology.

Drawing on my own experience with gene editing in mouse embryos, this session will outline how the different tools work and present different techniques for their application in the preimplantation embryo. Importantly, I will also introduce and present examples of the disadvantageous aspects of gene editing technology which currently limit the safety and feasibility of germline editing. Lastly, I will also discuss new developments in the field which are tackling some of the unpredictable consequences of gene editing techniques.

SELECTED ORAL COMMUNICATIONS

SESSION 02: NOVEL APPROACHES FOR PREDICTING EMBRYO VIABILITY

Monday 24 June 2019 Mozart 10:00 - 11:30

O-003 Mapping the follicular fluid bio-molecular profile: Dynamic interactions set the algorithm for oocyte maturation, embryo development and successful outcomes in IVF cycles

N. Chimote[1], **B. Chimote**[2]

[1]*Vaunshdhara Fertility Centre, Embryology & Reproductive Endocrinology, Nagpur, India ;*

[2]*Vaunshdhara Fertility Centre, Embryology- Reproductive Endocrinology, Nagpur, India*

Study question: To evaluate bio-molecular components in follicular-fluid and assess if they share dynamic correlationships to influence embryo development and pregnancy outcomes in IVF cycles

Summary answer: Evaluated biomolecular components in follicular-fluid correlate with individual embryonic parameters and also interact dynamically to set the algorithm for successful outcomes in IVF cycles

What is known already: The molecular mechanisms controlling endometrial-receptivity have remained an enigma because apart from the ovarian steroids estrogen and progesterone, cyclical remodeling of endometrium is also regulated at paracrine level by myriad growth-factors, cytokines and proteases. Hence, no factor has yet univocally been established as a predictive-marker. We envisaged that 'follicle-maturation' is the rate-determining step that sets off a cascade mechanism triggering oocyte-maturation, fertilization, embryo development, implantation, pregnancy. Therefore, we attempted the holistic approach of profiling representative biomarkers in the follicular-fluid microenvironment to not just obtain thresholds of individual biomarkers but also to assess if they share systematic correlations predictive of pregnancy-outcome.

Study design, size, duration: Prospective study of n=1150 (Power of study >85%) women (mean age 30.22±4.25 years, BMI 23.97±4.53, W/H ratio 0.88±0.06) undergoing antagonist stimulation protocol with r-FSH for IVF (September 2015-December 2018). On day of ovum pick-up, original aspirate per follicle was pooled per patient. Biomolecules like AMH, E_2, DHEAS, IGF-1, PAI-1, G-CSF and GM-CSF were evaluated in pooled FF by radioimmunoassay/ELISA as applicable, using diagnostic kits. Each protein-biomolecule was expressed as a ratio of total protein content.

Participants/materials, setting, methods: Elderly women (age>35 years), women with polycystic-ovaries, endometriosis were excluded. Embryo-transfer (ET) was done either at Day3-cleavage stage or day5 blastocyst stage. Micronized progesterone was provided as luteal-phase support. All cycles were divided into low, high groups to study correlation of each FF-biomarker with individual embryonic parameters. All cycles were later divided into pregnant and non-pregnant groups to study biomarker inter-relations and their correlation with pregnancy. Clinical pregnancy, live birth rate were main outcome measures.

Main results and the role of chance: FF-AMH correlated with oocyte-quality (Pearsonr=0.48); lower-levels increased the odds of top-quality oocytes. FF-PAI-1 correlated with oocyte-maturity (Pearsonr=0.51), lower-levels increased the odds of obtaining MII-oocytes. FF-DHEAS correlated with fertilization (Pearsonr=0.39); higher-levels increased the odds of fertilization. FF-IGF-1 correlated with embryo-quality (Pearsonr=0.40); higher-levels increased the odds of top-quality embryos. FF-GCSF and FF-GMCSF correlated with embryo quality (Pearsonr= 0.36 and 0.45).

Thresholds of FF-biomarkers for clinical pregnancy/live-births were: FF-AMH (<1.8 ng/mg protein;ROC_{AUC}:85%); FF-PAI-1 (<504.4 ng/mg protein;ROC_{AUC}:76%); FF-DHEAS (>1850ng/ml;ROC_{AUC}:69%); FF-E_2 (>160000 pg/ml;ROC_{AUC}:69%); FF-IGF-1 (>60ng/mg protein;ROC_{AUC}:78%).

FF-AMH showed strong positive correlation with FF-PAI-1 (Pearsonr=0.66) whereas these both inversely correlated with FF-E_2 (Pearsonr= -0.43; Pearsonr= -0.046) and FF-IGF-1 (Pearsonr= -0.27; ns). FF-DHEAS and FF-IGF-1 shared strong positive correlation with FF-E_2 (Pearsonr= 0.43 and Pearsonr=0.58). FF-IGF-1 directly correlated with FF-GCSF (Pearsonr=0.31) and FF-GMCSF (Pearsonr=0.36).

FF-AMH and FF-PAI-1 inversely correlated with serum E_2 on day7 (Pearsonr= -0.62; Pearsonr= -0.42) and day14 (Pearsonr= -0.66; Pearson r= -0.50) as well as serum progesterone on day7 (Pearsonr= -0.51; Pearsonr= -0.68) and day14 (Pearsonr= -0.63; Pearsonr= -0.80) post embryo-transfer. The likelihood of live-birth was highest when all biomarkers maintained their algorithmic thresholds; major deviations from threshold values of any parameter increased the odds of no-pregnancy, biochemical pregnancy, early pregnancy loss or miscarriage.

Limitations, reasons for caution: Several yet unknown factors are presumably involved in the implantation process. This study represents just a few biomarkers present in follicular- fluid, their individual significance, their interrelationships and eventually their co-relationship with pregnancy outcome. Multi-centric systematic studies are needed to corroborate these findings and account for the probable confounding factors.

Wider implications of the findings: Follicular-fluid is a metabolite reservoir, a medium for exchange of biologically active components responsible for follicular/oocyte growth, fertilization and embryonic development. Our results suggest that the dynamic interactions (probably initiated by AMH) within this micro-environment set off an algorithmic cascade for embryo-development, further triggering a receptive endometrium conducive for pregnancy.

Trial registration number: Not applicable

O-004 Artificial intelligence (AI) technology can predict human embryo viability across multiple laboratories with varying demographics with high accuracy and reproducibility.

Study question: Can artificial intelligence (AI) and computer vision provide improvement to embryo viability prediction using static 2D images of Day 5 embryos from multiple laboratories?

Summary answer: The development of a general AI model produced 32% improvement in accuracy regarding embryo viability assessment compared to traditional embryologist morphology assessment.

What is known already: Recent studies have shown that artificial intelligence (deep learning) and computer vision can increase the efficacy of embryo selection and prediction of clinical pregnancy using images of human embryos. This automated, non-invasive approach to embryo selection can be used as a cohort ranking tool whereby embryos with certain morphological features are ranked in order of their likelihood to result in a positive pregnancy with a fetal heartbeat. A validation study of the current AI model using ~5000 images of Day 5 blastocysts resulted in an accuracy of 67.7% in identifying embryo viability by positive fetal heartbeat across two blind datasets.

Study design, size, duration: Approximately 20,000 static 2D images of Day 5 blastocysts with related pregnancy, pre-implantation genetic testing for aneuploidy (PGT-A) outcomes, demographic and clinic geographical location information have been collected. Images were divided into three groups: training, validation and blind test sets. An AI model was trained, validated and tested on 2217 embryo images from Day 5 blastocysts followed by a further blind set of 286 images from a separate clinic and demographic.

Participants/materials, setting, methods: 7,847 separate traditional phase-contrast microscope images from patients undergoing fertility treatment at 12 IVF laboratories in four countries were used to train and develop the Life Whisperer's embryo viability assessment model (LW General Model v1). Images of Day 5 blastocysts which had a blastocoel cavity and were subsequently transferred individually were used for this study. This study was determined exempt from IRB review by Sterling IRB, USA (#6467).

Main results and the role of chance: 5282 images from Monash IVF Group (Repromed, Adelaide, SA, Australia) were split into training (~74%), validation (~7%) and two blind validation (~19%) datasets. A blind validation data set is used to conduct an unbiased accuracy assessment to ensure the model is generalizable to all embryo images. The accuracy in identifying viable embryos is calculated as a percentage of the number of viable embryos (i.e. blastocysts that resulted in a successful pregnancy) identified by the AI model divided by the total number of viable embryos in the dataset. The same process applies to non-viable embryos.

The total mean accuracy of the embryo viability assessment model when applied to both blind validation datasets was 74.1% for identifying viable embryos, 65.3% non-viable embryos and 67.7% total accuracy across both viable and non-viable embryos. When comparing the accuracy in identifying viable/non-viable embryos for the model versus world-leading embryologists, the AI model correctly identified embryo viability 66.7% compared to 51.0% by embryologists.

After subsequent training on a mixed demographic dataset, a blind test of 74 images from three independent laboratories (Ovation Fertility Austin, San Antonio and Indianapolis), resulted in the model correctly identifying viable embryos at 84.6%, non-viable at 57.1% and total accuracy at 71.6%.

Limitations, reasons for caution: While the analysis of the blind validation datasets is small, our results provide evidence that AI can reduce the variability of morphological embryo selection across multiple laboratories and embryologists. Additional training on larger datasets is currently ongoing to further improve the generalizability of the AI model.

Wider implications of the findings: Embryo selection is heavily based on morphological/morphokentetic assessment and other invasive technologies including embryo biopsy for embryo ploidy classification. For the first time, this data represents how an AI model can be applied across a multi-centered, mixed demographic dataset resulting in ~70% overall accuracy for viable and non-viable embryo identification.

Not Applicable

O-005 The presence of filopodia in human blastocysts is associated with the probability of clinical pregnancy with fetal heart.

J. Eastick[1], S. Cooke[2], C. Venetis[3], M. Chapman[4]

[1] *IVFAustralia, Embryology, New Lambton Heights, Australia ;*
[2] *IVFAustralia, Scientific Director, Greenwich, Australia ;*
[3] *IVFAustralia, Clinical, Greenwich, Australia ;*
[4] *IVFAustralia, Clinical, Greemwich, Australia*

Study question: The aim was to determine if the presence of filopodia in human blastocysts is associated with probability of clinical pregnancy with fetal heart after transfer.

Summary answer: The presence of filopodia in human blastocysts is associated with the probability of clinical pregnancy with fetal heart after transfer.

What is known already: Filopodia have been described as "string like" structures that connect the inner cell mass to the trophectoderm cells and have been hypothesised to be a communication network. In human embryos, their presence past the expansion stage has been suggested to be negatively

associated with the implantation potential of blastocysts. Using time-lapse image analysis, the filopodia can now be seen and accurately categorised, and artificial intelligence has been shown to be an accurate method of predicting clinical pregnancy with fetal heart beat (CPFH).

Study design, size, duration: This was a two-centre case-control study performed between February 2018 and December 2018. The study involved 200 single blastocyst transfers from 181 women undergoing both IVF and ICSI utilising fresh oocytes. 100 of these resulted in a CPFH (cases) while 100 did not (controls). All embryos had been cultured in Embryoscope+ post-insemination and until day 5.

Participants/materials, setting, methods:
Inseminated zygotes were placed into Embryoscope+ for culture until day 5. The presence of filopodia was examined after the transfer for each blastocyst, by an assessor blind to the outcome of the transfer who reviewed the time-lapse video. AI software (Ivy) was also applied to the entire fertilised cohort to identify the blastocyst for transfer with the highest CPFH probability. Generalized estimating equation was used for analysis to control for the clustered nature of data.

Main results and the role of chance:
A blastocyst which resulted in CPFH after transfer, compared to the controls, had a higher chance of having a filopodia (Odds ratio-OR: 3.34, 95% CI:1.28-8.74). Furthermore, the filopodia seemed to be present for longer (12.2hrs vs 10.6hrs; P=0.035) and in the ultrastructure of the filopodia, more vesicles were seen travelling along the filopodia (4.6 vs 3.7; P=0.006) in blastocysts resulting in CPFH as compared to those that did not. The filopodia presence, appearance length and ultrastructure vesicles has not been reported to be linked to positive CPFH previously.

Limitations, reasons for caution:
The Embryoscope+ only allows 11 focal planes to view the embryos thus the possibility exists for underrepresentation of the filopodia. Results whilst interesting, should be confirmed in larger prospective studies.

Wider implications of the findings:
With modern time-lapse incubators allowing viewing and timing of blastocyst ultrastructure in multiple focal planes, its logical that new methods of assessing embryos are expected. The study of filopodia represents an ultrastructure marker that can aid in the identification of blastocysts with the highest potential to produce a clinical pregnancy.

Trial registration number:
not applicable

O-006 Time of morulation and trophectoderm quality are associated with live birth after euploid blastocyst transfer: a multicenter study

L.F. Rienzi[1], D. Cimadomo[1], A. Delgado[2], M.G. Minasi[3], G. Fabozzi[1], R. Del Gallego[2], M. Stoppa[1], J. Bellver[2], A. Giancani[1], M. Esbert[4], A. Capalbo[5], J. Remohì[2], E. Greco[3], F.M. Ubaldi[1], M. Meseguer[2]

[2]*IVI-RMA, IVI-Valencia, Valencia, Spain*
[3]*European Hospital, Center for reproductive medicine, Rome, Italy*
[4]*IVI-RMA, IVI-Barcelona, Barcelona, Spain*
[5]*Igenomix, Igenomix Italia, Marostica, Italy*

Study question: Does the morphodynamic characterization of human euploid blastocysts' preimplantation development increase the prognostic value upon their reproductive competence?

Summary answer: Time of morulation (tM) and trophectoderm (TE) quality after blastulation (tB) increase the prediction upon euploid blastocysts' chance to result in a live birth (LB).

What is known already: To date, the definition of a normal chromosomal constitution through comprehensive-chromosome-testing represents a powerful predictive parameter upon blastocyst's reproductive potential. However, more than 40-50% of euploid blastocysts fail to implant. The assessment of preimplantation embryo development via time-lapse has been broadly investigated to find a possible correlation between morphokinetic parameters and the clinical outcomes after IVF. Although, some conflicting data and limited evidence have been shown. The predictive value of morphokinetics during IVF cycles including preimplantation-genetic-testing of aneuploidies (PGT-A) has been instead limitedly investigated, and therefore needs further assessment.

Study design, size, duration: In Phase1, 511 first single embryo transfers (SETs) of vitrified-warmed euploid blastocysts (N=147 center1; N=364 center2; training set) from 1069 PGT-A cycles between January-2016 and September-2017 were retrospectively recruited. A predictive model of LB was defined. In Phase2, this model was tested in a validation set including 319 consecutive SETs from 546 PGT-A cycle performed between September-2017 and June-2018 in 3 IVF centers. The ongoing pregnancy rate (OPR) was defined as primary outcome.

Participants/materials, setting, methods: Only cycles conducted through continuous media in time-lapse incubator were included. In Phase1, all timings of development up to tSB (starting-blastulation) were compared among implanted and non-implanted euploid blastocysts. Static assessment of TE and inner cell mass (ICM) at tB was also performed. Logistic regressions outlined the parameters associated with LB. The model was applied to the validation set in Phase2 and its predictivity estimated through Receiver operating characteristic (ROC) curve analysis.

Main results and the role of chance: The average LB rate after euploid SET in Phase1 was 40%, consistent at both centers. The euploid blastocysts resulting in a LB at both centers showed a concordant significantly faster development than non-implanted/miscarried ones for tPB2, t4, t5, t8, s3, cc3, tM and tSB. Similarly, a high-quality ICM and the TE at tB were concordant as positively associated with a LB. However, the multivariate logistic regression outlined only tM and TE quality as putative predictors. Therefore, we defined 80hr as the cut-off tM, corresponding to the 50th percentile of prediction of a LB after vitrified-warmed SET in the training set. A model was then created based on TE quality (high or low) and tM (<80hr or ≥80hr), which showed a significant AUC of 0.65 from the ROC curve analysis. The predictive model was validated on an independent dataset composed of 319 euploid SETs from 3 different IVF centers. The euploid blastocysts characterized by a high-quality TE at tB and a tM <80hr resulted in an OPR of 61.2% (N=41/67), while those with low-quality TE at tB and a tM≥80hr resulted in an OPR of 30.0% (N=15/50; p<0.01). However, the ROC curve showed a poorly clinically-significant AUC of 0.59.

Limitations, reasons for caution: This model is limited to euploid blastocysts produced from a population of patients indicated to PGT-A and cultured in continuous media with oxygen control in time-lapse incubators. Moreover, time-lapse timings beyond tSB were not accounted due to different blastocyst biopsy approaches adopted, namely with and without zona-opening in day3.

Wider implications of the findings: The reproducibility of predictive models based on time-lapse parameters is highly dependent on culture conditions, that must be consistent. Moreover, these data by shedding light on the time of morulation, incite future investigations of this crucial phase of preimplantation development. A stage entailing massive morphological, cellular and molecular changes.

Trial registration number: None.

O-007 Dynamic and cytological analyses of pronuclei and centrosome positions in relation to the first cleavage plane in human embryos

M. Nakaoka[1], K. Yumoto[1], T. Shimura[1], Y. Mio[1]

[1]*Mio Fertility Clinic, Reproductive Centre, Yonago, Japan*

Study question: How are the pronuclear axis and the positions of centrosomes related to determination of the first cleavage plane?

Summary answer: The pronuclear axis is involved in determining the first cleavage plane and is related to the positions of centrosomes, which subsequently become mitotic spindle poles.

What is known already: Several studies have investigated how the site of the second polar body affects plane formation during the first cleavage, with suggestions that the second polar body position defines the first cleavage plane in human embryos. However, these ideas are controversial. Recently, time-lapse monitoring has been used to monitor and analyze early-stage embryonic development in a clinical setting. By using time-lapse monitoring, we previously obtained data which suggested that both the axis and locations of male and female pronuclei are involved in determining the first embryonic cleavage plane, and thereby affect further development.

Study design, size, duration: From January to December 2015, we conducted time-lapse imaging (EmbryoScope®) of 1062 cultured oocytes from infertile couples after intracytoplasmic sperm injection (ICSI). Of these oocytes, 798 were normally fertilized, showing male and female pronuclei (2PN), and we analyzed 607 embryos that formed the first cleavage plane and developed to the two-cell stage. Furthermore, seven frozen/thawed 2PN zygotes, donated by patients who had completed treatment and given informed consent, were used for immunofluorescence analysis.

Participants/materials, setting, methods: A straight line connecting the centers of the pronuclei was defined as the 2PN axis. ICSI oocytes were cultured in an EmbryoScope®, with images acquired every 15 minutes for 40 hours. Immunofluorescence analysis of centrosomes and nuclear membranes of 2PN zygotes was performed using a rabbit polyclonal anti-pericentrin antibody and a goat polyclonal anti-lamin B antibody. Images were obtained using an FV1000 laser scanning confocal microscope (Olympus).

Main results and the role of chance: We obtained suitable images from 476 out of 607 analyzed embryos. Of these, 427 (89.7%) formed a cleavage furrow parallel to the 2PN axis at the first cleavage, while the remaining 49 formed a cleavage furrow perpendicular to the 2PN axis. In the 2PN zygotes, we identified centrosomes and nuclear *membranes* using anti-pericentrin and anti-lamin B antibodies, respectively. We confirmed the presence of two pericentrin signals in all seven 2PN zygotes. Six of the zygotes showed two pericentrin signals aligned around the interface between the male and female pronuclei, and the angle between the line connecting the two centrosomes and 2PN axis ranged from 90 to 110 degrees. The remaining zygote showed two pericentrin signals; one was located around the interface between the male and female pronuclei while the other was distinctly distant from the interface of the two pronuclei. In addition, the angle between the line connecting the two centrosomes and the 2PN axis of this zygote was about 170 degrees. This irregular positioning of centrosomes might be the reason for some embryos forming a cleavage furrow perpendicular to the 2PN axis.

Limitations, reasons for caution: Although the sample size for immunofluorescence analysis in this study was small, it was extremely difficult to collect the human zygotes for ethical reasons. Further studies, including analysis of centrosome dynamics by live-cell imaging, may help define the mechanisms that underlie determination of the first cleavage plane in human embryos.

Wider implications of the findings: Our findings suggest that the 2PN axis strongly influences the positions of the centrosomes, which become mitotic spindle poles and define the first cleavage plane. Furthermore, aberrant centrosome positioning in relation to the 2PN axis might cause some embryos to form the first cleavage furrow perpendicular to the 2PN axis.

Trial registration number: not applicable

O-008 First polar body fragmentation is not a marker of in vitro oocyte aging and does not affect embryo quality nor cumulative livebirth rates

M. Carvalho[1], S. Mota[1], F. Leal[1], I. Pereira[1], C. Rodrigues[1], A. Aguiar[1], S. Sousa[1], J. Nunes[1], C. Calhaz-Jorge[1]

[1]Reproductive Medicine Unit - Hospital de Santa Maria- Lisboa, Department of Obstetrics- Gynaecology and Reproductive Medicine, Lisboa, Portugal

Study question: Is first polar body (IPB) fragmentation a consequence of an increased time between oocyte retrieval and injection and does it compromise ICSI outcome?

Summary answer: IPB fragmentation is unrelated with in vitro oocyte aging and its occurrence does not affect fertilisation, embryo quality or cumulative livebirth rates.

What is known already: The IPB is a byproduct of oocyte meiotic division that degenerates up to 24h following its formation. Traditionally, the presence of a fragmented IPB is considered a morphological indicator of postovulatory in vitro aging, deterioration and impaired developmental potential, with previous studies suggesting that it may be associated with hindered embryo development and decrease both implantation and pregnancy rates. However, these results derive from studies with small sample sizes and do not ascertain whether IPB fragmentation is a reliable time-dependent marker of overmaturity of the oocyte at the time of ICSI.

Study design, size, duration: Retrospective cohort analysis of 1175 ICSI cycles performed between 2007 and 2017. Only metaphase II oocytes at the time of denudation were considered and categorized according to whether they presented an intact or fragmented IPB at the time of injection. We evaluated the effect of increasing time between oocyte retrieval and ICSI on the incidence of IPB fragmentation, as well as the prognostic value of IPB fragmentation on fertilisation, embryo quality and cumulative livebirth rates.

Participants/materials, setting, methods: Multivariable multilevel mixed-effects regression was performed to account for relevant potential confounding factors and the clustering of oocytes derived from the same treatment cycle. Adjusted odds-ratios (aORs) with 95% confidence intervals (CIs) were calculated for each variable included in the regression models. Timing between oocyte retrieval and injection was exclusively dependent on laboratory workload and the best quality embryos were selected for transfer regardless of IPB morphology.

Main results and the role of chance: IPB fragmentation was identified in 47.9% of the oocytes, with up to 85% of the cycles having at least one oocyte with this feature. The mean time elapsed between oocyte retrieval and injection was 5.6h ± 0.8h and the occurrence of IPB fragmentation was unrelated to this time interval (aOR 1.001, 95% CI 0.999-1.002). Female age, body mass index, smoking habits, stimulation regimen or total number of oocytes retrieved were unrelated with the occurrence of IPB fragmentation. However, multivariable regression model showed that higher dosages of exogenous FSH (aOR per each 100 IU 1.014, 95% CI 1.003-1.522) was associated with a higher risk of IPB fragmentation, as well as the use of recombinant FSH (aOR 1.242, 95% CI 1.014-1.522). IPB fragmentation did not affect fertilisation rates (aOR 0.918, 95% CI 0.824-1.022) nor did it affect embryo quality (aOR 0.992, 95% CI 0.786-1.251). Most importantly, our results did not support an association between the presence of IPB fragmentation and clinical pregnancy (aOR 0.919, 95% CI 0.551-1.533), miscarriage (aOR 1.230, 95% CI 0.516-2.930), livebirth (aOR 0.906, 95% CI 0.553-1,483) or cumulative livebirth (aOR 0.958, 95% CI 0.685-1.568) rates, which were 38.2%, 17.4%, 31.1% and 32.6%, respectively.

Limitations, reasons for caution: This study is limited by its retrospective nature and the restriction of our patient population to women who are entitled to treatment reimbursement according to national legislation (<40 years old). For that reason, a possible effect of more advanced maternal ages in the occurrence of IPB fragmentation cannot be excluded.

Wider implications of the findings: Being the largest study evaluating the clinical relevance of IPB fragmentation, our analysis provides evidence that this morphological feature is not a reflection of in vitro aging nor is it a relevant predictive marker of embryo implantation potential, thus providing reassurance when rescheduling injection timings according to laboratory workload.

Trial registration number: Not applicable.

O-009 Antimullerian Hormone as a driving force of PCOS, independently from insulin-resistance

G. Robin[1], M. Deknuydt[1], A.L. Barbotin[2], P. Pigny[3], S. Catteau-Jonard[1], D. Dewailly[1]

[1]Lille University Hospital, Reproductive Endocrinology Unit, Lille, France
[2]Lille University Hospital, Reproductive Biology Unit, Lille, France
[3]Lille University Hospital, Hormonology laboratory, Lille, France

Study question: In women with Polycystic Ovarian Syndrome (PCOS), do high serum Anti-Müllerian Hormone (AMH) levels discriminate a phenotype that would be more LH- than insulin-dependent?

Summary answer: Among PCOS women with the highest serum AMH levels, high serum LH levels and other ovarian PCOS features are more common while insulin-resistance is less.

What is known already: The presence of high serum LH levels in PCOS women is a common feature that theoretically contributes to worsen ovarian hyperandrogenism by stimulating theca cells. The serum AMH level is closely related to the follicle number per ovary (FNPO) at ultrasound. Therefore, serum AMH level and FNPO are both elevated in PCOS. Recent experimental data in mice argue in favor to a stimulating effect of AMH on the activity of GnRH neurons, which could explain the positive relationship between serum LH and AMH levels that is observed in PCOS women but there is very little evidence to support this hypothesis.

Study design, size, duration: This is a retrospective monocentric cross-sectional study included 639 patients with PCOS according to Rotterdam Criteria and 137 control women that were recruited from January 2009 to January 2016 in an academic institution.

Participants/materials, setting, methods: Clinical (menstrual disorder, hyperandrogenism, BMI, waist circumference), hormonal (gonadotropins, AMH, androgens, SHBG), metabolic (fasting insulin) and ultrasound (ovarian area, FNPO) data were recorded consecutively and included in a database. Discriminant analysis (DA) was used to identify and to rank in order of importance the different variables potentially involved in serum AMH levels in PCOS patients, compared to control women. Only the first (Q1) and fourth (Q4) quartiles of each population were used for the DAs.

Main results and the role of chance: In controls, only age, FNPO and obviously AMH were significantly different between Q1 and Q4. In PCOS patients, the frequencies of oligo-anovulation and hyperandrogenism were greater in the Q4 than in the Q1 group. As well, serum levels of total Testosterone, Androstenedione, 17 hydroxy-progesterone and LH ranked significantly higher, as did the FNPOs and ovarian areas. In contrast, serum FSH levels, BMIs, waist circumferences and plasma insulin (I) levels ranked significantly lower and obesity was less frequent in Q4 than in Q1. The SHBG levels ranked similarly between the 2 groups.

In PCOS, the distribution of phenotypes A, C and D was different between the two groups ($p < 0.0001$). Mild phenotypes (C and D) were more common in Q1 while phenotype A was more frequent in Q4.

In the controls, after stepwise DA, FNPO and age discriminated independently and significantly Q4 from Q1 ($p<0.0001$ each), with R^2 at 0.62 and 0.27, respectively. In PCOS patients, the FNPO, LH, FSH, phenotype and BMI variables discriminated Q4 from Q1, independently and significantly, with R^2 at 0.371, 0.304, 0.166, 0.108, and 0.075, respectively ($p < 0.0001$ for all). In contrast, T and A were not included in any significant model.

Limitations, reasons for caution: Our controls did not represent the general population since they were recruited in an ART centre. As previously published, we used in-house thresholds to define the follicle excess with FNPO and/or serum AMH level. Women with PCOS were relatively young, which could have minimized the effect of age.

Wider implications of the findings: Our data in humans corroborate experimental data in mice and support the hypothesis that in some patients, high AMH levels, through stimulation of LH secretion, drive PCOS. In such an AMH-dependant PCOS phenotype, hyperandrogenism and oligo-anovulation would be prominent features while the role of insulin-resistance would be of less importance.

Trial registration number: non applicable

O-010 Anti-Müllerian hormone levels in adolescence in relation to long-term follow up for presence of polycystic ovary syndrome

M. Caanen[1], H. Peters[1], M. Van Hooff[2], P.M. Ven[3], A.M.M. Jüttner[1], J.S. Laven[4], C.B. Lambalk[1]

[1]*Amsterdam UMC- location VUmc, reproductive medicine, Amsterdam, The Netherlands*

[2]*Franciscus Hospital, Department of Obstetrics and Gynaecology, Rotterdam, The Netherlands*

[3]*Amsterdam UMC- location VUmc, Clinical Epidemiology and Biostatistics, Amsterdam, The Netherlands*

[4]*Erasmus MC University Medical Center-, Obstetrics & Gynaecology, Rotterdam, The Netherlands*

Study question: Can serum anti-Müllerian hormone (AMH) levels and/or polycystic ovary syndrome (PCOS) associated features in adolescence predict the presence of PCOS in adulthood?

Summary answer: Our results confirm that AMH measured in adolescence correlate with PCOS features, however AMH as prognostic marker does not contribute to diagnosing PCOS in adulthood.

What is known already: PCOS associated features as oligo-amenorrhea, hyperandrogenism and polycystic ovarian morphology correlate with high AMH. However, diagnosing PCOS in adolescence is difficult and there is a strong call for a marker that can predict the occurrence of PCOS in adulthood. Whether AMH measured in adolescence can predict PCOS in adulthood is still unknown.

Study design, size, duration: This long-term follow-up study is based on a unique adolescent study on menstrual irregularities performed between 1990-1997 by the VU University Medical Center, Amsterdam. By the use of stored material we assayed 271 adolescent blood samples for AMH. In addition, we contacted this study group more than two decades after the initial study for a questionnaire on their current menstrual cycle pattern and presence of PCOS features in adulthood.

Participants/materials, setting, methods: In 271 adolescents with a mean age of 15.2 years various data on menstrual cycle information, physical information, ovarian morphology and hormonal measurements could be combined with AMH serum levels. In 160 of the 271 (59%) participants we collected information in adulthood about their menstrual cycle pattern and presence of PCOS (features) by a questionnaire.

Main results and the role of chance: AMH levels at adolescence were significantly higher in girls with oligo-amenorrhea compared with regular cycling girls: 5.5 versus 3.1 µg/L, $P < 0.001$. Adolescents with PCOM had significantly higher AMH levels with a mean AMH of 5.2 µg/L, compared to 3.1 in the non-PCOM group ($P < 0.001$). AMH levels correlated with the presence of hyperandrogenism.

In the follow-up study, the mean age was 39.6 years. 22.5% of these women reported oligomenorrhea and 11.9% were identified as having PCOS. Women with PCOS in adulthood had a mean adolescent AMH of 4.7 compared with 3.6 µg/L in the non-PCOS group ($P = 0.051$). Women with oligomenorrhea in adulthood had a significantly higher adolescent AMH of 4.5 compared with 3.5 µg/L in adults with regular cycles ($P = 0.025$). ROC curve analysis of AMH at adolescence showed poor area under the curve for PCOS and oligomenorrhea in adulthood: 0.638 and 0.623, respectively.

Of the adolescent cohort with an oligo-amenorrhea, 23.1% had adult PCOS; compared to 6.5% in adolescents with a regular cycle. Also, 40.4% of the oligomenorrheic adolescents were classified as adult oligomenorrhea. Given adolescent oligomenorrhea, using high AMH as factor to predict adult PCOS or adult oligo-amenorrhea was of no value.

Limitations, reasons for caution: The adult PCOS diagnosis is based on a self-reported questionnaire, without physical examination and/or ovarian ultrasound which may have caused that we have missed some women with PCOS.

Wider implications of the findings: This is the first very long-term follow-up study investigating AMH and PCOS features in adolescence as marker for adult PCOS. Our results show that adolescent AMH can distinguish between PCOS features, however it does not contribute as prognostic marker for PCOS. We do not recommend routine use in clinical practice.

Trial registration number: Dutch Trial Registry, NTR5871

O-011 Optimizing follicle-stimulating hormone concentration during human IVM

J. Cadenas[1], L.A. Zuniga[1], Z. Ghezelayagh[1], Y. Wakimoto[2], D. Nikiforov[1], S.E. Pors[1], C.Y. Andersen[1]

[1]*University Hospital of Copenhagen- Rigshospitalet, Laboratory of Reproductive Biology- The Juliane Marie Centre for Women- Children and Reproduction, Copenhagen, Denmark*

[2]*Hyogo College of Medicine, Department of Obstetrics and Gynecology, Nishinomiya, Japan*

Study question: What is the optimal concentration of follicle-stimulating hormone (FSH) during human *in vitro* maturation (IVM) in terms of oocyte maturation rate?

Summary answer: The FSH concentration can be reduced to 40 mIU/mL without reducing the rate of oocyte maturation.

What is known already: Exogenous FSH is commonly used for ovarian stimulation *in vivo* as well as for oocyte maturation *in vitro*. Nonetheless, there is increasing evidence suggesting that elevated FSH levels can impair oocyte developmental capacity. To our knowledge, no study has defined the optimal FSH concentration for human IVM. Hence, the great number of immature oocytes recovered from the surplus medulla tissue of non-stimulated patients receiving ovarian tissue cryopreservation for fertility preservation will potentially be able to benefit patients and improve reproductive outcome. Additionally, patients that cannot receive ovarian stimulation may also benefit from optimized conditions for human IVM.

Study design, size, duration: This is a control-versus-treatment study. Immature oocytes were recovered from surplus tissue of 22 patients (age 14-40 years) who had one ovary excised for fertility preservation by ovarian tissue cryopreservation. Most oocytes derived from follicles with diameters below 3mm. Immature oocytes with similar diameters and that did not show signs of degeneration, such as darkened cytoplasm, or misshapen zona pellucida, were selected and homogeneously distributed into culture media with different concentrations of FSH.

Participants/materials, setting, methods: A total of 566 immature oocytes were divided into three categories according to their cumulus mass: cumulus-oocyte complexes (COCs) with large cumulus mass (L-COCs), small cumulus mass (S-COCs) and naked oocytes (N-Oocytes), and then submitted to 48h IVM in the presence of increasing concentrations of recombinant FSH (Rekovelle, Ferring, Copenhagen, Denmark): 20 mIU/mL, 40 mIU/mL, 70 mIU/mL or 250 mIU/mL. As outcome parameters, oocyte nuclear maturation and diameter were recorded.

Main results and the role of chance: On average, 26 oocytes were recovered per ovary (range 8-73), being 42% L-COCs (N=239), 39 % S-COCs (N=218), and 19% N-Oocytes (N=109). After IVM, mean oocyte diameters were similar ($P > 0.05$) among all treatments (range 113.3-114.1 µm, zona pellucida not included). Including all oocyte categories (L-COCs, S-COCs, and N-Oocytes), the three treatments with FSH above 20 mIU/mL i.e., 40, 70, and 250 mIU/mL, significantly increased oocyte nuclear maturation (22% MII vs. 35% MII, respectively) ($P < 0.03$). Regardless of the FSH concentration, oocyte maturation increased when increasing cumulus cell mass (18% N-Oocytes, 28% S-COCs, and 35% L-COCs) ($P < 0.01$) and oocyte diameter ($P < 0.0001$). Thus, considering only oocytes with cumulus cells (S-COCs and L-COCs) (N=457), there was an increase in oocyte maturation of almost 13% when FSH exceeded 20 mIU/mL (from 24.7% to 37.4% MII) ($P < 0.03$), resulting in an average of 8 MII oocytes per ovary. There were no significant differences in oocyte maturation when FSH concentration increased from 40 to 250 mIU/mL.

Limitations, reasons for caution: Since Danish legislation does not consider IVM as clinical practice, the obtained MII oocytes could not be fertilized *in vitro*. Therefore, only oocyte nuclear maturation, and no cytoplasmic maturation and fertilizing capacity, was assessed. Hence, further experiments are needed to elucidate the developmental capacity of these oocytes.

Wider implications of the findings: Similar maturation rates were achieved using 40 mIU/mL FSH to those described in non-stimulated patients with 75 mIU/mL FSH. Reducing FSH concentration could diminish its detrimental effect on oocytes. Using oocytes from small antral follicles (1-5 mm) can improve the fertility preservation of patients by complementing ovarian cortical tissue freezing.

Trial registration number: Not applicable

O-012 NK3R antagonist ameliorates metabolic status and reverses obesity in mice

Y. Shi[1], X. Zhu[1], Y. Liu[1]

[1] *Shanghai Medical College- Fudan University- Shanghai, Hospital and Institute of Obstetrics and Gynecology, Shanghai, China*

Study question: Does NK3R antagonist (NK3Ra) play a role in weight loss and improving glycolipid metabolism?

Summary answer: NK3Ra can promote fat conversion and metabolic efficiency, improve insulin resistance and glucose tolerance, and thus improve the overall metabolism of the body.

What is known already: NKB binding with its receptor NK3R induces kisspeptin release and further regulates the pulsed release of GnRH in the hypothalamus. NK3Ra can ameliorate endocrine disorders by decreasing LH and androgenlevel. Recent studies have shown that lipid metabolism can affect the NKB-NK3R signaling pathway, thereby affecting reproductive endocrine function and adolescent sexual maturation. But the role of NK3R in metabolic regulation is unclear.

Study design, size, duration: A prospective, randomized mouse experimentation aiming to identify the effect of NK3Ra on the improvement of metabolic disorders were conducted. Fifty female Balb/C mice were randomly divided into 5 groups of equeal size for high-fat diet, constant light, high-fat diet + constant light, NK3Ra + high-fat diet + constant light and controls. All mice were sacrificed 14 weeks after induction of the metabolic disorder model.

Participants/materials, setting, methods: The mice were weighed regularly and micro-CTwas conducted before sacrificed. Glucose and insulin tolerance tests were conductedand serum levels of glycolipid correlated indexe was detected by chemical colorimetry. The adipose tissues were observed and UCP1 expression was detected using immunohistochemistry. The marker molecules level of adipose synthesis and deposition were detected using RT-qPCR. The Luminex detecting technique was used to determine expression differences of inflammatory markers. Data were analyzed using GraphPad Prism 6.

Main results and the role of chance: We found that the weight of mice in NK3Ra group was significantly decreased, and the volume of subcutaneous fat and visceral fat was significantly reduced, indicating that NK3Ra can promote the decomposition and utilization of body fat. The serum levels of total cholesterol, triglyceride and low density lipoprotein in NK3Ra group decreased, while the levels of high density lipoproteinand apolipoprotein increased, which proved that NK3Ra could improve fat transport and metabolic efficiency in mice. NK3Ra significantly reduced the levels of IL-1 and MCP-2 in serum, indicating that NK3Ra can improve the level of inflammatory reaction caused by metabolic disorders to a certain extent, thus breaking the vicious circle of mutual intensification between metabolic disorders and inflammation. NK3Ra can trigger the beiging of white adipocytes, accordingly, the expression of UCP1 increases. Fatty acid binding protein 4, peroxisome proliferator-activated receptor gamma, resistin and leptin were significantly decreased in the adipose tissue of mice in NK3Ra group, indicating that NK3Ra could inhibit adipose synthesis and deposition. In addition, NK3Ra can also improve insulin resistance and glucose tolerance in mice.

Limitations, reasons for caution: These findings are based on a small sample size of mice. The results need to be confirmed by human clinical trials.

Wider implications of the findings: NK3Ra are known to be improve the endocrine state by reducing LH pulse frequency and androgen level, combined with the results of this study, we conclude that NK3Ra may offer therapeutic benefit in the treatment of diseases with reproductive endocrinedisorders and glycolipid metabolism problems, such as PCOS.

Trial registration number: not applicable

O-013 Anti-Müllerian Hormone (AMH) as a quantitative and qualitative marker of euploid blastocysts

A. Arnanz[1], N. De Munck[1], A. Nkuhlu[1], I. ElKhatib[1], A. Bayram[1], A. Liñan[2], L. Melado[3], B. Lawrenz[3], H. Fatemi[4]

[1] *IVIRMA Middle East Fertility Clinic LLC, IVF lab, abu dhabi, United Arab Emirates*
[2] *IVIRMA Middle East Fertility Clinic LLC, IVF lab, Muscat, Oman*
[3] *IVIRMA Middle East Fertility Clinic LLC, Gynaecology, abu dhabi, United Arab Emirates*
[4] *IVIRMA Middle East Fertility Clinic LLC, Director Middle East Operations, abu dhabi, United Arab Emirates*

Study question: Is AMH an effective tool to predict the percentage of euploid embryos and blastocyst formation irrespective of the age of the patient?

Summary answer: Higher AMH levels are associated with a higher rate of euploid embryos and increased blastocyst formation on day 5.

What is known already: AMH is an established marker of the ovarian reserve and it is strongly correlated with female age. However, it has been

suggested that AMH is not only a quantitative but also a qualitative biomarker of oocyte/embryo competence and it has been demonstrated that high AMH levels, e.g. due to the Polycystic Ovary Syndrome, are at increased risk of poor blastocyst development. Reduced ovarian reserve might be *per se* associated with decreased oocyte developmental competence leading to increased aneuploidy rates in embryos independent of the age of the patient.

Study design, size, duration: A retrospective analysis was performed between March 2017 and August 2018 including couples planned for Preimplantation Genetic Testing for Aneuploidies (PGT-A). Patients were split into two groups and were analyzed individually; (i) the fresh group comprised of couples who underwent PGT-A with only fresh oocytes (n=516) and (ii) the vitrified group (n=184) in which vitrified oocytes were accumulated from 1.97 (±1.26)previous ovarian stimulation cycles, as a strategy to increase the number of potential euploid embryos.

Participants/materials, setting, methods: Vitrification and warming were performed with the Cryotop method (Kitazato, Biopharma). Trophectoderm biopsy samples were subjected to Next Generation Sequencing (NGS) to screen the cells. AMH serum levels (ng/ml) were determined using a commercial fully automated assays Elecsys® (Roche) and values >5 were excluded. Blastulation rate was defined as the number of fertilized embryos capable of cavitating on day 5.

Main results and the role of chance: Linear regression analysis was conducted to verify the predictability of AMH values and the percentage of euploid embryos and blastulation rate on day 5. A Poisson regression model was used to correlate AMH levels with the number of euploid embryos according to the number of embryos biopsied. In the fresh group, average maternal age was 35.8 years (± 5.95), AMH 1.95ng/ml (±1.27), 54% (±33%) blastulation rate on Day 5, 46% (±35%) euploid rate. Higher AMH values were found to have a statistically significant effect on the percentage of euploid embryos (p=0.001) and blastocyst formation on day 5 (p<0.001) as well as for the number of euploid embryos (p<0.001). In the vitrified group, average maternal age was 38.55 (± 5.35), AMH 1.2ng/ml (±1.06), 8.43 (±5.57) MII oocytes warmed, 86% (±21%) survival rate, 34% (±33%) blastulation rate on day 5, 31% (±39%) euploid rate. As in the fresh group, higher AMH values were found to have a statistically significant effect on the percentage of euploid embryos (p=0.009) as well as for the number of euploid embryos (p=0.003). However, no significant differences were found between higher AMH levels and blastocyst formation (p=0.249).

Limitations, reasons for caution: Retrospective design of the study.

Wider implications of the findings: The independent relationship between AMH and the percentage of euploid embryos suggests that AMH is not only a quantitative but also a qualitative biomarker of oocyte-embryo competence. As the effect of AMH on blastocyst formation is lost after oocyte vitrification, the use of oocyte accumulation should be further evaluated.

Trial registration number: N/A

O-014 Time span for recovery and degree of change of ovarian reserve markers after discontinuation of long-term use of combined oral contraceptives

K. Birch Petersen[1], S.K. Landersø[2], H.S. Nielsen[2], M.S. Kroman[2], S.A. Lunding[2], E.C. Larsen[3], A.N. Andersen[2]

[1]*Zealand University Hospital, Fertility Clinic, Køge, Denmark*
[2]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[3]*Danish Fertility Clinic, Danish Fertility Clinic, Copenhagen, Denmark*

Study question: How early does the ovarian reserve markers Anti-Müllerian-hormone (AMH) and antral follicle count (AFC) normalize after discontinuation of long-term use of combined oral contraceptives (COC)?

Summary answer: After discontinuation of COC the ovarian reserve markers increased with 59% (AMH) and 48% (AFC), and normalization occurred within two months.

What is known already: Combined oral contraception is the most preferred contraceptive method in the Western world. Cross-sectional studies reported 20-40% lower levels of AMH and AFC during COC-use. Women use COC for years to decades while postponing childbearing; many women therefore wish to address their ovarian reserve during contraceptive usage. The recovery of AMH/AFC after discontinuation has not been investigated systematically for long-term-users of COC and it is not fully elucidated when a recovery occurs.

Study design, size, duration: The study was conducted as a prospective cohort investigating the ovarian reserve markers during COC-use and serially in a 3-month period after discontinuation. The study population comprised 74 women from the general population with a history of long-term use of COC and who wished to withdraw COC for three months. The women were included in the study between 2016 to 2018. In total, 69 women completed the 3-month follow-up period.

Participants/materials, setting, methods: Inclusion criteria: COC-use for ≥3 consecutive years, age between 24-41 years. Intervention: Six serial examinations including investigation of the ovarian reserve markers (AMH, AFC and ovarian volume) and analyses of reproductive hormones on the following time-points: During COC-use, 5-7 and 14 days after discontinuation, and for 3 consecutive menstrual cycles (cycle day 2-5). AMH was measured with the Roche Elecsys-assay. Statistical analyses included linear regression and mixed models for repeated measurements adjusted for relevant co-variates.

Main results and the role of chance: Mean age was 29.5 years (SD3.7) and mean duration of COC-use was 11.6 (SD3.7) years. Nearly 80% regained spontaneous menstrual cycle within 35 days after the COC-caused withdrawal bleeding after COC-discontinuation. Six women met the Rotterdam criteria for PCOS by the end of the follow-up period. Mean values of AMH increased significantly from 15.9 pmol/L, (SD10.4) (2.2 ng/ml) to 26.3 (SD19.7) (3.7 ng/ml), p<0.0001, and AFC increased from 19.1 (SD10.5) to 26.8 (SD14.2), p<0.0001, during the three months follow-up after discontinuation of the COC. This corresponded to an increase in AMH and AFC of 59% and 48%, respectively. There was a significant increase in AMH and AFC from baseline until second menstrual cycle, but not from the second to third. Longer duration of COC-use and higher age were significantly associated with lower absolute change in AFC (p=0.02 and p=0.01, respectively), whereas women that fulfilled Rotterdam criteria for PCOS was associated with higher increments (p=0.002). Age and PCOS-status were significantly associated with AMH increments in a likewise manner (p=0.03). We believe these results were not caused by chance due to the low p-values in combination with a reasonable number of participants and within-individual comparisons and a priori statistical power calculations.

Limitations, reasons for caution: We have used an improved and validated AMH assay and hereby reduced earlier reported assay variability. The prospective design and repeated measurement within the same individual decrease risk of bias. The number of individuals is, however, limited in order to assess whether the findings also account for subgroups of individuals.

Wider implications of the findings: This study highly contributes to the understanding of the ovarian reserve markers during COC-usage, and since AMH and AFC is often included in the testing of the ovarian reserve, the results from this study can directly contribute as a guide to testing of women in terms of their ovarian reserve.

Trial registration number: Clinical trials: NCT02785809 Regional Ethical Committee: H-16021266

Study question: What is the efficacy of IUI and IVF treatments with regards to success, risks and costs?
Summary answer: IUI should be the first line treatment choice providing significantly better overall benefits than IVF when pregnancies, risks and cost values are factored in.
What is known already: Most success and risks factors are known individually. However, for the first time an integrated analysis of success and risks from an extremely large database generated independently of researchers removes selection biases. Risk factors relating to multiple births, fetal reductions, terminations and OHSS have not previously been addressed on a large scale. Previous cost-effective analyses have avoided factoring in the risks of treatment procedures, while cost effectiveness studies artificially favour IVF, having incorrectly been compared against substandard abnormal IUI practices. IVF clinics have innovative ways of presenting inflated success rates which can be misleading to stakeholders and patients.
Study design, size, duration: A retrospective observational study was performed, based on 319,105 IVF/ICSI and 30669 IUI cycles registered on the HFEA database from 2012-2016. Additional data on associated risks was gained under the Freedom of Information (FOI). Direct costing analyses used updated Bank of England figures for multiple birth costs, while cost effective studies was based on each techniques ability to deliver one live birth against prevailing tariffs. Data submission to the HFEA is on a mandatory requirement.
Participants/materials, setting, methods: Normal IUI and IVF practice data was obtained from the large UK regulated HFEA database for 2012-2016, combined with FOI requested for the associated risks. The data was collected entirely by HFEA staff removing any selection biases. Direct cost studies incorporated the COMBS (2005) model whereas indirect cost relied upon incremental cost-effective ratios (ICER). Statistics z-analyses on trends was considered statistically significant showing $p < 0.05$.
Main results and the role of chance: From 2012-2016 there was a significantly increased 10.4-fold ($p<0.05$) practice of IVF over IUI while IVF: IUI twins was 38.4-fold and 7.6-fold triplets. Multiple births from IVF appear to be managed by fetal reductions and terminations. For the period 2012-16 the there was a 11.5%/cycle PR (pregnancy rate) yielding 8.6% twins and 0.93% triplets. The IVF/ICSI revealed 27%/cycle LBR yielding 13.7% twins and 0.25% triplets and minimal quadruplets. OHSS per birth and cycle treatment was 0.9% and 0.25% respectively. Fetal reduction was 0.2% of all births, and 0.81% termination of all births. Multiple birth as a proportion of all births was significantly higher following IVF than following IUI [IVF: 13.88% (13.65-14.11); IUI: 9.59% (8.62-10.56). RR: 1.45 (1.31-1.60) $p<0.05$]. Approximately 50% contribution to IUI multiple births came from private IVF clinics that also produced relatively high IUI success rates. New costing analyses are represented by 1 IUI success made up of 91.2%: 7.9%:0.85% singleton, twin and triplet respectively whereas for IVF/ICSI this is 86.2%:13.6%:0.13%. The UK IVF industry is worth over £300 million but provides a risk cost burden of over £500 million. IUI is cheaper than IVF/ICSI with baseline success rates, extending to £35,000-55,000/LB saving with 15-17%/cycle IUI.
Limitations, reasons for caution: Further costs due to OHSS, fetal reduction, termination, low birth weight IVF singletons, embryo freezing, and embryo culture costs and add on procedure remain undisclosed. Stimulation methodology is not revealed. More desirable was numbers of women, mean numbers of IUI and IVF cycles undertaken, both unavailable from the UK HFEA.
Wider implications of the findings: IUI is better than IVF for patients and stakeholders after factoring in success, risks and cost effectiveness. IVF risk burden nationally exceeds the total value of the IVF industry and these burdens have not previously been disclosed. IVF success is inherently interlinked to NICE initiated decline of UK IUI practices.
Trial registration number: Not applicable

O-016 Prediction of successful ICSI cycles by Oxidation-reduction potential (ORP) and sperm DNA fragmentation (SDF) analysis. A Prospective study

A. Morris[1,2], I. Siebert[3], A. Agarwal[4], R. Henkel[1,4]

[1]University of The Western Cape, Medical Biosciences, Cape Town, South Africa
[2]Tygerberg Fertility Clinic, Obsterics and Gynecology, Cape Town, South Africa
[3]Stellenbosch University, Obsterics and Gynecology, Cape Town, South Africa
[4]American Center for Reproductive Medicine, Department of Urology, Cleveland, U.S.A.

Study question: Does the clinical utilization of SDF and ORP tests helps in accurate prediction of fertilization in ICSI cycles?
Summary answer: SDF and ORP testing could be used as a valuable diagnostic tool in IVF clinics to predict fertilization but not blastulation in ICSI cycles.
What is known already: Seminal oxidative stress (OS) and sperm DNA fragmentation (SDF) are two advanced sperm function tests that are increasingly used in the evaluation of infertile men. OS has recently been identified as a major mediator in the various causes of male infertility. It is well established in the literature that a high percentage of SDF due to various factors including OS has adverse effects on ART outcomes.
Study design, size, duration: This prospective pilot study evaluated a total of 50 patients undergoing ICSI treatment for male factor infertility (n=50). The study was carried out from June 2017 to December 2018 and was approved by Biomedical Ethics Committee of the University of the Western Cape, Cape Town, South Africa. All participants signed written informed consent form.
Participants/materials, setting, methods: The flourometric TUNEL assay (Promega Corporation, Madison, USA) and the MiOXSYS system (Aytu Bioscience, Englewood, CO) were used to measure SDF and the oxidation-reduction potential (ORP), respectively. The data generated was then correlated with the fertilization and blastulation rates. Statistical analysis including ROC curve analysis was performed. The study included patients using autologous fresh gametes only and excluded all day 3 embryo transfers and advanced maternal age.
Main results and the role of chance: ROC curve analysis to predict fertilization and blastulation rates used published cut off values of 36% TUNEL-positive cells for SDF and 1.36 mV/10^6 sperm/ml, respectively for ORP. For SDF ($P<0,0001$ for fertilization and $P=0,0897$ for blastulation), the ROC curve analysis resulted in a sensitivity of 67,6% and 89,7%, specificity 84,6% and 50.0%, positive predictive value 92,6% and 89,7% and negative predictive value 47,8% and 50,0% for fertilization and blastulation, respectively. [APA1] The areas under the curve [AUC] were 0,830 and 0,699 for fertilization and blastulation rate, respectively. For ORP ($P<0.001$), the analysis showed a sensitivity of 100.0%, a specificity of 62.9%, a positive predictive value of 55.6% and a negative predictive value of 95.0% with an AUC of 0.834 for fertilization. However, no significance was seen for blastulation ($P=0.8146$).
Limitations, reasons for caution: The results observed in this study should be confirmed using a larger number of samples.
Wider implications of the findings: The study demonstrated strong predictive capabilities of SDF and seminal ORP measurement in the clinical setting. This information is useful in providing the clinician with a valuable diagnostic tool for prediction of fertilization in ICSI cycles.
Trial registration number: Not Applicable.

O-017 Impact of paternal age, ejaculatory abstinence length and semen quality on the outcomes of intracytoplasmic sperm injection (ICSI) in an egg-sharing donation program

A. Setti[1,2], D. Braga[1,2], B. Zanetti[2], L. Vingris[3], A. Iaconelli Jr.[2,4], E. Borges Jr.[2,4]

[1]Fertility Medical Group, Scientific research, Sao Paulo, Brazil
[2]Associação Instituto Sapientiae, Scientific research, Sao Paulo, Brazil
[3]Fertility Medical Group, IVF laboratory, Sao Paulo, Brazil
[4]Fertility Medical Group, Clinical department, Sao Paulo, Brazil

Study question: Can paternal age, ejaculatory abstinence length (EA) and semen quality influence ICSI outcomes in recipients' cycles from the same donor in an egg-sharing donation program?

Summary answer: Increasing paternal age and EA, and poor semen parameters negatively impact ICSI outcomes, from fertilization rate to pregnancy, in recipients' cycles from the same donor.

What is known already: The impact of male partner characteristics on IVF is often ignored, even though male-factor infertility is known to play a role in 50% of the cases. Indeed, the male factor infertility is equally important to establish the success of assisted reproduction cycles. However, few studies have focused on the influence of male factors on IVF outcomes, with conflicting results, probably due to confound variables introduced in the analysis, when it comes to autologous cycles. Considering this, the use of an egg-sharing donation program may be extremely useful to study the impact of partner characteristics and semen parameters on ICSI outcomes.

Study design, size, duration: Data analyzed in this historical cohort study were obtained via chart review of 268 vitrified oocyte donor ICSI cycles, and 321 oocyte recipients undergoing 427 oocyte recipient ICSI cycles, participating in an egg-sharing donation program, between January/2015 and May/2017. For that sample size, computed achieved post-hoc power was 95.7%. Oocyte donors were between the age of 19 and 35 years, and recipients were between the age of 26 and 59 years.

Participants/materials, setting, methods: This study was performed in a private university–affiliated IVF center. General Mixed Models fit by restricted maximum likelihood, generated using covariates as fixed effects and egg-donors and egg-recipients as random effects, with unstructured covariance structure, were used to investigate the impact of paternal age, EA and semen quality on recipients' ICSI outcomes. The results are expressed as regression coefficient (B), standard error (SE), exponentiation of B (ExpB), 95% confidence interval (CI), and p-value.

Main results and the role of chance: Fertilization rate was negatively affected by paternal age (B: -0.276, p: 0.001) and positively affected by sperm count (B: 0.075, $p < 0.001$). High-quality embryos rate on day 3 was negatively correlated with paternal age (B: -0.040, p: 0.021) and EA (B: -0.003, p: 0.028). Normal embryo development (cleavage speed) rate on day 3 was negatively affected by paternal age (B: -2.750, p: 0.001) and EA (B: -0.300, p: 0.036), and positively affected by the percentage of progressive sperm motility (PSM, B: 0.017, p: 0.024). Blastocyst development rate was negatively influenced by paternal age (B: -0.070, p: 0.043) and EA (B: -0.589, p: 0.016), and positively influenced by sperm count (B: 2.155, p: 0.015) and total motile sperm count (TMSC, B: 1.057, p: 0.038). Paternal age was negatively correlated with high-quality blastocysts rate (B: -44.058, p: 0.031). Implantation rate was negatively affected by paternal age (B: -0.060, $p < 0.001$) and EA (B: -0.012, $p < 0.001$), and positively affected by sperm count (B: 0.025, $p < 0.001$), PSM (B: 0.183, $p < 0.001$) and TMSC (B: 0.008, p: 0.009). Paternal age was associated with reduced odds of pregnancy (ExpB: 0.664, p: 0.033).

Limitations, reasons for caution: In Brazil, egg donation may not be conducted for profitable purposes, so oocytes are donated from patients undergoing IVF treatments. Thus, the oocytes included in this study originated from infertile couples. Nevertheless, the evaluation of paternal characteristics on oocytes from infertile couples is a realistic situation in assisted reproduction.

Wider implications of the findings: Further tracking of the impact of paternal characteristics on ICSI outcomes should be encouraged. Despite paternal age is uncontrollable, and there are only so many things that can be done concerning semen quality, shortening of EA length could be used as a strategy to optimize ICSI outcomes.

Trial registration number: None.

O-018 Long-term cryostorage of semen in a human sperm bank does not affect clinical outcomes

C. Huang[1], H.L. Wu[1], R.X. Gan[2], L. Lei[3], X.B. Yuan[3], S.H. Jiang[3], L.Q. Fan[1], W.B. Zhu[1]

[1]*Reproductive & Genetic Hospital of CITIC-Xiangya, Human Sperm Bank, Changsha- Hunan, China*

[2]*Reproductive & Genetic Hospital of CITIC-Xiangya, Reproductive Center, Changsha- Hunan, China*

[3]*Institute of Reproductive and Stem Cell Engineering, Basic Medicine College, Changsha-Hunan, China*

Study question: Does the duration of donor sperm storage affect the chances of success among women undergoing medically assisted reproduction?

Summary answer: Long-term cryostorage of semen in a human sperm bank does not affect clinical outcomes.

What is known already: Cryopreservation of donor semen is a widely used technique in artificial insemination by donor (AID) and in vitro fertilization (IVF) for azoospermia and fertility preservation. Although cryopreservation has negative effects on the plasma membrane of sperm, no data have been reported on the effects of long-term storage of sperm on clinical outcomes to date.

Study design, size, duration: This study included 119,558 specimens retrieved using a clinical information database of young adult men who were qualified sperm donors at the Hunan Province Human Sperm Bank of China, from January 1 2001, to December 31 2016. Clinical information included semen parameters before and after freezing, the date of the semen analysis and clinical outcomes after semen use.

Participants/materials, setting, methods: Three groups of semen categorized by their lengths of crystorage were analyzed: 0.5–5, 6–10, and 11–15 years. Between-group differences were tested using the Chi-square test. Sperm motility before and after cryostorage was compared using the paired sample *t*-test and the Wilcoxon signed-ranks (paired) test.

Main results and the role of chance: The sperm's frozen-thaw survival rate decreased from 85.72% to 73.98% after 15 years of cryopreservation ($P < 0.01$). The clinical pregnancy rate of women undergoing AID was 23.09%, 22.36% and 22.32%, the clinical abortion rate was 10.06%, 10.02% and 12.00% and the the live birth rate was 82.17%, 80.21% and 80.00% in the groups with 0.5–5, 6–10 and 11–15 storage years, respectively. The clinical pregnancy rate of women undergoing IVF was 64.29%, 64.94% and 53.48% in the groups with 0.5–5, 6–10 and 11–15 storage years, respectively. The clinical abortion rate was 12.26%, 11.38% and 17.39% and the live birth rate was 81.63%, 79.11% and 73.91%, in the groups with 0.5–5, 6–10 and 11–15 years, respectively. The clinical pregnancy, abortion and live birth rates were not significantly different between donor sperm with 6–10 and 11–15 storage years and sperm with the shortest storage length (0.5–5 storage years).

Limitations, reasons for caution: The study's limitations include lack of data on congenital abnormalities based on pregnancy outcomes and lack of a clear medical diagnosis; Our findings are not based on the general population of men, as the sperm donors in the study had better sperm quality than most men.

Wider implications of the findings: Although long-term cryostorage might not affect clinical outcomes, sperm banks should provide sperm in their order of cryopreservation.

Trial registration number: not applicable

O-019 Patients with childhood cancer who underwent thoracic or abdominal irradiation have poor gonadal function in adulthood

Y. Duca[1], A. Di Cataldo[2], G. Russo[2], E. Cannata[2], A. Alamo[1], G. Burgio[1], M. Compagnone[1], R.A. Condorelli[1], S. La Vignera[1], A.E. Calogero[1]

[1]*Section of Andrology and Endocrinology, Department of Clinical and Experimental Medicine, Catania, Italy*

[2]*Section of Pediatric Oncohematology, Department of Clinical and Experimental Medicine, Catania, Italy*

Study question: Which therapy used to treat childhood cancers has the worst effect on the reproductive function?

Summary answer: Patients treated with chemotherapy plus non-cranial radiotherapy have worse testicular function than patients treated with cranial irradiation plus chemotherapy or chemotherapy alone.

What is known already: Altered sperm parameters, hypogonadism and infertility are potential long-term sequelae in adult males treated for childhood cancer. Cranial irradiation with doses >22 Gy has been associated with pituitary dysfunction, while it has been shown that testicular irradiation and treatment with high doses of alkylating agents are responsible for gonadal dysfunction.

Low inhibin B, high FSH and total (left + right) testicular volume (TV) ≤24 mL are considered predictive factors for azoospermia in childhood cancer survivors. The age of treatment does not seem to influence reproductive outcomes.

Study design, size, duration: Seventy-nine patients who underwent annual hematological follow-up visit in 2018 at the Pediatric Oncohematology Clinic of the "Gaspare Rodolico" University Hospital, University of Catania, were enrolled in this cross-sectional study.

Participants/materials, setting, methods: Patients had been treated with chemotherapy alone, chemotherapy plus radiotherapy, and/or bone marrow transplantation and were declared disease-free for at least 5 years. Patients who underwent testicular irradiation or orchiectomy for testicular neoplasia, and who were in testosterone replacement therapy at the time of the visit were excluded. All patients underwent scrotal ultrasound; 71 patients underwent blood sampling for LH, FSH and total testosterone (TT) measurement; 21 patients did also sperm analysis.

Main results and the role of chance: At the time of enrollment, patients' mean age was 23 years (range 16-38). At the time of diagnosis, patients' mean age was 6 years (range 1-16). Main diagnoses were: acute lymphoblastic leukemia (n. 53), non-Hodgkin's lymphoma (n. 10), Hodgkin's lymphoma (n. 5), hepatoblastoma (n. 3), acute myeloid leukemia (n. 2), nephroblastoma (n. 2). 50 patients had been treated with chemotherapy alone; 25 with chemotherapy plus radiotherapy; 4 patients underwent bone marrow transplantation. Overall, 33% of patients showed total TV <24 ml, 31% had TT <3.5 ng/mL, 48% had decreased sperm count (half of them were azoospermic, the other half had oligozoospermia). As expected, patients who underwent bone marrow transplantation showed the worst gonadal function. Patients who underwent chemotherapy plus cranial irradiation showed no statistically significant differences in gonadotropin and TT levels, TV, and sperm count compared to patients who underwent chemotherapy alone. Patients treated with chemotherapy and thoracic or abdominal irradiation had higher FSH levels ($p<0.001$) and lower TV ($p=0.001$) than patients treated with chemotherapy alone. Regarding the age of treatment, patients treated at an age ≥10 years showed higher FSH levels ($p=0.027$), however data became not statistically significant when we excluded patients who underwent thoracic or abdominal irradiation.

Limitations, reasons for caution: These are preliminary data. The number of patients is small, nevertheless enrollment is continuing. We have not been able to find in the old medical records the exact dosages of some drugs and radiotherapy administered. Many patients did not want to undergo sperm analysis.

Wider implications of the findings: Our data are in agreement with other recent studies showing that, even at a dosage of 24 Gy, cranial irradiation doesn't affect reproductive outcomes. On the contrary, thoracic and abdominal irradiation have a strong negative effect on testicular germinal function. Better shielding of the gonads is, therefore, needed during irradiation.

Trial registration number: Not applicable

O-020 ICSI using surgically retrieved testicular sperm of non-azoospermic men with high sperm DNA fragmentation index and blastocyst ploidy: a safe approach

Study question: Is blastocyst euploidy affected by the use of surgically retrieved spermatozoa from non-azoospermic men with high sperm DNA fragmentation (SDF) for intracytoplasmic sperm injection (ICSI)?

Summary answer: The probability of having euploid blastocysts is not affected by the use of testicular sperm from non-azoospermic men with elevated SDF for ICSI.

What is known already: Recent studies have reported that the use of testicular sperm in preference over ejaculated sperm for ICSI have a positive effect on the chances of pregnancy, in particular, among non-azoospermic men with high SDF in their ejaculate. However, concerns were raised regarding a possible detrimental effect of using testicular sperm from these men due to the reportedly higher aneuploidy rates in spermatozoa harvested from the seminiferous tubules of azoospermic individuals. Yet, data concerning trophectoderm biopsy analysis using comprehensive chromosome testing that allow the assessment of the whole karyotype of embryos resulting from surgically retrieved spermatozoa is lacking.

Study design, size, duration: Single-center retrospective analysis of 940 trophectoderm biopsies from 362 infertile couples subjected to ICSI with own ejaculated (280 patients; 764 embryos) or surgically retrieved sperm (82 patients; 176 embryos) between 2016-2017. Preimplantation genetic testing for aneuploidy (PGT-A) was indicated because of advanced maternal age, severe male factor, recurrent miscarriage/implantation failure, and concerns about the ploidy status of embryos. SDF analysis was carried out using the sperm chromatin dispersion test in all eligible non-azoospermic men.

Participants/materials, setting, methods: Biopsied trophectoderm cells were analyzed by next-generation sequencing analysis (NGS). Logistic regression was applied to the dataset. The dependent variable was blastocyst genetic status (euploid/aneuploid) whereas the independent variables were female age, male age, origin of sperm for ICSI (testicular/ejaculated), sperm DNA fragmentation index (DFI) as well as the reason for using surgically retrieved sperm (obstructive azoospermia [OA], non-obstructive azoospermia [NOA], and elevated (>30%) DFI [high DFI]). Computations were performed using JMP 13.

Main results and the role of chance: The mean female and male ages were 38.9±3.6 and 42.4±6.7 years, and the mean number of biopsied blastocysts per patient was 2.6. Overall, the percentage of euploid embryos in our cohort was 36.4% whereas the mean number of euploid blastocysts per patient was 0.73. The fitted model selected female age as the only relevant predictor ($p<0.0001$), but the origin of sperm and the reason for using testicular sperm had a nested effect on blastocyst euploid within female age. Male age and DFI results did not affect blastocyst euploidy. The logistic model generated the probability that a mature oocyte become a euploid blastocyst once injected with either ejaculated or surgically retrieved sperm, adjusted by female age. There was a significant ($p<0.0001$) decrease in the probability of a blastocyst being euploid with every year of female age, irrespective of the type of sperm used for ICSI. The use of testicular sperm from men with high DFI had no significant effect on blastocyst euploidy when compared to ejaculated sperm and testicular sperm from OA men. In contrast, use of testicular sperm from NOA men had an overall adverse effect on blastocyst euploid ($p=0.03$), but the effect varied according to female age.

Limitations, reasons for caution: The impact of other covariates on embryo genetic status could not be assessed from the dataset. Other limitations are the study's retrospective nature and the difference in the number of embryos subjected to PGT-A according to sperm origin and the reason for using testicular sperm for ICSI.

Wider implications of the findings: Embryos resulting from ICSI using either testicular sperm of non-azoospermic men with high DFI or ejaculated sperm have similar chances to be euploid, depending only on female age. Our data corroborate the safe utilization of surgically retrieved sperm from non-azoospermic men with high SDF for ICSI.

Study question: Does the endometrial preparation protocol (artificial cycle vs natural cycle vs stimulated cycle) affect reproductive outcomes of Frozen / thawed embryo transfer (FET) ?
Summary answer: In FET, artificial cycles were significantly associated with a higher miscarriage rate and a lower live birth rate compared to stimulated or natural cycles.
What is known already: FET represent a growing part of embryo transfers. Three protocols are used for the endometrial preparation: the natural cycle (NC), the stimulated cycle (SC) with gonadotrophin stimulation and, the more widely used, the artificial cycle (AC) with sequential estrogen/progesterone treatment. To date, there is no consensus on the optimal endometrial preparation regarding outcomes. However, some studies have reported a higher miscarriage rate with the artificial cycle compared to the natural or stimulated cycles. But no significative difference were found on ongoing pregnancy rate or live birth rate (LBR). Furthermore, no studies have compared the three protocols in a large population.
Study design, size, duration: A multicentric retrospective study was conducted in nine french reproductive units, using the same software to record medical files, between 1st January 2012 and 31th December 2016. The primary outcome was miscarriage rate at 10 weeks of gestation. A sample size calculation was made to detect an increase of 5% in the miscarriage rate (21 to 26%) with risk alpha 0.5 and power 0.8 : 1126 pregnancies were needed in each group, 3378 in total.
Participants/materials, setting, methods: The data were collected by automatic extraction using the same protocol. All the consecutives autologous FET cycles were included : 14421 cycles (AC 8139, NC 3126 and SC 3156) corresponding to 3844 pregnancies (HCG > 100 IU/L) (AC 2214, NC 812 and SC 818). An online questionnaire was conducted for each center to describe its routine practice for FET, particularly the reason of choice of a protocol over another one.
Main results and the role of chance: The AC represented 56.5% of the FET cycles. The mean age (SD) was 33.5 (4.3). The mean number of embryo replaced was 1.5 (0.5). The groups were comparable except for history of dysovulation p=0.01 and prior delivery p=0.03, significantly higher in AC. Overall, the miscarriage rate was 31.5%, AC 36.5%, NC 25.6%, SC 23.6%. Univariate analysis, showed a significant association of miscarriage with age > 38y, history of miscarriage, dysovulation and duration of freezing > 6 months. After adjustment (multivariate regression), the miscarriage rate remained significantly higher in the artificial vs the natural cycle OR 1.63 (95% CI) [1.35-1.97]; p < 0,0001 and in the artificial vs the stimulated cycle OR 1.87 [1.55-2.26]; p < 0,0001. Overall the LBR per transfer was 17.8 %, AC 16.9%, NC 18.8%, SC 19.3%, p < 0,003. There was no significative difference between the natural and the stimulated cycle. The biochemical pregnancy rate (HCG 10-100 UI/L) was comparable between the three protocols, 10.7% per transfer.
Limitations, reasons for caution: This study is limited by its retrospective design, which included selection bias. Routine practice within centers were heterogeneous. In AC, however, luteal phase support and timing of embryo replacement were similar. The univariate analysis showed no difference between centers. Moreover, a large number of parameters were included in the analysis.
Wider implications of the findings: Our study shows a significant decrease in LBR when using artificial cycle for endometrial preparation before FET. These results suggest either a larger use of natural or stimulated cycle, or an improvement of artificial cycle by individualizing hormonal substitution to patients in order to avoid the excess of pregnancy losses.
Trial registration number: not appplicable

O-022 Microbiota in Endometrial Fluid and Vaginal Secretions in Infertile Women with a History of Repeated Implantation Failure

K. Kitaya[1], Y. Nagai[2], W. Arai[2], Y. Sakuraba[2], T. Ishikawa[1]

[1]*Reproduction Clinic Osaka, IVF Center, Osaka City, Japan*
[2]*Varinos Inc., Department of Bioinformatics, Tokyo, Japan*

Study question: Is specific microorganisms or microbiota in the endometrial fluid (EF) and vaginal secretions (VS) associated with etiology and pathogenesis of repeated implantation failure (RIF)?
Summary answer: Some unusual local microorganism and dysbiotic flora were found in EF and VS of infertile women with a history of RIF.
What is known already: Despite that the uterine cavity and vagina are closely located, their bacterial communities are different in the same individuals and seems not to be hormonally regulated during the acquisition of endometrial receptivity. While Lactobacillus-dominated microbiota (LDM, defined as >90% Lactobacillus species) in the EF of the receptive phase was reported to be associated with favorable reproductive outcome, non-LDM (<90% Lactobacillus species) was found to decrease implantation, clinical pregnancy, ongoing pregnancy, and live birth rates. The local microbial environment in the female reproductive tract, however, remains largely unknown in infertile patients with a history of RIF.
Study design, size, duration: A preliminary analysis of a registered ongoing prospective case-control study. From September 2017 to October 2018, the paired EF and VS samples were obtained from twenty-eight infertile women with a history of RIF (defined as three or more serial negative serum pregnancy tests following transfer of five or more morphologically good blastocysts) and eighteen infertile women undergoing the first in vitro fertilization attempt (the control group) under a given informed consent.
Participants/materials, setting, methods: Sampling was performed carefully avoiding contamination on day 6 to 8 after luteinizing hormone surge in the natural cycle, human chorionic gonadotropin trigger in the oocyte pick up cycle, or on day 5 following initiation of luteal support in the hormone replacement cycle. Extracted genomic DNA was pyrosequenced for V4 region of 16S ribosomal RNA using next-generation sequencer. The sequences were clustered to operational taxonomic units (OTU) and assigned to bacterial taxonomy using QIIME.
Main results and the role of chance: The OTU sequences in the EF and VS microbiota were similar ($p = 0.52$ and 0.65, respectively) between the RIF (mean 29,283 and 38,188, range 2,824–43,657 and 18,232–43,936, respectively) vs control group (mean 22,745 and 36,973, range 1,065–38,877 and 28,898–42,210, respectively). Shannon-index and Chao1 richness (alpha-diversity) of EF microbiota in the RIF (mean ± SE, 0.893 ± 0.567) was also comparable ($p = 0.60$) to the control group (mean ± SE, 1.431 ± 0.931), whereas the unweighted UniFrac distance (beta-diversity) in the EF (but not VS) microbiota showed a significant difference ($p = 0.0089$) between the two groups. LDM rate in the EF and VS was similar ($p = 0.12$) between the RIF (64.3% and 67.9%, respectively) and control group (38.9% and 44.4%, respectively) as well as the detection rate of the bacterial vaginosis-associated genera such as Gardnerella, Atopobium, and Prevotella (39.3%, 7.1%, and 17.9% in the RIF and 27.7%, 16.7%, and 44.4% in the control group, respectively, p =

0.107). Meanwhile, Burkholderia was detected in 25% of EF in the RIF group, whereas it was undetectable in any of EF in the control group (p = 0.032, relative risk 4.53, 95% CI 0.006-1.68)

Limitations, reasons for caution: The limitation of this study is that the design is not a randomized controlled trial, although it is prospective. A current potential bias is the small sample size.

Wider implications of the findings: The beta-diversity in EF microbiota was significantly different between infertile patients in the RIF group and control group. Burkholderia was detected in a quarter of EF in the RIF group, but not in any of the control group, suggesting a potential involvement of this pathogen in RIF.

Study question: Does mid-luteal endometrial scratching prior to the stimulation cycle increase pregnancy rates in women with one failed IVF/ICSI cycle?

Summary answer: Based on a preliminary analysis, mid-luteal scratching using an endometrial biopsy catheter may not significantly improve pregnancy rates in women with one failed IVF/ICSI cycle.

What is known already: Previous trials on endometrial scratching have been reported to have methodological limitations and high risk of bias making it unclear whether this procedure improves pregnancy rates. Even the recent large, properly designed PIP trial suffers from the fact that a very heterogeneous study population was included and the timing of scratching was not standardized (scratching was permitted at any time during a ~30 day time frame before start of stimulation). An RCT in a more homogeneous population which standardizes timing and method of scratching may provide additional information on the effectiveness of scratching.

Study design, size, duration: A multicenter, non-blinded, randomized controlled trial was conducted between January 2016 and July 2018 in the Netherlands. Women were allocated 1:1 to endometrial scratching or no procedure, using a web-based system that ensured allocation concealment. Using an expected difference in live birth rate (LBR) after the IVF/ICSI cycle following randomization of 9% (39% vs. 30%, respectively), the sample size was set at 900 participants (80% power and two-sided alpha of 0.05).

Participants/materials, setting, methods: Participants with a failed first IVF/ICSI cycle (≥1 embryo transfer) were eligible. Endometrial scratching was performed using an endometrial biopsy catheter in the mid-luteal phase prior to ovarian stimulation. The primary outcome was LBR from the fresh embryo transfer post-randomization; secondary outcomes included cumulative pregnancy outcomes. This abstract reports preliminary complete case results for the secondary outcomes biochemical and clinical pregnancy rate (BPR; CPR), as the 12-month follow-up period and data collection are still ongoing.

Main results and the role of chance: A total of 942 women were included in the trial (471 scratch/471 control). Baseline characteristics, duration and cause of infertility were comparable between the two groups. The participation rate was 89% (942/1060 eligibles). The BPR was 34.3% (137/399) in the scratch and 30.9% (119/385) in the control group (RR 1.11 [95%CI 0.91-1.36]). The CPR was 26.9% (105/390) in the scratch and 26.1% (99/380) in the control group (RR 1.03 [95%CI 0.82-1.31]). Ongoing pregnancy rate (OPR) and LBR cannot be reported reliably as follow-up and data collection are ongoing, but the completed data will be available at ESHRE. Important strengths include the fairly homogeneous study population and the standardization of the timing and method of scratching. The 12-month follow up period is unique as it offers the possibility to study longer-term effects of endometrial scratching on cumulative pregnancy rates which will also be presented at ESHRE. The high participation rate in this trial is probably due to the fact that endometrial scratching is not offered as part of clinical care in the Netherlands. This improves the inference for the effect of endometrial scratching for daily practice.

Limitations, reasons for caution: The presented results are based on preliminary complete case analysis which is due to ongoing follow-up. Also, despite strict inclusion criteria, some heterogeneity in the study population still exists, for example in the number of embryo transfers prior to randomization.

Wider implications of the findings: Preliminary analysis of this second largest RCT with strict inclusion criteria and standardized scratching method showed a small but non-significant difference in BPR, but no difference in CPR. Follow-up will show if endometrial scratching results in a clinically important difference for LBR or cumulative pregnancy outcomes (12-month follow-up).

Trial registration number: This trial was prospectively registered in the Dutch Trial Register (Nederlands Trial Register) under number 'NTR 5342'.

O-024 Endometrial preparation for frozen-thawed embryo transfer (FET) in an artificial cycle: Transdermal versus vaginal estrogen

R. Corroenne[1], H. El Hachem[2], C. Dreux[1], P. Jeanneteau[1], C. Verhaeghe[1], P. Descamps[1], P. May-Panloup[1], P.E. Bouet[1]

[1]Angers University Hospital, Department of Reproductive Medicine, Angers, France
[2]Clemenceau Medical Center- Beirut- Lebanon, Department of Reproductive Medicine, Beirut, Lebanon

Study question: Is there any difference in endometrial thickness and patient satisfaction between transdermal and vaginal estrogen for endometrial preparation for FET in an artificial cycle?

Summary answer: Transdermal estrogen significantly increases endometrial thickness after 10±1 days of treatment and improves patient satisfaction compared to the vaginal route, with comparable pregnancy outcomes.

What is known already: To date, there is no consensus on the optimal hormonal preparation regimen for artificial FET, despite its widespread use in everyday practice. Several studies have compared oral, vaginal and transdermal estrogen for endometrial preparation before FET, and have shown comparable pregnancy outcomes. A recent prospective randomized trial compared transdermal and oral estrogen, and showed significantly better endometrial thickness with transdermal estrogen on day 10±1, but better patient satisfaction with oral estrogen. However, to our knowledge, no study has compared endometrial thickness and patient satisfaction between the transdermal and vaginal route in artificial FET.

Study design, size, duration: We performed a prospective monocentric cohort study between January and December 2017 at the Angers university hospital. All artificial FET cycles were included (n=318). The two administration routes were explained to the patients during the consultation with the physician or the head nurse before initiating treatment, and the choice between the two was left to the patient. 119 (37.3%) chose transdermal and 199 (62.6%) chose vaginal estrogen, and all signed an informed consent before inclusion.

Participants/materials, setting, methods: All patients who had an artificial FET using transdermal or vaginal estradiol and filled the satisfaction survey after treatment were included. The main objective was to compare the endometrial thickness between the two routes after 10±1 days of treatment. Secondary outcomes were the patient satisfaction on transfer day (score over 10), the side effects, the serum hormone levels, the duration of treatment and the cycle outcome.

Main results and the role of chance: Patients' characteristics were comparable between the two groups. The endometrial thickness at 10±1 days was significantly higher in the transdermal group compared to the vaginal (9.9 vs 9.3 mm, p=0.03, respectively.) The serum estradiol level was significantly lower in the transdermal group (268 vs 1332 pg/ml, p<0.001, respectively), but the progesterone levels were comparable between the transdermal and vaginal groups (0.5 vs 0.6 ng/ml, p=0.61, respectively). The mean duration of treatment was significantly shorter in the transdermal group (13.6 vs 15.5 days, 0>0.001), and significantly fewer patients required ultrasound reassessment for endometrial thickness compared to the vaginal group (10.1% vs 30.6%, p<0.001, respectively). The overall patient satisfaction score was significantly higher in the transdermal group (8.2 vs 7.4, p=0.04), with significantly more patients reporting no side effects compared to the vaginal group (42.4% vs 22.8%, p=0.03, respectively). 86% of patients (36/42) who received the two types of preparation in two successive cycles reported favoring the transdermal route. Finally, live birth rates were comparable between the transdermal and the vaginal route (18% vs 19%, p=0.1, respectively).
Limitations, reasons for caution: The main limitation of our study is the lack of randomization and the monocentric design. Moreover, the patient satisfaction survey answers could have been influenced by the outcomes (positive or negative) of previous FET cycles using one route or the other.
Wider implications of the findings: Transdermal estrogen for endometrial preparation in artificial FET cycles was associated with better endometrial thickness, shorter treatment duration, fewer side effects, and higher patient satisfaction compared to the vaginal route. Therefore, it could be the preferred administration route for artificial FET. Larger randomized trials are needed to confirm our findings.
Trial registration number: Clinical Trial NCT03518528.

O-025 Development and validation of an original test to evaluate human endometrial receptivity and embryo implantation

S. Messaoudi[1], I. El Kasmi[1], C. Le Saint[1], J. Choi[1], F. Bissonnette[1,2], I.J. Kadoch[1,2]

[1]*ovo clinic, ovo r&d, Montréal, Canada*
[2]*University of Montreal Hospital Center, Obstetrics and Gynecology, Montreal, Canada*

Study question: Could we predict endometrial receptivity and embryo implantation by RT-qPCR expression analysis of genes involved in endometrial receptivity and maternal-fetal dialogue?
Summary answer: Adhesio RT, diagnostic tool, can predict receptivity and embryo implantation by RT-qPCR using an original panel of genes involved in endometrial receptivity and maternal-fetal dialogue.
What is known already: Implantation failure caused by suboptimal endometrial receptivity is a main issue. An endometrium is receptive to an embryo in a spatially and temporally restricted period called the implantation window which is usually more or less delayed in recurrent implantation failures. Therefore, it appears essential to identify inadequate endometrial receptivity to offer personalized care management. Molecular diagnostic tools currently available to characterize this process are very limited. In this study, a new diagnostic tool for endometrial receptivity and embryo implantation based on the transcriptomic signature is presented for the first time.
Study design, size, duration: As a result of a single site study at ovo clinic from December 2016 to March 2019, the development and clinical validation of a new test, Adhesio RT, allowed us to analyze 215 biopsies of which 50 endometrial biopsy samples and 35 autologous endometrial co-culture samples were analyzed by using microarray technology and 130 biopsies from IVF-patients with a known pregnancy outcome were used for clinical validation.
Participants/materials, setting, methods: 50 biopsies were performed in natural cycle during the optimal theoretical implantation window LH+7 to LH+11 (35 with successful clinical pregnancy 15 with implantation failure). Similarly, a total of 29 co-culture biopsies were performed on autologous-endometrial co-culture (14 endometrial cells cultured in absence of embryo, 5 in presence of good-quality embryo successfully transferred, 10 with good quality embryo but with implantation failures). Samples were analyzed using microarrays and selected biomarkers were assessed using RT-qPCR.
Main results and the role of chance: Adhesio RT included 10 new selected genes by using a new approach that incorporates two specific transcriptomic signatures obtained by different bioinformatic and statistical technologies applied to microarray analyses: A first specific transcriptomic signature of 1717 genes specifically modulated associated to biopsies from patients with successful clinical pregnancy *versus* biopsies from patients with implantation failure. Gene ontology analyzes revealed that cell division, cellular proliferation, cell adhesion and mitotic cycle are the most over-represented biological terms in this group of genes. A second specific transcriptomic signature of 60 genes associated to endometrial co-culture successfully transferred was obtained using class prediction approach. Gene expression was validated by RT–qPCR. Clinical validation was performed on 130 biopsies from IVF-patients with a known pregnancy outcome.
Limitations, reasons for caution: Successful implantation is a complex process requiring a receptive endometrium, a viable embryo and synchronized dialogue between maternal and embryonic tissues. Adhesio RT only focuses on receptive endometrium and dialogue between maternal and embryonic tissues.
Wider implications of the findings: Evaluation of receptivity and embryo implantation of an endometrium with this new molecular signature can predict IVF success and may help in the management of endometrial preparation for embryo transfer and optimizes chances of successful pregnancy for many couples.
Trial registration number: Not applicable.

O-026 Uterine immune profiling for patients with unexplained recurrent miscarriage.

L. Sedille[1], G. Kayem[2], M. Petitbarat[3], A. Mekinian[4], M. Bornes[5], L. Prat-Ellenberg[6], N. Lédée[7]

[4]*Hôpital Saint Antoine, Médecine Interne, Paris, France*
[5]*Hôpital Tenon, Gynécologie-Obstétrique, paris, France*
[6]*Hôpital des Bluet, assistance médical a la procréation, Paris, France*
[7]*Hôpital des Bluets, Assistance médicale à la procréation, Paris, France*

Study question: Is an endometrial immune evaluation able to identify uterine immune mechanisms generating unexplained recurrent miscarriages (RM)?
Summary answer: Local immune deregulation was detected in 83% of the cases. Personalized treatment adapted to the patient's endometrial immune profile may help patients with RM.
What is known already: We previously documented immune deregulation in infertile patients with repeated history of embryo implantation failures. Endometrial remodeling events begin before implantation and are a vital process for pregnancy, preparing future maternal immune tolerance and regulating the placentation process. During "the implantation window", an influx of immune cells occurs and nearly completely switches local immunity from an adaptive (Th1) to an innate (Th2) type. This transient immune switch, together with adequate uNK-cell activation, appears fundamental in enabling local maternal tolerance and fetus survival. An over-activation can generate embryo rejection, while an under-activation can disturb embryo adhesion and local angiogenesis.
Study design, size, duration: Between 2014 and 2018, 180 patients with a history of unexplained RM underwent endometrial immune profiling. If an immune deregulation was diagnosed (over or low-endometrial immune activation), treatment was adapted accordingly. A three-month follow-up was conducted to evaluate subsequent live birth rate if a pregnancy occurred during that period with or without medical assistance.
Participants/materials, setting, methods: Recurrent miscarriage was defined as at least three miscarriages during the first trimester despite a negative checkup (auto-immunity, thrombophilia, caryotype). An endometrial biopsy was performed under substituted cycle in the luteal phase. We quantified uNK by immunohistochemistry using anti-$CD56^+$IgG and mRNA of IL-15 (uNK cells activation/maturation state), IL-18 (Th-1/Th-2 cytokines balance) and TWEAK/Fn-14 (immuno-regulation) by Real-Time PCR.
Main results and the role of chance: Among the 180 patients, 83% (149/180) had deregulation of their endometrial immune environment at the time of the evaluation. An over-activation was diagnosed in 45%, an under-activation was diagnosed in 23.9% and concomitent under and over activation

(a Th-1 deviation of the endometrial environment with immatures NK cells) was diagnosed in 13.9%. Depending on the immune profile, personalized treatment was suggested to counteract the identified mechanisms. In case of pregnancy in the three months following the evaluation birth rate was only 16% if no deregulation had been observed. In patients with treated deregulation birth rate was 49 % (51.8%, 48% et 40% respectively in the over-under or mix deregulated group).

Limitations, reasons for caution: Only a randomized control study among deregulated RM patients may confirm these results.

Wider implications of the findings: When deregulation is diagnosed on endometrial immune profiling in patients with unexplained RM (83%), the effective understanding of local endometrial immune deregulations may be useful to provide treatment that reduces the risk of a new miscarriage.

Trial registration number: not applicable

Monday 24 June 2019 Haydn 4 10:00–11:30

O-027 Travelling from France for CBRC: an internet survey as a first step to measure this phenomenon

V. Rozée[1], E. La Rochebrochard de[2]

[1]*Institut National d'Etudes Démographiques - INED, Research units "Fertility- family and sexuality" and "Sexual and reproductive health and rights", Paris Cedex 20, France*

[2]*Institut National d'Etudes Démographiques - INED- INSERM- Univ. Paris-Sud-UVSQ, Research units "Fertility- family and sexuality" and "Sexual and reproductive health and rights"- CESP, Paris Cedex 20, France*

Study question: The objective was to explore some essential features of use of CBRC by French patients in order to design a larger survey quantifying CBRC.

Summary answer: CBRC in France is characterized by strong information and social networks (whatever the socio-demographic profiles, ART used, or destinations) that make a larger survey possible.

What is known already: CBRC is described as a worldwide, growing and multifaceted phenomenon, concerning people with diverse sociodemographic characteristics and reasons for crossing borders. France is one of the top four European countries whose residents seek CBRC elsewhere. However, the scale of CRBC cannot be estimated from existing studies because they are mainly qualitative or based on non-representative samples. A preliminary statistical work proposed a cutting-edge methodological study design to quantify the CBRC population based on the benchmark-multiplier method. However, the information channels and social networks mobilized by CBRC patients first need to be tested.

Study design, size, duration: A three-month online cross-sectional survey was conducted in 2018 to explore CBRC. It was approved by the Ined Data Protection Officer (2017-CIL-0013). The survey was diffused by specialized associations and related professional networks. Inclusion criteria were: planning to travel or having already travelled to another country for CRBC, and being resident in France. This questionnaire (designed with Voozanoo® software) included questions on ART techniques planned or already used, destination countries, experience sharing and information sources.

Participants/materials, setting, methods: The internet survey was completed by 419 respondents. Analysis was based on the 348 (83%) respondents who met the inclusion criteria and fully completed the questionnaire. Descriptive statistics were obtained using SAS® software to analyse respondents' profiles and journeys, destinations and networks used.

Main results and the role of chance: Based on the internet survey, CBRC patients from France showed diverse sociodemographic profiles (single women, same-sex and heterosexual couples). They used ART in many different countries in Europe but also in the USA and Canada. However, Belgium and Spain were the main destinations for French residents. An important finding was the complexity of CBRC pathways, as a single respondent could successively have used different ART techniques in different countries. All respondents used Internet as the main CBRC information source, together with specialized associations and French medical doctors. Moreover, three out of four respondents knew at least one person using ART abroad. It will therefore be possible to use these important interpersonal and social networks to broadcast the large planned survey and to include a large sample. A large proportion of CBRC patients shared and intended to share their CBRC project with family (3/4), friends (3/4) and colleagues (1/2). This demonstrates that in France CBRC is no longer a highly sensitive and taboo issue. This is the time to launch a large survey with a good prospect of acceptability.

Limitations, reasons for caution: It is not possible to ensure the representativeness of the internet sample. Some profiles and techniques may be underrepresented, especially single men, male couples and surrogacy. For the larger survey, the questionnaire will be broadcast through more associations and clinics for better coverage of the CBRC population.

Wider implications of the findings: Based on these findings, an ambitious research project on CBRC from France is now planned to produce a first estimate of the size of the CBRC population. More broadly, this will allow further use of the cutting-edge benchmark-multiplier method for studies on CBRC from other European countries.

Trial registration number: Not applicable.

O-028 Why do patients return for more treatment? A 10-year analysis from a single IVF centre from inception

I. Robertson[1], Y. Cheong[1], J. Paget[2], R. Banks[3]

[1]*University of Southampton, Human Development and Health, Southampton, United Kingdom*

[2]*Complete Fertility Centre, Princess Anne Hospital, Southampton, United Kingdom*

[3]*Virtus Health Limited, Complete Fertility Centre, Southampton, United Kingdom*

Study question: To investigate the return rate for further assisted conception treatment after initial treatment, the time lapsed before returning and the factors that most significantly influence the return rate.

Summary answer: Statistically significant factors included age, previous cycle failure, failed fertilisation (reduced return), higher eggs numbers, availability of supportive app and frozen embryos (increased).

What is known already: Drop-out from assisted conception treatment is common. Patients must overcome disappointment, physical and psychological burden and often financial obstacles in order to return for further treatment. Studies have analysed medical factors associated with early dropout 1,2 but there has been little focus on those who do return for further treatment.

1. Gameiro S et al, Why do patients discontinue fertility treatment? A systematic review of reasons and predictors of discontinuation in fertility treatment. *Hum Reprod Update* 2012;18: 652-669.

2. Troude P et al. Medical factors associated with early IVF discontinuation. *Reprod Biomed Online* 2014;28: 321-329.

Study design, size, duration: Single centre retrospective database study, with 6034 cycles of ovulation induction, intrauterine insemination, IVF/ ICSI and frozen embryo transfer undertaken by 3114 patients from 2008-2018. Age, nationality, primary diagnosis, number of previous treatment cycles, number of previous pregnancies, couple category, funding source, availability of MediEmo supportive App and postcode/ CCG were recorded. Cycle specific characteristics of treatment type, stimulation protocol, number of eggs collected/fertilised, number of embryos transferred, and cycle success/ failure were also obtained.

Participants/materials, setting, methods: Analysis was performed using multi-level mixed effects modelling to account for the repeated nature of the data, with multiple cycles for some patients. Linear regression models were used for time elapsed between cycles. NHS and self-funded patients were modelled separately to identify key characteristics. The end point for those with a failed cycle (no live birth) is whether a new cycle begins within one year and, for those who had successful cycle, within 3 years.

Main results and the role of chance: Over half of the patients who had one treatment cycle return for further treatment cycles (n=1571, 58.0%). Of the cycles analysed, 4147 (68.7%) were self-funded and 1887 (31.3%) were NHS-funded. Following a failed cycle, the average time to return for further treatment was 5 months. Following a successful cycle, the average time to return was 2.5 years.

Patients who did not succeed in having a live birth were more likely to return if they had a higher number of eggs collected [OR 4.39; p<0.001], frozen embryo(s) [OR 9.39; p<0.001], were single women [OR 2.32; p<0.001], same sex couples [OR 1.83; p<0.001] and had used the MediEmo App [OR 2.46; p<0.001]. They were less likely to return for further treatment with increasing age [for each year increase OR 0.958; p<0.001], increased number of previous cycles [OR 0.924; p=0.049], those who already had a frozen embryo transfer [vs IVF: OR 1.31; p=0.03] or had previous failed fertilisation [OR 0.254; p<0.001]. Success group modelling results are imminently awaited.

Limitations, reasons for caution: This study is limited by its retrospective nature and is based on a single centre's data over time within the UK.

Wider implications of the findings: These results should interest fertility centres and compliment the available literature on characteristics of patients who drop out from assisted conception treatment.

Trial registration number: Not Applicable

O-029 The coaching program; 'Smarter Pregnancy' is the first effective mHealth intervention to adopt healthy nutrition and lifestyle behaviours in subfertile couples: a randomised controlled trial

E. Oostingh[1], R. Steegers-Theunissen[1], W. Koster[1], M. Van Dijk[1], S. Willemsen[2], F. Broekmans[3], A. Hoek[4], M. Goddijn[5], N. Klijn[6], E. Van Santbrink[7], E. Steegers[1], J. Laven[1]

[1]*Erasmus University Medical Center, Obstetrics and Gynecology, Rotterdam, The Netherlands*

[2]*Erasmus University Medical Center, Biostatistics, Rotterdam, The Netherlands*

[3]*Utrecht University Medical Centre, Obstetrics and Gynecology, Utrecht, The Netherlands*

[4]*University Medical Centre Groningen, Obstetrics and Gynecology, Groningen, The Netherlands*

[5]*Amsterdam University Medical Centre, Obstetrics and Gynecology, Amsterdam, The Netherlands*

[6]*Leiden University Medical Centre, Obstetrics and Gynecology, Leiden, The Netherlands*

[7]*Reinier de Graaf Gasthuis, Obstetrics and Gynecology, Delft, The Netherlands*

Study question: What is the effectiveness of 24 weeks coaching of the mHealth program 'Smarter Pregnancy' to adopt healthy nutrition and lifestyles in couples undergoing IVF/ICSI treatment?

Summary answer: The mHealth coaching program 'Smarter Pregnancy' significantly enhances the adoption of healthy nutrition and lifestyle behaviours among subfertile couples undergoing IVF/ICSI treatment.

What is known already: Periconceptional healthy nutrition and lifestyle improve reproduction, pregnancy outcome and long-term health in mothers and offspring. While the amount of nutrition and lifestyle programs on the mobile phone (mHealth) is overwhelming, evidence on effectiveness is often lacking. At the Erasmus MC in Rotterdam, we have developed and launched in 2012 the online, web-based coaching program 'Smarter Pregnancy' [www.smarterpregnancy.co.uk] for the mobile phone to adopt healthy nutrition and lifestyle behaviours. In a previous survey that included more than 2,000 couples, we already showed a high compliance (65%) and effectiveness to adopt healthy behaviours (30-70%) and increase the chance of pregnancy (~20%).

Study design, size, duration: Multicentre randomized controlled trial conducted between July 2014 and March 2017 in six IVF clinics throughout the Netherlands. Couples undergoing IVF or ICSI treatment were randomly assigned to the intervention group (308 women, 106 men) or the control group (318 women, 116 men).

Participants/materials, setting, methods: After baseline screening on vegetable, fruit and folic acid supplement intake (nutrition) and smoking and alcohol use (lifestyle), the intervention group received tailored coaching on the identified unhealthy behaviours comprising of feedback, seasonal recipes, tips, and incentives by email or text message. The control group received a condensed 'light' version of the program. Primary outcome was the difference in improvement of adopting healthy behaviours after 24 weeks of coaching, expressed as a risk score.

Main results and the role of chance: Compared with controls, women (β=0.78, 95%CI 0.46 to 1.09) and men (β=0.83, 95%CI 0.42 to 1.28) in the intervention group showed a significantly larger improvement in adopting healthy behaviours. Women in the intervention group also showed a significantly larger improvement of healthy lifestyle behaviours (β=0.11, 95%CI 0.02 to 0.20).

Limitations, reasons for caution: The power of the study is not enough to evaluate the clinical effectiveness, such as the chance of pregnancy. Although folate blood levels are correlated with the reported nutrition behaviours, the completion of self-administered questionnaires by the participants may have induced desirability- and recall bias.

Wider implications of the findings: The enhanced adoption of healthy nutrition and lifestyle behaviours may have clinical implications, such as an increased chance of pregnancy, that warrants further research.

Trial registration number: Dutch Trial Register: NTR4150, http://www.trialregister.nl/trialreg/admin/rctview.asp?TC=4150

O-030 Fertility treatments in early onset female cancer survivors – A Finnish register-based study on 8,929 survivors

J. Melin[1,2], L. Madanat-Harjuoja[1], E. Hirvonen[1], K. Seppä[1], N. Malila[1], J. Pitkäniemi[1], M. Gissler[3], A. Tiitinen[4]

[1]*Finnish Cancer Registry, Institute for Statistical and Epidemiological Cancer Research, Helsinki, Finland*

[2]*Kymenlaakso Central Hospital, Department of Obstetrics and Gynecology, Kotka, Finland*

[3]*National Institute for Health and Welfare, Information Services Department, Helsinki, Finland*

[4]*Helsinki University Hospital, Departement of Obstetrics and Gynecology, Helsinki, Finland*

Study question: Do female early onset cancer survivors receive more fertility treatments compared to female siblings without a history of cancer?

Summary answer: Female early onset cancer survivors have an increased use of assisted reproductive technology (ART) from 2003 onwards compared to siblings.

What is known already: The population of early onset cancer survivors has been expanding over the past four decades, with 5-year survival rates reaching 80% in Western Europe. As survival rates increase, so does the risk for chronic health conditions, including gonadal dysfunction among female cancer survivors. Many studies have shown reduced pregnancy rates in female cancer survivors compared to the general population. There are, however, only a few studies focusing on fertility treatments among female cancer survivors. In one of them, survivors were as likely as their siblings to seek medical help for their infertility, but less likely to receive fertility treatments.

Study design, size, duration: In this retrospective, register-based study, data from Finnish registers on cancer, birth and prescribed medications were merged to identify 8,929 survivors (diagnosed with cancer between 1953 and 2012 at the age of 0-39 years) and 9,495 siblings without previous deliveries.

Participants/materials, setting, methods: Fertility drug purchases in cancer survivors and siblings in 1993-2012, at the age of 16-41 years, were identified from the Reimbursement Register on Prescribed Medicines. A Poisson regression model was used to estimate incidence rate ratios (IRR) for the use of fertility drugs (sub-classified into ovulation inductions and ARTs) between survivors and siblings, adjusting for attained age and calendar time. Heterogeneity in the IRR between time periods and age intervals was also estimated.

Main results and the role of chance: Fertility treatments were more common in cancer survivors compared to siblings, as 6.1% of survivors compared to 3.8% of siblings had bought fertility drugs (IRR 1.43, 95% confidence interval [CI] 1.25-1.65, p<0.001). A sub-classification of fertility treatments into ovulation inductions and ARTs, showed increased use of ART (IRR 2.41, 95 % CI 1.97-2.96, p<0.001), whereas the use of ovulation induction was similar in survivors and siblings. Analyses by calendar time periods showed the IRR for the use of ART to be significantly higher in the most recent decade, from 2003 onwards, compared to 1993-1997.

Limitations, reasons for caution: In this study, information on the indication for fertility treatment was unavailable and only fertility treatments with autologous oocytes could be included. Limited duration of follow-up was available for women diagnosed with cancer in the most recent calendar time period.

Wider implications of the findings: Female early onset cancer survivors have an increased risk for subfertility, which should be acknowledged by clinicians. However, our results mirror a more active approach among clinicians towards offering fertility treatments to cancer survivors during the most recent years.

O-031 Comparison of reproductive outcomes of female couples undergoing Reception of Oocytes from PArtner (ROPA) versus classic IVF-ICSI

A. Nuñez[1], D. García[1], P. Giménez-Bonafé[2], R. Vassena[1], A. Rodríguez[1]

[1] *Clinica Eugin, Assisted reproduction, Barcelona, Spain*
[2] *Universidad de Barcelona, Department of Physiological Sciences, Barcelona, Spain*

Study question: Is live birth after Reception of Oocytes from PArtner (ROPA) comparable to classic *in vitro* fertilization-intracytoplasmic sperm injection (IVF-ICSI) in lesbian couples?
Summary answer: ROPA presents a higher rate of live birth rates compared to classic IVF-ICSI.
What is known already: This study focuses on IVF and ROPA in lesbian couples. In IVF, a woman is both the provider of the oocytes and the recipient of the embryos, while in ROPA the process is shared between the partners: one of them undergoes ovarian stimulation and ovum pick-up, whilst the other undergoes endometrial preparation and carries the pregnancy. Although ROPA is increasing popular among lesbian couples, no clear understanding of its outcomes is present in the literature, making it difficult for clinicians to counsel properly these couples.
Study design, size, duration: This is a retrospective matched cohort study of lesbian couples in one large fertility center. The study included 70 couples that underwent for the first time ROPA, matched (1:2) with 140 patients of similar characteristics that underwent, also for the first time, classic IVF-ICSI, making a total of 210 couples. This study includes embryo transfers (ETs) performed between February 2012 and May 2018.
Participants/materials, setting, methods: ROPA and IVF couples were matched 1:2 by these variables: age of the woman providing the oocytes (±5 years), number of transferred embryos and day of ET. Laboratory and clinical outcomes are compared between groups. We provide descriptive statistics, univariable (Chi^2 test) and multivariable analyses (logistic regression) adjusted for: age of the woman providing the oocytes, BMI of the recipient, and number of previous treatments (intrauterine inseminations). A p-value <0.05 is considered statistically significant.
Main results and the role of chance: The mean age and BMI of women were: 33.9 years (SD 4.5) and 24.2 (SD 4.5) in the ROPA's oocyte provider; 34.3 years (SD 5.8) and 24.0 (SD 4.3) in the ROPA's recipient; 34.2 years (SD 3.9) and 23.8 (SD 3.9) in IVF/ICSI. 65.7% (n=92) of couples undergoing IVF/ICSI had underwent previous IUI treatments, against 24.3% (n=17) of the ROPA couples ($p<0.001$). Most ETs were performed on D2-3 (86.2%) with transfer of 2 embryos (80%). Regarding laboratory outcomes, ROPA led to 9.1 (SD 4.5) mature oocytes (MII) vs. 8.2 (4.5) in IVF/ICSI (p=0.16). Fertilization rate was 73.6% in ROPA vs. 76.2% in IVF/ICSI (p=0.37). Clinical outcomes in ROPA vs. IVF/ICSI were: biochemical pregnancy rate 68.6% vs.46.4% (p=0.002); clinical pregnancy rate 57.1% vs. 38.6% (p=0.011), ongoing pregnancy rate 55.7% vs. 35.7% (p=0.006), and live birth rate was 53% vs. 29.3% (p=0.001). After adjusting for potential confounders, we still observe a significant improvement in ROPA for biochemical (OR=2.71, 95%CI 1.33, 5.52; p=0.006), clinical (OR=2.4, 95%CI 1.19, 4.87; p=0.015), ongoing pregnancy (OR=2.39, 95%CI 1.18, 4.83; p=0.015), and live birth (OR=3.49, 95%CI 1.63, 7.49; p=0.001). Our results suggest that ROPA might be more efficient than classical IVF-ICSI in lesbian couples.
Limitations, reasons for caution: Study limitations include an "oocytes' age" significantly lower in ROPA, more IVF/ICSI patients going into this treatment after previous failed IUIs (worse prognosis), and ROPA recipients undergoing endometrial preparation but not ovarian stimulation (better uterine conditions). Adverse events during pregnancy and perinatally were not evaluated in this study.
Wider implications of the findings: ROPA offers improved treatment participation for lesbian couples, and it might improve reproductive outcomes through the possibility of selecting between 2 oocyte providers and 2 gestational mothers. As oocyte donation pregnancies present higher hypertensive disorders, a careful evaluation of risks and benefits is recommended before this treatment.

[5] *Bispebjerg University Hospital, Department of Occupational and Environmental Medicine, Copenhagen NV, Denmark*
[6] *Copenhagen University Hospital- Rigshospitalet, Department of Breast Surgery, Copenhagen, Denmark*

Study question: Is the risk of breast cancer (BC) increased after assisted reproductive technology (ART) treatment?
Summary answer: An increased risk of BC after ART treatment was apparent among women initiating ART treatment when aged 40+ years.
What is known already: The majority of BC cases are sensitive to estrogen. Ovarian stimulation in ART treatment has been suggested to increase the risk of BC by influencing endogenous estrogen levels. The level of ovarian response to hormone stimulation is dependent on age, and thus, age is an important factor in the choice of ART treatment protocol. Nulliparity is a risk factor for BC. Previous studies on ART treatment and BC have varied in their findings. Several previous studies suffer from lack of power and short follow-up time. The latency time for development of BC has been estimated at 10+ years.
Study design, size, duration: The Danish National ART-Couple II (DANAC II) cohort includes all women treated with ART at Danish fertility clinics in 1994-2015. Each woman in ART treatment was age-matched with ten women from the background population without a history of ART treatment. The women were followed until first cancer diagnosis, death, migration or end of study December 31st 2015. The cohort consisted of 58,534 women treated with ART and 567,178 women without a history of ART treatment.
Participants/materials, setting, methods: Multivariable analyses were conducted using cox proportional hazards regression. Having a primary cancer diagnosis other than BC was incorporated as a competing risk. Adjustment for confounders included baseline nulliparity, educational level, partnership status, treatment year, endometriosis and PCOS and time-dependent adjustment for age. Stratified analyses were conducted to assess effect modification by age at treatment initiation. Also, the risk of being diagnosed with BC was observed over time in order to detect potential patterns.
Main results and the role of chance: During follow-up 3894 women were diagnosed with BC, 464 (0.8 %) among ART-treated women and 3430 (0.6 %) among untreated women. Overall, women undergoing ART treatment had a higher risk of BC than non-ART women (HR 1.10, 95% CI 1.07-1.13). Female cause of infertility was not associated with an increased risk of BC (HR 1.03, 95 % CI 1.00-1.06). Among women initiating ART treatment when aged 40+ years the risk of BC gradually increased during 12 years after ART treatment initiation compared to untreated women (12-year HR 1.53, 95% CI 1.24-1.90). Considering that a higher prevalence of nulliparity among ART treated women could explain this finding, ART treated and untreated women with a first birth at age 40+ were subsequently compared. The increased risk was also apparent when restricting analyses to women with a first birth after ART treatment at 40+ years of age compared with untreated women with a first birth at similar age (HR 1.65, 95 % CI 1.40-1.94).

Limitations, reasons for caution: Although hormone dosages and number of ART treatments are relevant risk factors for development of BC, the selection of individuals to be exposed to more treatments is not random. It depends on both achieved pregnancies and who chooses to terminate treatment, and such results would be difficult to interpret.
Wider implications of the findings: It is possible that ovarian stimulation increases the risk of BC among women who initiate ART treatment when aged 40+. An increased risk could be due to age-related vulnerability to hormone exposure or to higher doses of hormones during ART treatment.

O-033 Health of 2 year-old singletons born after in vitro maturation of oocytes compared to peers born after controlled ovarian stimulation: results from a cohort study

F. Belva[1], M. Bonduelle[1], M. Roelants[2], S. Vermaning[1], A. Buysse[1], S. Desmyttere[1], F. De Schrijver[1], J. De Schepper[3], F. Hes[1], H. Tournaye[4], M. De Vos[4]

[1]UZ Brussel, Medical Genetics, Jette- Brussels, Belgium
[2]Environment and Health/Youth Health Care- KU Leuven, Department of Public Health and Primary Care, Leuven, Belgium
[3]UZ Brussel, Department of Paediatric Endocrinology, Jette- Brussels, Belgium
[4]UZ Brussel, Center for Reproductive Medicine, Jette- Brussels, Belgium

Study question: Does in vitro maturation (IVM) of immature oocytes affect the health of 2 year-old singletons born to mothers with polycystic ovaries (PCO)?
Summary answer: This study comprising 76 singletons born after IVM showed no significant differences in anthropometry compared with 111 peers born after conventional controlled ovarian stimulation (COS).
What is known already: The paucity of available data related to children's health following IVM is an important impediment to a more widespread use of this technology. Concerns that prolonged culture time might affect growth which may be linked to epigenetic alterations in IVM oocytes have not been confirmed.

Previous reports on the neonatal outcome after IVM are generally reassuring, but many studies have flaws that hamper the interpretation of outcomes. Moreover, only few studies reported health outcomes after IVM beyond infancy, and particularly data on growth and overall health in children born after IVM of immature oocytes from mothers with PCO are lacking.
Study design, size, duration: This single-center cohort study compared anthropometry and health outcomes in 76 singletons born after ICSI with transfer of in vitro matured oocytes (IVM group) with 111 singletons born after ICSI (COS group). All participants were born to mothers who were diagnosed with polycystic ovary syndrome (PCOS) phenotype A, C, D or polycystic ovary morphology (PCOM) and reached the age of 2 years between November 2012 and April 2018. Only singletons living in Belgium were eligible.
Participants/materials, setting, methods: Anthropometric parameters and health status data were collected at birth, 4 months and at 2 years in cohorts of singletons followed since birth. Singletons born after COS were randomly selected by a computer program for follow-up until young adulthood. Results were adjusted for neonatal (birth weight z-score, birth order), treatment (day and mode of transfer, number of embryos transferred) and parental (maternal smoking, age, BMI, anti-Mullerian hormone level, gestational diabetes, hypertensive disorder, paternal BMI) characteristics.
Main results and the role of chance: Mothers giving birth to a child conceived by IVM were younger than mothers in the control group, but their body mass index was comparable. The proportion of children born to mothers with PCO phenotype A was higher in the IVM group than in the COS group (48.7% versus 12.6%). Overall no differences were found for body weight, height and head circumference z-score between IVM and COS children at birth, at 4 months or at 2 years (all $P>0.05$). In addition, z-scores of waist and mid-upper arm circumference were comparable in IVM and COS children at 2 years of age. Adjustment for neonatal, treatment and parental characteristics did not change the outcome. Finally, although the hospital admission rate was higher among IVM children (34.2% versus 18%; $P=0.01$), the majority of the hospitalisations was for (minor) infectious pathology. The frequency of surgical interventions up to 2 years was not different between IVM children and peers born after ICSI ($P>0.05$). Comparing neonatal (birth weight), treatment (day of transfer, number of embryos transferred, mode of transfer) and maternal (age, BMI, AMH levels) characteristics between participating IVM and COS and non-participating IVM and COS children respectively, no differences were found.
Limitations, reasons for caution: Although our study describes the largest cohort to date of singletons born after IVM applied to mothers with a well-defined PCO phenotype, the current sample size only allowed to detect moderate differences in anthropometry. Also, follow-up of children born after IVM for other indications than PCO is highly recommended.
Wider implications of the findings: We did not observe adverse effects of IVM on health parameters in offspring up to 2 years of age when compared to COS without IVM, but future studies should focus on cardiovascular and metabolic outcomes in these children and adolescents given their mother's PCO status.
Trial registration number: not applicable

O-034 Perinatal outcomes from vitrified blastocysts following prolonged initial embryo culture

N. Gibson[1], B. Marron[2], C. Noble[1], R. Fleming[1], M. Gaudoin[3]

[1]GCRM, Laboratory, Glasgow, United Kingdom
[2]University of Glasgow, Medical, Glasgow, United Kingdom
[3]GCRM, Medical, Glasgow, United Kingdom

Study question: To compare the perinatal outcomes of vitrified day-6 blastocysts with vitrified day-5 blastocysts
Summary answer: The perinatal outcomes were similar, with a higher mean birthweight centile than expected, with a tendency to the day-6 blastocysts being heavier.
What is known already: Compared with cleavage stage embryos, births after transfer of blastocyst embryos are associated with increased incidence of babies who are "large for gestational age" (LGA), possibly due to the prolonged embryo culture to day-5. Day-6 blastocysts, with their 20% longer culture, are frequently cryopreserved and transferred in a subsequent cycle. Comparative studies between day-5 and day-6 vitrified blastocysts show variable outcomes in terms of warming survival, implantation rates and subsequent birth outcomes.
Study design, size, duration: Retrospective analysis of frozen embryo transfer treatment cycles from blastocysts vitrified on either day-5 or day-6 between September 2010 and December 2016 in a single UK centre. The day-5 group comprised 754 cycles in 580 women. The day-6 group comprised 177 cycles in 138 women.
Participants/materials, setting, methods: All vitrified blastocysts were subsequently transferred as if they were day-5 blastocysts. Cycles where day-5 and day-6 blastocysts were transferred together and cycles involving donated oocytes were excluded. Definitions: small for gestational age (SGA) is birthweight $<10^{th}$ centile for expected gestation; LGA is birthweight $>90^{th}$ centile (UK birthweight charts)
Main results and the role of chance: The day-5 group comprised 754 cycles in 580 women. The day-6 group comprised 177 cycles in 138 women. There was no difference in BMI or circulating AMH but the day-5 group were younger at the time of vitrification (34.5 ± 4.2 years vs. 35.7 ± 3.6, $P<0.001$). The proportion of embryos surviving the warming procedure was higher in the day-5 group (88% vs. 83%, $P<0.01$). There was no difference in the live birth rate (39.1% vs. 39.6%, $P=0.908$). When only singleton births were analysed, (day-5, N = 254; day-6, N = 54) there was no difference in mean birthweight (3488 ± 578g vs. 3558 ± 594g, respectively, $P=0.417$), gestational age at delivery (272 ± 15 days vs. 273 ± 14, $P=0.781$), birth centile (60 ± 28 vs. 65 ± 24, $P=0.254$), proportion of SGA (5.1% vs. 1.9%, $P=0.306$) or LGA (16.9% vs. 18.5%, $P=0.778$). Nevertheless there was a tendency for singletons resulting from the day-6 blastocysts to be heavier in absolute terms and larger

for gestational age, despite the mothers actually being older at the time of vitrification and subsequent embryo transfer.
Limitations, reasons for caution: The study population dates from when we started vitrifying embryos to the recent past and current survival rates are considerably higher. There were only 54 singleton live births in the day-6 group and a larger dataset is required to confirm the above findings.
Wider implications of the findings: Day-5 singletons (cf. cleavage stage) are heavier, possibly attributable to the longer culture media exposure. However, the longer-term potential epigenetic/health effects remain to be evaluated. Day-6 singletons, having had an additional initial 20% culture media exposure, showed a tendency to be bigger still, which could have longer-term health implications.
Trial registration number: Not applicable

O-035 Obstetric and perinatal risks in 8,368 singletons and 1,167 twins conceived after fresh and frozen blastocyst transfers in the Nordic countries – a CoNARTaS collaboration

A.L. Spangmose Pedersen[1], S. Opdahl[2], S. Malchau[3], E. Ginström Ernstad[3], L.B. Romundstad[2], W. Ulla-Britt[3], C. Bergh[4], A.K. Henningsen[1], A. Pinborg[1]

[1]*The Fertility Clinic- Copenhagen University Hospital- Rigshospitalet- Copenhagen-Denmark, Department of Obstetrics and Gynaecology, København, Denmark*
[2]*Norwegian University of Science and Technology- Trondheim- Norway, Department of Public Health and Nursing- Faculty of Medicine and Health Sciences, Trondheim, Norway*
[3]*Institute of Clinical Sciences- Sahlgrenska Academy, Department of Obstetrics and Gynaecology, Sahlgrenska, Sweden*
[4]*Reproductive Medicine- Sahlgrenska University Hospital- Gothenburg- Sweden, Department of Obstetrics and Gynaecology- Institute of Clinical Sciences, Gothenburg, Sweden*

Study question: Are obstetric and perinatal outcomes similar in children conceived after blastocyst (BT) and cleavage stage transfers (CT)?
Summary answer: Extended embryo culture to the blastocyst stage has the potential to compromise perinatal outcomes of the infants and to increase the risk of same-sex twins.
What is known already: Blastocyst transfer optimizes the selection of top-quality embryos and increases pregnancy and live birth rates per transfer. However, concerns have been raised as extended culture may increase obstetric complications and impair perinatal outcomes. Studies show higher risks of preterm birth (PTB) and large for gestational age (LGA) among infants conceived after BT compared with CT. Children conceived after BT are also prone to have a higher risk of monozygotic twins.
Study design, size, duration: Nordic registry-based cohort study including two cohorts: 69,751 singletons and 18,154 twins conceived after assisted reproductive technology (ART) in the Nordic countries. Herein 8,368 singletons conceived after BT and 61,383 singletons conceived after CT; Denmark including singletons born 1997-2014 (BT: n=1,152; CT: n=23,344), Norway 2010-2015 (BT: n=397; CT: n=6,686) and Sweden 2002-2015 (BT: n=6,819; CT: n=31,353). The twin cohort consisted of 1,167 children conceived after BT and 16,987 children conceived after CT.
Participants/materials, setting, methods: Data were obtained from the large Nordic cohort (Committee of Nordic ART and Safety - CoNARTaS) containing information from the national ART and Medical Birth Registries. Obstetric and perinatal outcomes, and risk of same-sex twinning after fresh and frozen BT and CT were compared using linear mixed model regression analyses to account for the correlation of outcomes amongst siblings. Adjustments were made for fertilization method (IVF/ICSI), sex, country, birth year, parity (first/later) and maternal age.
Main results and the role of chance: In the adjusted multiple regression analyses, singletons conceived after fresh BT had a higher risk of being LGA (adjusted odds ratio (aOR) 1.23 (95%CI 1.05; 1.44)) compared with fresh CT-singletons. Singletons conceived after frozen BT had a higher risk of PTB both when calculated based on the second-trimester ultrasonography (aOR 1.39 (95%CI 1.18; 1.65)) and from the day of embryo transfer (aOR 1.23 (95%CI 1.07; 1.40)) compared with frozen CT singletons. In singleton pregnancies a higher risk of placenta previa both after fresh (aOR 2.04 (95%CI 1.73; 2.41)) and frozen (aOR 1.68 (95%CI 1.16; 2.44)) BT compared with CT was observed. We found no excess risks of perinatal (aOR 1.08 (95%CI 0.65; 1.82)) nor neonatal deaths (aOR 1.20 (95%CI 0.74; 1.96)) comparing singletons conceived after BT and CT, fresh or frozen. Adjusted analyses showed a higher risk of twin births after single embryo BT compared with single embryo CT; for fresh cycles aOR was 1.79 (95%CI (1.48; 2.15) and for frozen cycles aOR was 1.30 (95%CI (1.05; 1.62), compared with single fresh or frozen CT. Furthermore, twins conceived after single embryo fresh BT had increased risk of same-sex twins (aOR 2.51 (95%CI 1.31; 4.82)) compared with single embryo fresh CT.
Limitations, reasons for caution: Retrospective cohort studies may have inadequate adjustment for potential confounding factors, however with this large controlled cohort we assume that residual confounding is limited. Though we were not able to adjust for years of infertility or type of cryopreservation in FET children (vitrification or slow freeze technique).
Wider implications of the findings: Blastocyst transfer is associated with a higher risk of PTB, LGA and placental complications. These results are important since an increasing number of all ART treatments are performed with BT.
Trial registration number: ISRCTN11780826

O-036 Growth of children born after frozen compared to fresh embryo transfer during the first five years

A. Terho[1], S. Pelkonen[1], S. Koivurova[1], J. Salo[2], R. Toikkanen[3], S. Nuojua-Huttunen[4], T. Pokka[2], M. Gissler[5], A. Tiitinen[6], H. Martikainen[1]

[4]*Gyneko, Private clinic, Oulu, Finland*
[5]*National Institute for Health and Welfare, Terveyden ja hyvinvoinnin laitos, Helsinki, Finland*
[6]*University of Helsinki, Obstetrics and Gynaecology, Helsinki, Finland*

Study question: Is the growth of term-born frozen embryo transfer (FET) children and fresh embryo transfer (fresh ET) children comparable until five years of age?
Summary answer: Childhood growth is similar between FET and fresh ET children after adjustments for age at measurement, maternal BMI and parity.
What is known already: Birth weights of FET children have been shown to be higher than fresh ET children's or even spontaneously conceived children's in multiple studies. Knowledge on the childhood growth patterns of these children is still very limited. There is some evidence of catch-down or catch-up growth for FET and fresh ET children, which might have implications on their long–term health.
Study design, size, duration: A prospective observational cohort of all term-born (gestational weeks 37-42) FET and fresh ET singletons born in Oulu University Hospital, Northern Finland, in 2006-2011, n=130 for FET and n=201 for fresh ET. After lost-to-follow-up and exclusion of subsequent births to the same mother, the group sizes were n=110 for FET and n=181 for fresh ET.
Participants/materials, setting, methods: Using unique personal ID codes given to every Finnish citizen/permanent resident, information on the infertility treatment, pregnancy and postnatal period were matched from the hospital database. Growth data were then obtained from municipal child health clinics. Mean weights, lengths/heights and head circumferences (HC) were compared between the groups at birth; 4, 8, 18 months; 3 and 5 years. Adjustments were made for exact age at measurement (gestational age at birth), maternal BMI and parity.
Main results and the role of chance: In our data there were no significant differences between FET and fresh ET children for birth weight (3537 and 3525 grams, respectively), length (50.3 and 50.3 centimeters) or HC (35.0 and 35.0 centimeters) after adjusting for gestational age at birth, maternal BMI and parity. There was a trend towards fresh ET children (especially girls) being heavier and taller with a larger HC at 4 months and taller with a larger HC at 8 months, but after adjusting for age at measurement, maternal BMI and parity, the difference was no longer statistically significant. After adjustments, fresh ET children had a larger HC (p=0.045) at 3 years, but this difference disappeared by 5 years of age. Fresh ET girls were significantly taller than FET girls at 3 years (p=0.034), but no longer at 5 years of age. There were no significant differences in other potential confounding factors such as maternal age, smoking, gestational diabetes, blood pressure disorders

or paternal height between the groups. Accurate pregnancy and growth data, including exact age at measurement, were available, as 99.6% of Finnish children are followed at the municipal child health clinics. Missing measurement values for each growth measurement point varied randomly between 1.4 and 12.4%.

Limitations, reasons for caution: Due to the single-center setting of our study, the study groups are limited in size. This should be taken into consideration when interpreting the results. However, Finland's unique, prospective, high-coverage, free-of-cost child health clinic follow-up made accurate information available for both groups, adding to the reliability of these results.

Wider implications of the findings: Similar childhood growth patterns between FET and fresh ET children give reassurance about the safety and feasibility of embryo freezing practice, thus enabling widespread use of single-embryo transfer policy.

Trial registration number: not applicable

O-037 Risk of higher blood pressure in 3 to 6-year-old singleton born with Ovarian Hyperstimulation Syndrome

Y. Fu[1], M. Tang[1], H. Yan[1], F. Zhang[1], X. Hu[1], L. Xing[1], Y. Zhu[1]

[1]Women's Hospital- School of Medicine- Zhejiang University, Department of Reproductive Endocrinology, Hangzhou, China

Study question: Does ovarian hyperstimulation syndrome (OHSS) produce an effect on blood pressure (BP) of preschool singleton born following IVF/ICSI?

Summary answer: Preschool singletons born following OHSS in the fresh embryo transplantation (ET) cycle showed higher systolic/diastolic blood compared with spontaneously conceived children and non OHSS children.

What is known already: A large registry-based study found the increasing disorders of cardiovascular and metabolism in IVF children but underlying mechanism is still unknown. OHSS, which shows high estrogen and progesterone during early pregnancy is considered as a good model to study the effects of ovarian stimulation and high sex hormone on the health and development of the offspring. Few studies have investigated any association between OHSS and cardiovascular or metabolic function in subsequent children. Of these studies, some indications of increased cardiovascular and cognitive dysfunction among OHSS-children need further investigation.

Study design, size, duration: The prospective, assessor-blinded study included 1780 women and their corresponding singletons after recruiting women who accepted IVF/ICSI and gave birth to single-births from 2003 to 2014. Follow-up has lasted more than 10 years, and is still ongoing. And we recruited 83 children spontaneously conceived children (SC) as the control group.

Participants/materials, setting, methods: We recruited 83 spontaneously conceived children, 126 children born to OHSS-ET women, 1069 children born to non OHSS-ET women, 98 children conceived by women who developed into moderate or severe OHSS after oocyte retrieval and selected the frozen-thawed embryo transfer (FET), 487 children conceived with non OHSS-FET. BP, heart rate, anthropometrics, and metabolic index of those children were assessed. We applied several multiple regression analyses to investigate the effect of OHSS in the early pregnancy.

Main results and the role of chance: By the single factor analysis, the systemic blood pressure (SBP) and diastolic blood pressure (DBP) in the SC group (SBP: 99.84±8.9; DBP: 55.27±8.8) were significantly lower than the OHSS-ET group (SBP:101.93±8.17; DBP: 58.75±8.48), while the blood pressure was similar between the SC group and other three ART group. Meanwhile the BP were significantly lower in the non OHSS-ET group (SBP: 99.49±8.91; DBP: 56.55±8.02) than in the OHSS-ET group. After using multiple regression analysis to adjust current, early life, parental and ART characteristics, the differences in both SBP and DBP (B (95% confidence interval)) between non OHSS-ET and OHSS-ET remained significant (SBP: -3.257 (-5.231 to -1.284); DBP: -3.084 (-4.920 to -1.248)). And the BP showed no significant difference complementary, when compared non OHSS-FET group with OHSS-FET group or non OHSS-ET group. In addition, the anthropometrics, fast glucose, serum lipid and thyroid index did not differ among the ART groups.

Limitations, reasons for caution: Office BP and heart rate measurements were performed twice on the single day without using gold standard assessment. The study did not perform further mechanism experiments, although OHSS may be an independent risk factor leading to elevated blood pressure in offspring.

Wider implications of the findings: It is the first large sample study to investigate the effect of OHSS on offspring by setting the OHSS-FET and non OHSS-FET control group. Meanwhile, It also provides a clinic evidence of the impact of early environment on the offspring's cardiovascular health.

Trial registration number: not applicable

O-038 Maternal age gradient in children's birth outcomes among mothers conceiving with Medically Assisted Reproduction

A. Goisis[1], A. Barbuscia[2], M. Myrskyla[3], P. Martikainen[4], H. Remes[4], E. Somigliana[5], K. Reija[6]

[1]University College London, Department of Social Science, LONDON, United Kingdom

[2]London school of Economics and Political Science, Social Policy, London, United Kingdom

[3]Max Plank Demographic Institute for Demographic Research, mpidr, Rostock, Germany

[4]University of Helsinki, Population Research Unit, Helsinki, Finland ; [5]Università degli Studi di Milano, Dept of Clinical Sciences and Community Health, Milano, Italy

[6]National Institute for Health and Welfare, Department of Children- Young People and Families, Helsinki, Finland

Study question: Are mothers who conceive through Medically Assisted Reproduction (MAR) at higher risk of poorer birth outcomes because they give birth at advanced maternal ages?

Summary answer: Amongst MAR mothers, the risk of poorer birth outcomes does not increase with maternal age at birth until very advanced maternal ages (40+).

What is known already: Existing evidence shows that children conceived through MAR are at higher risk of poorer birth outcomes. As many women undergo MAR treatments at advanced ages, which is itself a well-known risk factor for adverse birth outcomes, it has been suggested that the older age of MAR mothers might play an important role in the observed association between the use of MAR treatments and poorer birth outcomes. However, no existing large-scale study has directly tested this association.

Study design, size, duration: Finnish population register and other administrative registers. The base dataset was a 20% random sample of households with at least one child aged 0–14 at the end of 2000. This study included children who were born in 1995–2000 because the information on whether the child was conceived through MAR or naturally was available from 1995 onward.

Participants/materials, setting, methods: The outcome measures were whether the child had low birth weight (LBW, <2500 g at birth) and whether the child was delivered preterm (<37 weeks of gestation). Conception through MAR was identified from purchases of prescription medication from the National Prescription Register. Linear probability models were used to analyse and compare maternal age gradients in birth outcomes for mothers who conceived through MAR or naturally before and after adjustment for maternal characteristics.

Main results and the role of chance: A total of 56,026 children, of whom 2,676 were conceived through MAR treatments, were included in the study. Amongst mothers who conceived naturally, when compared with maternal ages 30-34 years, maternal ages of 35–39 years and ≥40 years were associated with percentage increases of 1.1 points (95% confidence intervals: 0.6, 1.6) and 1.5 points (95% confidence intervals: 0.5, 2.6), respectively, in the probability of low birth weight. In contrast, amongst mothers who used MAR to conceive, the risk increased by 6 percentage points (95% confidence intervals: 0.2, 12) for maternal ages ≥40 – who represent only 7% of mothers who conceive through MAR. Maternal ages 35-39 were not at increased risk of LBW (-1.3; 95% confidence intervals: -4.5, 1.8). Adjustment for maternal characteristics (i.e. if the mother suffered from acute/chronic conditions before pregnancy, household income and if the mother smoked during pregnancy) only marginally attenuated the associations. The results were similar for preterm delivery.

Limitations, reasons for caution: Limited number of confounders were included in the study because of the administrative nature of the data used in the study.

Wider implications of the findings: This is the first study to analyse and question the role of advanced maternal age in explaining the increased risk of poorer birth outcomes amongst children conceived through MAR. This question is of high importance in light of the widespread and increasing use of MAR treatments, especially among older women.

O-039 Planning IVF treatment in the context of female ageing

O-040 Poor ovarian reserve: Do adjuvant therapies really work?

F.J. Broekmans[1]

[1]*Broekmans- Frank J., Reproductive Medicine, Utrecht, The Netherlands*

Abstract text
Poor ovarian reserve: Do adjuvant therapies really work?

Frank J Broekmans,
Professor Reproductive Medicine and Surgery

Department for Reproductive Medicine

University Medical Center Utrecht

Assisted reproduction technology is applied as a treatment mode for couples with both explained and unexplained infertility. The first step in this treatment is the creation of multiple follicles with the purpose of obtaining the oocytes held within these follicles, creating embryos in the IVF laboratory and replacing the embryos into the uterine cavity. Ovarian stimulation is mostly applied by using exogenous FSH. The response of the ovaries to this exogenous FSH exposure demonstrates a high degree of variation.

From a clinical significance point of view the low ovarian response defined as the yield of less than 5 oocytes is related to an unfavourable prognosis for live birth. The low responder may either have not more than a few antral follicles available or may suffer from a too low FSH exposure to assure the development of all of a normal number of antral follicles present in the ovaries. This leads to a relevant difference between the 'expected' and 'unexpected' low responder, where the latter often has the better prognosis for live birth, although female age will have a crucial additional role here.

Most clinicians try to foresee the low ovarian response category in order to increase the FSH dosage and bring the ovarian response into the normal range (5-15 oocytes), with the expectation that the prospects of pregnancy for the couple will improve. FSH dosage adjustments will most frequently neither alter oocyte number nor improve live birth prognosis in the low responder, especially when the condition is expected, for instance when the AMH or AFC is very low, or in case of female age above 38 years.

Regarding options to enlarge the number of antral follicles by factors that affect the continuous recruitment of follicles from the primordial follicle pool, research has focussed on the paracrine system that regulates this autonomous process. To subtly interfere herein is not easy, and compounds that could alter paracrine settings have sofar failed to show an obvious benefit. Yet many of adjuvant factors researched in fact lean on indirect changes in FSH exposure, thereby negating the relative limited role for FSH in the continuous recruitment.

For drugs like aromatase-inhibitors, oestrogen receptor modulators, androgens, aspirin, LH or growth hormone, effects on oocyte yield in subsequent or concomitant FSH ovarian stimulation have not been consistent or even clearly absent, as are any benefits for prognosis. This may urge for more in-depth research in the feasibility of outside manipulation of this process. Part of this research focusses on 'rejuvenation' of the ovary from its near-depleted state, simply by mechanical tissue disrupture, or by intra-ovarian instillation of paracrine growth factors. All these options are now awaiting rigorous scientific proof of efficacy.

[4]*Department for Reproductive Medicine, Ghent University Hospital, Ghent, Belgium*

Abstract text
ESHRE has been developing guidelines since 2010, based on a structured evidence-based approach, which is considered the gold standard of medical guidance. Evidence-based guidelines are primarily based on high quality evidence, and are appropriate for areas where such evidence is available for most of the guideline's key questions. Guideline groups can formulate strong and conditional recommendations, depending on the quality of the supporting evidence and other factors including patient perspective, healthcare context and clinicians' expertise. For some topics in the field of Human Reproduction and Embryology, it became clear that an adapted methodology and nomenclature would be appropriate. Therefore, ESHRE has recently developed a manual for the development of (consensus-based) recommendations for good practice. The methodology described is more applicable in areas where there is an opportunity to reduce uncertainty and improve quality of care, but where evidence for most aspects is absent or limited. Topics for recommendations for good practice are different and often more practically oriented than these for evidence-based guidelines. During the presentation, the ESHRE methodology for development of recommendations for good practice, the rationale, and the differences and similarities with evidence-based guidelines, will be discussed. This presentation will be an introduction to the presentation of 2 papers based on the methodology on transvaginal oocyte pick up and ectopic pregnancy.

Abstract text
Study Question: What is good practice in ultrasound, and more specifically during the different stages of transvaginal oocyte retrieval?

Summary Answer: This document provides good practice recommendations covering technical aspects of transvaginal oocyte pick up.
What Is Already Known: Ultrasound guided transvaginal oocyte pick up is a widely performed procedure, but standards for best practice are not available.
Study Design Size, Duration: A working group collaborated on writing recommendations on the practical aspects of transvaginal oocyte pick up.
Participants/Materials, Setting, Methods: This document focused on transvaginal oocyte pick up. Further documents in this series will provide recommendations for other ultrasound procedures in infertility and assisted reproduction.
Main Results And The Role Of Chance: The document presents general recommendations for transvaginal oocyte pick up, and specific recommendations for its different stages, including prior to, during and after the procedure. In addition, information is provided on equipment and materials, possible risks and complications, audit and training.
Limitations Reasons For Caution: The recommendations of this paper were mostly based on clinical expertise as at present only few clinical trials have focused on the oocyte retrieval techniques, and almost all available data are observational. In addition, studies focusing on oocyte pick up were heterogeneous with significant difference in techniques used, which made drafting conclusion and recommendations based on these studies even more challenging.
Wider Implications Of The Findings: These recommendations complement previous guidelines on the management of good laboratory practice in assisted reproduction techniques. Some useful troubleshooting/checklist recommendations were given for easy implementation on clinical practice. These recommendations were aimed to contribute to the standardization of a rather common procedure which is still performed with great heterogeneity.

Abstract text
Current serum biomarkers of reproductive potential, such as follicle-stimulating hormone, oestradiol, and anti-Müllerian hormone (AMH), are used to estimate the number of growing follicles in the ovary and to predict the ovarian response to gonadotropin stimulation during assisted reproduction. However, these biomarkers are not derived from the oocyte, and hence only provide an indirect assessment of oocyte function. They provide no information on oocyte quality, which is the rate-limiting factor in female fertility. Bone morphogenetic protein-15 (BMP15) and growth differentiation factor-9 (GDF9) are essentially secreted solely by the oocyte, and are critical for folliculogenesis, oocyte quality and fertility, making these ideal candidates as biomarkers of oocyte function. However, measurement of BMP15 and GDF9 is difficult as serum concentrations of these proteins are expected to be low/undetectable, as these are locally-acting growth factors, and each adult ovary has only ~300,000 oocytes, with the majority of these in a quiescent state. Furthermore, BMP15 and GDF9 exhibit unusual structural variations, including non-covalent dimersation, and there are few molecular tools available to detect these. Currently, there are no validated means to quantitate their concentrations in serum. Our research program aims to develop and validate assays to measure BMP15 and GDF9 in female serum and to investigate their use as biomarkers of female reproductive function. Enzyme-linked immunosorbent assays (ELISAs) for BMP15 and GDF9 were developed in-house and validated for specificity (<0.01% and <0.03%, respectively), sensitivity (24 and 26 pg/ml, respectively) and reproducibility. Recombinant protein standards diluted in parallel with serum samples in dose-response experiments, and serum BMP15 and GDF9 were stable after 3 repeated freeze thaw cycles (1 and 10% reduction in detection, respectively). Validated ELISAs were applied to serum samples from women undergoing infertility treatments (n=154), and from peri- and post-menopausal women (n=28). BMP15 and GDF9 were determined in women relative to age, AMH and number of oocytes retrieved after superovulation for IVF. Serum BMP15 and GDF9 were detectable in 61% and 29% of women, respectively. BMP15 and GDF9 varied 64- and 15-fold, respectively, between women but did not change within an individual during ovarian stimulation with gonadotropins. Furthermore, there was no difference is serum BMP15 or GDF9 between women relative to ovarian stimulation treatment, or between stimulated and unstimulated women. Serum GDF9, but not BMP15, correlated with the number of oocytes retrieved (p=0.058) and was significantly lower in poor responders (p=0.032). Conversely, and where detectable, serum BMP15, but not GDF9, was significantly lower in women over 55 years, compared with women of reproductive age (p=0.018). There was no association between AMH and either of these growth factors. This is the first study to develop and validate assays to quantitate BMP15 and GDF9 in human serum, and to correlate concentrations with female reproductive potential. As oocyte paracrine factors, predictably, BMP15 and GDF9 concentrations were low in serum, in the pg/ml range, several orders of magnitude lower than AMH, making them undetectable in some women with this first-generation assay. Although assay sensitivities require improvement, this study demonstrates the diagnostic potential of oocyte-secreted BMP15 and GDF9 as serum biomarkers in reproductive medicine.

INVITED SESSION

SESSION 11: FERTILIZATION IN THE RESEARCH AND HUMAN IVF LABORATORIES

Monday 24 June 2019 Haydn 4 11:45–12:45

O-045 Breakthroughs in human fertilization

E. Bianchi[1], G. Wright[1]

[1]*Wellcome Sanger Institute, Cell Surface Signalling Laboratory, Hinxton- Cambridge, United Kingdom*

Abstract text
The Molecular basis of sperm-egg recognition
In sexually reproducing species, fertilization represents the first step toward the generation of a new genetically distinct individual. Male and female gametes, which in mammals possess very distinct features, have to recognise and fuse with one another for fertilization to be successful. Spermatozoa are constantly produced in large numbers: they are small motile cells with a densely packed DNA, very scarce cytoplasm and a tail that propels them along the female reproductive tract. The oocytes are rare, with only a few hundred produced over the entire reproductive life of an individual, have a large cytoplasm to support the early embryonic developmental stages, are immotile, and protected by a mesh made of glycoproteins (the Zona Pellucida, ZP). After migrating along the female reproductive tract, the sperm become capable of penetrating the oocyte, the first gamete interaction is the binding of the sperm to the ZP, followed by the passage through the ZP and into the perivitelline space. The last essential step before fusion is the binding of the cell membranes of sperm and egg. Cell fusion finally begins in the equatorial region of the sperm head and guarantees the delivery of the paternal DNA inside the maternal cytoplasm.

It is remarkable that the accurate descriptive knowledge that we have about fertilization does not correspond to a comparable level of understanding of the molecular events. The interactions established by cell surface proteins are

often weak and transient making them challenging to deal with using standard biochemical methods, in particular biochemical purifications that often employ stringent washing and denaturing conditions. This biochemical feature, together with the paucity of biological material, especially the very limited number of oocytes, have hindered the identification of membrane proteins required for the sperm-egg interaction. Only three cell surface proteins are known to be essential for fertilization: the binding pair JUNO and IZUMO1, and CD9. IZUMO1 is displayed on the head of acrosome-reacted sperm and binds the egg protein JUNO. Soon after fertilization, JUNO is lost from the egg membrane of mouse oocytes suggesting that it might be involved in establishing the membrane block to polyspermy. We have also shown that JUNO and IZUMO are necessary for sperm-egg binding but are not sufficient to induce fusion of the cell membranes, it is therefore likely that other proteins take part in this process. Alongside JUNO and IZUMO, the third protein known to be essential for fertilization is CD9. The similarity with other proteins of the tetraspanin family, its dynamic localization during fertilization, and the aberrant microvilli in mouse eggs lacking CD9, suggest that it plays a structural role in the organization of the egg cell surface.

Recently, a cell surface protein (HAP2) able to induce fusion in lower eukaryotes that is not conserved in mammals has been identified; moreover, a novel molecule named Bouncer required for fertilization in fish has also been discovered. With the interest raised by these discoveries and the development of biochemical methods becoming more and more sensitive, it is likely that the role of novel proteins will be elucidated in the next future. Undoubtedly the biggest unsolved question remains the identity of the molecule(s) inducing fusion of sperm and egg.

O-046 The first 24 hours of human development in vitro

M. Montag[1]

[1] *ilabcomm GmbH, CEO, Sankt Augustin, Germany*

Abstract text

The first 24 hours of the human embryo roughly comprise the journey of the human oocyte and sperm cell, from the time of fertilization until the initiation of the first cleavage generating the 2-cell stage embryo. In preparation for fertilization the oocyte has completed the first meiotic division and extruded the first polar body. The oocyte is arrested at metaphase-II by specific kinases and the paired chromatids are lined up in the metaphase-II spindle. This spindle-chromatid complex is usually located in the ooplasm at a position, which is underneath the first polar body. Fertilization itself is not a singular event – it is a complex course of ordered events that play into each other and are called the fertilization cascade. It is initiated by the presence of the sperm cell and by sperm-specific proteins that activate the oocyte and cause resumption of meiosis. Thus it is the sperm cell that ultimately activates the oocyte and triggers completion of the final maturation step. Oocyte activation causes that the block of the metaphase-II spindle is released enabling the spindle to initiate it´s main function: separation of the aligned chromatids, which gives rise to two sets of chromatids. One set remains inside the oocyte and the other set is extruded into the newly forming second polar body by the microtubules of the spindle. The process of formation of the second polar body usually takes around 1.5 to 3.5 hours the sperm has entered the oocyte. The formation of the female and male pronuclei is initiated at the same time. Both pronuclei can be seen as early as 4 to 5 hours after insemination. The male pronucleus is initially located close to the site where the sperm has entered the ooplasm or had been injected, whereas the female pronucleus is located underneath or close to the position where the second polar body was extruded. Over time, both pronuclei will enlarge and will be positioned by the oocyte´s cytoskeleton in the center of the oocyte. Once the entire DNA of each pronucleus is fully replicated and the pronuclei are positioned next to each other, the cell cycle machinery will get ready for the first cleavage to generate the 2-cell stage embryo. The nuclear membrane of both pronuclei will start to dissolve, the male and the female chromosomal material will be no longer separated, whereby forming the genome of the new embryo. For the process, which has been outlined above, many of the molecular and cellular events have been characterized. Using different imaging technologies we are able to visualize one or the other of these event and to follow the course of the very early development. At the same time we are able to detect deviations from the normal course. Such deviations may be linked to a patient factor, but they can also be an effect of suboptimal conditions in the laboratory. Therefore the normal development of the human embryo in the first 24 hours will be presented in conjunction with some of the key elements that are of prognostic and / or therapeutic importance.

SESSION 14: NURSES/MIDWIVES INVITED SESSION: COMMERCIALISATION OF EGG FREEZING: A DEBATE

Monday 24 June 2019 Haydn 3 14:00–15:00

O-051 Pro

Z. Gurtin[1]

[1] *University College London, Institute for Women's Health, London, United Kingdom*

Abstract text

Over the past decade, oocyte cryopreservation for elective reasons, more commonly referred to as 'social egg freezing', has grown exponentially. As we have recently begun to learn from qualitative studies, increasing numbers of women each year - in the US, Britain, Israel, Denmark, and more - are choosing to freeze their eggs, citing not being in a relationship, or "not being in the right relationship to have children", as the main reason for wishing to preserve their fertility for the future. While some women in the US are able to receive company or insurance-funded egg freezing, the great majority of egg freezing cycles around the world are offered in a private market, and paid for out of individuals' own pockets. That egg freezing has become commercialised is an undeniable reality. Indeed, this reproductive technology – appealing and marketed to a much broader population than traditional patients requiring fertility treatments – requires us to think critically about how to respond to such a commercialisation. In this talk, I will outline how a pragmatic and ethical response to social egg freezing must first accept the commercial nature of technology, before suggesting specific guidelines and recommendations for its practice.

O-052 Contra

G. Pennings[1]

[1] *Bioethics Institute Ghent (BIG) Ghent University, Department of Philosophy, Gent, Belgium*

Abstract text

The past decades, egg freezing has evolved from an experimental technique towards a clinically acceptable method to preserve the reproductive potential

of women of reproductive age. Today, it can offer a solution for women who risk to become infertile due to a medical treatment such as chemotherapy. In addition, it can be used by women who want to postpone motherhood for other reasons, for example because they have not found the right partner yet. While there might be several good reasons to freeze eggs to enhance women's reproductive life span, it nevertheless remains a medical procedure that requires proper counseling and the provision of correct, objective information.

Nowadays, there are several worrying tendencies that illustrate that egg freezing is increasingly being commercialized. Aggressive television campaigns and advertisements with flashy slogans are trying to convince women of all ages to freeze their eggs. In some countries, 'egg freezing parties' are being held to promote the technique and some multinationals even publicly announced that they are willing to pay the procedure of egg freezing for their female employees. In Spain, calls have even been made that in the future all women should freeze their eggs. This commercialization is worrying for several reasons.

First of all, the commercialization leads to misinformation and underestimation of the risks of the procedure. It creates the wrong perception as if egg freezing is recommended for women of all ages and situations while it is actually only needed and advisable for a selected group of women. Moreover, egg freezing is often 'sold' as a success formula with an almost 100% success rate, while in reality the chances of success are limited and depend on a number of factors.

Secondly, one can voice serious criticism on the way in which egg freezing is sold as a way to help women to combine their career and child wish. There is indeed a growing tendency for women to postpone having children. This may partly relate to women's individual life course, but it is also linked to social structures that make it difficult for women to have children at a young age. One cannot pretend to solve such a complex social problem with a purely medical solution such as egg freezing. There should be political and societal solutions that enable women and men to combine both a career and a family life.

Thirdly, egg freezing is part of a broader tendency of commercialization in healthcare. However, the decision as to who can use egg freezing should not be made by the free market. Women should have the right to use this technique, but they must be able to trust that it is done in a proper scientific way and within an ethically correct framework. In conclusion, egg freezing is a valuable medical technique that can be used to enhance the reproductive life span of certain women. However, it concerns a delicate and nuanced subject and therefore commercialization should be avoided. Consequently, clear international guidelines are urgently needed.

INVITED SESSION

SESSION 15: OOCYTE AGEING IN VIVO AND IN VITRO

Monday 24 June 2019 Haydn 2 14:00–15:00

O-053 Oocyte quality during reproductive aging: Are the chromosomal abnormalities the only problem

S. Ledda[1], **D. Bebbere**[1]

[1] *University of Sassari, Department of Veterinary Medicine, Sassari, Italy*

Abstract text

The negative correlation between age and fertility is well established in the scientific literature. Reproductive aging involves declines both in oocyte number and developmental capacity. Although part of the declining developmental competence can be ascribed to increased meiotic errors, other factors such as mitochondrial or metabolic dysfunction, abnormal gene expression or epigenetic dysregulation may play important roles. As oocyte maturation, fertilization and the earliest phases of embryo development occur in absence of transcription, they rely exclusively on maternal macromolecules deposited during oocyte growth, and are essentially under "maternal command". In addition, the oocyte is crucial for a proper definition of the embryo epigenome, as it regulates the two major DNA methylation reprogramming events during gametogenesis and early embryogenesis. The crucial remodelling of the oocyte epigenetic baggage during oogenesis often overlaps with potential interfering events, and advanced reproductive age was seen to increase the probability of occurrence. As the underlying molecular mechanisms remain poorly understood, studies in large animal models may deepen current understanding, to be potentially translated to human applications. We focused on the molecular mechanisms that shape oocyte developmental competence and that may be involved in reproductive aging using a sheep model. The expression of Maternal Effect Genes (MEGs), genes involved in epigenetic reprogramming (DNA methylating and demethylating enzymes) and DNA methylation dynamics were evaluated during oogenesis and early embryo development. MEGs code for a special class of maternal transcripts, expressed exclusively in oocytes and early embryos and required for post fertilization early cleavage. The analysed MEG panel comprised the components of the Subcortical Maternal Complex (SCMC), a multiprotein complex uniquely expressed in mammalian oocytes and early embryos, essential for zygote progression beyond the first embryonic cell divisions. The SCMC orchestrates multiple developmental events during oocyte-to-embryo transition, including embryonic genome activation (EGA), F-actin dynamics, genome stability, organelle organization, and DNA methylation. Mounting evidence indicates that these highly conserved maternal genes might contribute to human reproductive disorders and recurrent early embryo loss. We described a fine temporal regulation in MEG storage during folliculogenesis, with gene-specific patterns, and in methylation dynamics in terms of global methylation, hydroxymethylation and expression of the enzymes involved in their remodelling. Analysis over oocyte *in vitro* maturation and in a model of differential quality showed reduced abundance in low competence gametes for transcripts involved in several functions (MEGs, housekeeping genes, genes involved in pluripotency and cell cycle regulation); among them, a SCMC component (*KHDC3*), resembling what observed in MII oocytes of aged women (*NLRP5*). The association between developmental competence and maternal transcript dynamics was most evident in cleavage-stage embryos, as EGA approaches. Early embryos derived from developmentally incompetent oocytes consistently showed delayed transcript degradation, including SCMC components. We propose that the molecular shortage in the low competence oocyte impairs the early pathways of maternal mRNA clearance in the embryo, hindering further transition to EGA. The abnormal transcript persistence interestingly recalls the delayed developmental kinetics often observed in low quality oocytes in vitro. The epigenetic status of these embryos was affected as well, as the expression of genes involved in DNA demethylation (TETs) and relative cofactors (MBD1 and MBD3) was altered. The effect of maternal age on oocyte developmental competence has a high level of complexity and may be influenced by various maternal and environmental factors through interconnected mechanisms. While chromosome abnormalities, mitochondrial and metabolic dysfunction and production of oxygen radicals have already been described as implicated in poor oocyte quality associated with maternal age, less information is available on the molecular picture during oogenesis. Correct molecular storage during folliculogenesis and maternal transcript dynamics during early embryonic development appear to be closely associated with developmental competence.

O-054 The impact of DNA damage on oocytes and eggs

K. Jones[1]

[1] *University of Adelaide, Faculty of Science, Adelaide- SA, Australia*

Abstract text

The impact of DNA damage on oocytes and eggs

Mammalian oocytes are long-lived cells. The time between their creation in the fetal gonad and their eventual fertilization following ovulation can span up to 40-45 years. Here I explore the relationship between DNA damage and aging at distinct points in the life of the oocyte. Programmed DNA breaks occur systematically across the genome early in the life of the oocyte as part the process of meiotic recombination. These breaks, and then their subsequent repair, is an essential feature of mixing chromosomal content and tethering together the two pairs of homologous chromosomes that go on only to separate at the completion of meiosis I. However subsequent to recombination any DNA damage has the potential of being deleterious to the maturing oocyte or the embryo. Here I discuss the impact of DNA damage, principally double strand breaks, at two distinct timepoints in the life of the oocyte. Also, I reflect on the influence of maternal age in these processes. Firstly, in primordial follicles, where acute radio- or chemo-therapy damage can result in loss of oocytes, through activation of pro-apoptotic proteins. Even without exogenous insult primordial follicles appear to experience continual

DNA damage and interestingly the ability of oocytes to repair such damage declines with maternal age. Secondly, in fully grown oocytes at the germinal vesicle stage, where DNA damage will arrest maturing oocytes at metaphase of meiosis I. As such oocytes carrying DNA double strand breaks often fail to fully mature into eggs. Here oocytes appear to have an unusual ability to switch on the Spindle Assembly Checkpoint in response to DNA damage. This cellular checkpoint pathway is present in all cells but is normally activated by incorrect attachment of chromosomes to microtubules on the spindle. We currently do not understand mechanistically how DNA damaged oocytes use this pathway. However interestingly this checkpoint is compromised with maternal aging. As such one can expect an increase in mature eggs with DNA damage from older females. Although many of the above observations have been performed on mice, there are likely important clinically relevant points worthy of considering. These would be with respect to the impact of DNA damage on the ovarian reserve and the quality of oocytes remaining within the ovary at advanced maternal age, as well as the ability to recover more DNA damaged mature eggs from older females.

SESSION 16: ESHRE GUIDELINE ON OVARIAN STIMULATION

Monday 24 June 2019 Haydn 4 14:00–15:00

O-055 Report of the GDG Ovarian stimulation. The LOW responder: Time to stop dreaming!!

F.J. Broekmans[1]
[1]*Broekmans- Frank J., Reproductive Medicine, Utrecht, The Netherlands*

Abstract text
The LOW ovarian responder: time to stop dreaming?

Frank J Broekmans,
Professor Reproductive Medicine and Surgery
Department for Reproductive Medicine
University Medical Center Utrecht

In Assisted Reproduction Technology, the first step is the creation of multiple follicles with the purpose of obtaining the oocytes held within these follicles, creating embryos in the IVF laboratory and replacing the embryos into the uterine cavity. Ovarian stimulation is mostly applied by using exogenous FSH. The response of the ovaries may demonstrate a high degree of variation. The low ovarian response defined as the yield of less than 5 oocytes is generally related to an unfavourable prognosis for live birth. The low responder may either have not more than a few antral follicles available or may suffer from a too low FSH exposure to assure the development of all of a normal number of antral follicles present in the ovaries. This leads to a relevant difference between the 'expected' and 'unexpected' low responder, where the latter often has the better prognosis for live birth, although female age will have a crucial additional role here. Recent studies have revealed that when cumulative live birth rates are studied, the prognosis for the several subgroups of low responders m.ay not be so cumbersome as frequently concluded from single cycle studies. Most clinicians try to foresee the low ovarian response category in order to increase the FSH dosage and bring the ovarian response into the normal range (5-15 oocytes), with the expectation that the prospects of pregnancy for the couple will improve. FSH dosage adjustments will most frequently neither alter oocyte number nor improve live birth prognosis in the low responder, especially when the condition is expected, for instance when the AMH or AFC is very low, or in case of female age above 38 years. Regarding options to enlarge the number of antral follicles by factors that affect the continuous recruitment of follicles from the primordial follicle pool, research has focussed on the paracrine system that regulates this autonomous process. For drugs like aromatase-inhibitors, oestrogen receptor modulators, androgens, aspirin, LH or growth hormone, favourable effects on oocyte yield in subsequent or concomitant FSH ovarian stimulation have not been consistent or even clearly absent, as are any benefits for prognosis for live birth. This may urge for more in-depth research in the feasibility of outside manipulation of this process. Part of this research focusses on 'rejuvenation' of the ovary from its near-depleted state, simply by mechanical tissue disrupture, or by intra-ovarian instillation of paracrine growth factors. All these options are now awaiting rigorous scientific proof of efficacy. Until these new options have become a breakthrough, we may realise that especially the fate of low responder with a low antral follicle reserve cannot be changed.

SESSION 17: NEW PERSPECTIVES IN DIAGNOSIS AND TREATMENT OF UTERINE PATHOLOGIES

Monday 24 June 2019 Strauss 1+2 14:00–15:00

O-057 The accuracy of three-dimensional ultrasonography and magnetic resonance imaging in the diagnosis of congenital uterine anomalies based on ESHRE/ESGE Classification System

O.E. Dogan[1], **Y.E. Cekdemir**[2], **D. Acar Sayım**[1], **U. Mutlu**[2], **C. Altay**[2], **M. Seçil**[2]
[1]*Dokuz Eylul University, Obstetrics and Gynecology, İzmir, Turkey*
[2]*Dokuz Eylul University, Radiology, İzmir, Turkey*

Study question: What is the accuracy of three dimensional ultrasonography (3D-US) and magnetic resonance imaging (MRI) in diagnosing congenital uterine anomalies (CUA) according to the ESHRE/ESGE classification?
Summary answer: 3D-US is almost as accurate as MRI in diagnosing CUAs with the ESHRE/ESGE classification. However, MRI may have better performance for borderline anomalies.
What is known already: Two-dimensional ultrasound (2D-US) is the primary tool for diagnosing CUA, with a limited accuracy, especially in differentiating anomalies like septate and bicornuate uteri where visualization of the outer uterine contour in the coronal section is necessary. Having the advantage of scanning coronal section, both MRI and 3D-US has increased ability to precisely diagnose CUA. 3D-US has the advantage of being more available and cheaper compared to MRI. Endoscopic evaluation, as either laparoscopy and/or hysteroscopy, which was accepted traditionally as the "gold standard" in diagnosing CUA is being used less after the implementation of these 2 imaging modalities.
Study design, size, duration: Prospectively collected data was retrospectively analyzed derived from 27 patients presumably diagnosed with CUAs for a period of 6 months admitting to the gynecology department. The presence and type of uterine malformation was made in accordance with the ESHRE/ESGE classification system. American Society of Reproductive Medicine (ASRM) classification was also used for comparison.
Participants/materials, setting, methods: Patients with history of infertility, recurrent abortion or having suspicious findings for presence of CUA on examination or hysterosalpingography were selected. After performing 2D-US, patients were referred to the radiology department for the evaluation by 3D-US and MRI. Final diagnosis was provided by hysteroscopy and/or laparoscopy in indicated patients. Patients with uterine septum (U2) hysteroscopic septum resection was done. Cervical septum was preserved in patients with C1 anomaly, however longitudinal vaginal septa (V1) were excised.
Main results and the role of chance: The most common CUA was septate uterus (U2A-B; 66.67%, n=18). The incidences of other anomalies were: normal uterus (U0; 7.41%, n=2), dysmorphic uterus (U1A; 3.70%, n=1), bicorporeal uterus (U3a-b-c; 14.81%, n=4), unicorniate uterus (U4; 3.70%, n=1) and aplastic uterus (U5; 3.70%, n=1). Compared with MRI, 3D-US had

a sensitivity of 96.3%, and a false positivity of 3.7% in diagnosing uterine anomaly. One patient misdiagnosed as partial uterine septum (U2aC0V0) by 3D-US turned out to be normal (U0C0V0) under MRI. Cervical anomalies were: 3 (11.11%) septate (C1), 1 (3.70%) double cervix (C2), 2 (7.41%) unilateral dysplasia (C3) and 1 (3.70%) aplasia (C4). Three patients (11.11%) had longitudinal non-obstructing vaginal septum (V1), one (3.70%) had transverse vaginal septum (V3) and another (3.70%) had vaginal aplasia (V4). 3D-US and MRI both detected these anomalies excellently giving 100% accuracy. Nine cases (33.3%) of arcuate uterus (Class VI) were diagnosed according to ASRM classification, which were all diagnosed as partial uterine septum by ESHRE/ESGE classification. Four patients (14.8%) had partial bicornuate (Class IVb), which were diagnosed as complete septate, partial bicorporeal (n=2), and bicorporeal septate with the ESHRE/ESGE system. Diagnostic accuracy of 3D-US in detecting CUAs was excellent with a Kappa index of 0.93 ($p<0.001$).

Limitations, reasons for caution: Present study implies that 3D-US is as accurate as MRI, but latter may have better diagnostic performance in borderline cases or in rare type of anomalies. MRI has the advantage of diagnosing associated renal anomalies. Small number of anomalies other than septate and bicorporeal was the limitation of the study.

Wider implications of the findings: 3D-US displays a satisfactory level of agreement with MRI in the diagnosis of CUAs based on ESHRE–ESGE system. Our results are in accordance with the existing literature showing the non-inferiority of 3D-US. Therefore, as being cheaper and more available than MRI, 3D-US may be proposed as the non-invasive "gold-standard".

Trial registration number: 2019/01-50 is the trial registration number obtained from the clinical ethical committee of Dokuz Eylul University

O-058 Septum resection in women with a septate uterus: a cohort study

Study question: Does hysteroscopic septum resection improve reproductive outcome in women with a septate uterus?

Summary answer: In women with a septate uterus, septum resection does not increase live birth, nor does it decrease miscarriage and preterm birth compared with expectant management.

What is known already: A septate uterus is the most common uterine anomaly with an estimated prevalence of 2.5% in women of reproductive age. Women with a septate uterus are at increased risk for miscarriage, infertility and preterm birth. Currently guidelines recommend to surgically remove the intrauterine septum, but the underlying evidence is missing.

Study design, size, duration: We performed an international multicentre cohort study for which we collected data of 245 women with a septate uterus in 21 centres in the Netherlands, USA and UK. We identified women both prospectively (from September 2015 to July 2018) and retrospectively (from 2000 to August 2018) by searching electronic patient files.

Participants/materials, setting, methods: We included women with recurrent miscarriages, subfertility, previous preterm birth or without reproductive problems, who were diagnosed with a septate uterus. Women without an active wish to conceive or with a contra-indication for surgery were not eligible. Primary outcome was live birth. Secondary outcomes were miscarriage and preterm birth. To account for differences in patient population and follow up time we used multivariable Cox regression analysis and expressed differences as hazard rate ratios (HRR) .

Main results and the role of chance: In total, 260 women were included in the cohort. At the time of writing the abstract we missed complete case report forms of 12 women, such that 248 women were eligible for analysis.

Among the 148 women with a septum resection mean age was 32.2 years (SD 4.4), mean BMI was 25.5 (SD 5.1), 11 smoked (7.5%), 90 had at least one previous miscarriage (60%) and 36 (24%) had a previous live birth. Among the 100 women without a septum resection, mean age was 31.1 years (SD 4.7), mean BMI was 24.8 (SD 5.2), 5 smoked (5.1%), 50 had at least one previous miscarriage (50%) and 37 (37%) had a previous live birth. The live birth rates were 51% (76/148) following resection versus 71% (71/100) following expectant management (HRR 0.71, 95% CI 0.49 to 1.04). The number of women with at least one miscarriage was 49/148 (33%) versus 28/100 (28%) (HRR 0.98, 95% CI 0.59 to 1.64). Pre-term birth occurred in 25/76 (33%) versus 28/71 (39%) of the live births (RR 1.18, 95% CI 0.52 to 2.67). Hazard rates were adjusted for female age, BMI, smoking, previous miscarriages and previous live birth.

Limitations, reasons for caution: This was a non-randomised study. Despite correcting for the most important patient characteristics, our estimates might be confounded.

Wider implications of the findings: Our results suggest that in women with a septate uterus septum resection does not lead to improved fertility and pregnancy outcomes compared to expectant management.

Trial registration number: not applicable

O-059 A systematic review on reproductive outcomes after surgical treatment of asherman syndrome (AS)

T.C. Li[1], E.J. Guo[1,2], J.P.W. Chung[1], L.C.Y. Poon[2]

[1]Prince of Wales Hospital, Assisted Reproductive Technology Unit- Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

[2]Prince of Wales Hospital, Fetal Maternal Medicine Unit- Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: To assess the pregnancy outcomes in women who conceived following hysteroscopic surgical for AS

Summary answer: Pregnancy following surgical treatment of AS was associated with a number of adverse obstetric complications, including but not limited to placenta accrete syndrome.

What is known already: The reproductive outcome of women who underwent hysteroscopic adhesiolysis has been reported in a number of studies. However, the results are rather variable for a number of reasons. Firstly, there are a number of confounding variables including the severity of AS, recurrence of the adhesions after surgery, duration of follow up and co-existence of other infertility factors. Secondly, many of the reported series consisted of small numbers with a relatively wide confidence interval.

Study design, size, duration: This is a systematic review of 54 papers of variable quality searched from 3 databases including PubMed, Web of Science and Cochrane Library from the inception to April 2018 without restriction of regions, publication types or languages. Studies of pregnancy after AS, which included complications in the antenatal, intrapartum and postnatal period as well as neonatal complications were included in this review.

Participants/materials, setting, methods: Fifty-four studies including 4953 (4640 follow up) cases fulfilled the inclusion criteria and were included in the final analysis. All of the publications were full-text studies.

Main results and the role of chance: The pooled rate of pregnancy was 50.7% (95% CI [confidence interval]: 49.1 to 52.3) in 53 studies, early pregnancy loss was 17.7% (95% CI : 15.9 to 19.6) in 31 studies, ectopic pregnancy was 4.2% (95% CI: 2.8 to 6.3) in 9 studies, mid-trimester loss was 11.5% (95% CI: 7.6 to 17.8) in 7 studies, cervical incompetence was 12.5% (95% CI: 3.3 to 33.5) in 2 studies, placenta accrete syndrome was 10.1% (95% CI: 8.6 to 11.8) in 23 studies. The pregnancy rate in women with severe adhesion was significantly (P= 0.021) lower than that of women with mild adhesion.
Limitations, reasons for caution: The lack of consensus with regard to the use of post-operative adjuvant treatment to prevent adhesion reformation preclude a meta-analysis at the present time.
Wider implications of the findings: The findings may be used to counsel women with AS before surgical treatment and for planning antenatal care after conception.
Trial registration number: No.

O-060 Ultrasound guidance of hysteroscopic metroplasty, resection of intrauterine adhesions and hysteroscopic myomectomy: analysis of 1104 cases of intraoperative three-dimensional sonohysterography

J. Guerrero[1], J.P. Rouleau[1], D. Vasquez[1], R. Vicario[2], M. Costa[2], L.M.A. Pirollo[2], A. Rodriguez-Fuentes[1], A. Palumbo[1,2]

[1]Centro de Asistencia a la Reproducción Humana de Canarias, Reproductive Endocrinology and Infertility, Tenerife, Spain
[2]Quisisana Clinic, Reproductive Endocrinology and Infertility, Rome, Italy

Study question: What is the benefit of intraoperative three-dimensional (3D) sonohysterography performed during hysteroscopy?
Summary answer: Intraoperative 3D sonohisterography is an excellent method to monitor surgical correction of uterine anomalies, resection of intrauterine adhesions and submucous fibroids.
What is known already: Normal uterine anatomy and endometrium are prerequisites for normal implantation. Evaluation of the uterine cavity is therefore a crucial step for the diagnosis of infertility patients. 3D sonohysterography has been shown to be an excellent non-invasive diagnostic procedure. Hysteroscopic correction of intrauterine pathology is frequently performed prior to fertility treatment, but the role of ultrasound guidance to monitor these procedures has not been adequately evaluated. There is debate in the literature regarding the possible role of minor uterine anomalies such as arcuate uterus, but there is some evidence that an indentation >5.8 mm is associated with reduced implantation.
Study design, size, duration: Retrospective analysis of 1104 operative hysteroscopies performed in patients with uterine maltormations, intrauterine adhesions or submucous fibroids in a single private infertility clinic and a satellite office between September 2004 and January 2019. Surgeries were performed under ultrasound guidance using a Volusoni, VolusonE8 or Voluson730 ultrasound device with a 3D-RAB 4-8 transabdominal probe and a 3D-RIC 5-9 transvaginal probe (GE Healthcare, Austria). Surgeries were videotaped and ultrasound pictures/videos were recorded and subsequently reviewed.
Participants/materials, setting, methods: Surgeries were performed with either a compact hysteroscope (3,8 or 5 mm) with an operative channel using cold scissors, forceps or a bipolar electrode or with a resectoscope (7 or 9 mm) (Wolf, Germany). Intraoperatively a sonohisterography was performed either transabdominally or transvaginally with the hysteroscope in place in order to monitor the progress of the operation. Surgeries were performed with a full bladder. A foley catherer was left in place for 7 days postoperatively.
Main results and the role of chance: A total of 2151 hysteroscopies were performed during the study period. In 1047 cases the indication for surgery was polyp and ultrasound guidance was not required. The remaining 1104 were performed with 3D ultrasound guidance. Of these, 608 cases where uterine malformations including 95 complete septa, 168 incomplete septa, 269 arcuate uteri with an indentation >5.8mm, and 76 "T- shaped uteri"; 363 cases were severe intrauterine adhesions; 133 were myomectomies. Of the total, 147 patients had more than one pathology. In all cases the volumes acquired intraoperatively, which are identical to those obtained when performing office 3D sonohisterography, perfectly illustrate the progress of the operation, showing the limits of the uterus and avoiding the serosa . There were no cases of uterine perforation.
Limitations, reasons for caution: This technique requires expert ultrasonographers and high resolution 3D ultrasound devices. A potential limitation is the poor quality of image observed in obese and overweight patients.
Wider implications of the findings: Hysteroscopic correction of uterine malformations and severe intrauterine adhesions and submucous fibroid resection can be performed safely and effectively under 3D ultrasound guidance. Intraoperative 3D sonohysterography allows monitoring the progress of hysteroscopic procedures minimizing complications and indicating when the surgical procedure is complete.
Trial registration number: Not applicable

SESSION 18: GENETIC AND CELLULAR DETERMINANTS OF EMBRYONIC FUNCTION

Monday 24 June 2019 Mozart 15:15–16:30

O-061 An integrated chromatin accessibility and transcriptome landscape of human pre- and post-implantation embryos

Z. Shang[1], L. Liu[1], L. Leng[2], C. Liu[1], X. Dai[1], Q. Wang[1], S. Wang[1], T. Li[3], F. Chen[1]

[1]BGI-Shenzhen, BGI-Shenzhen, Shenzhen, China
[2]Central South University- Changsha, Institute of Reproductive and Stem Cell Engineering, Changsha, China
[3]Kunming University of Science and Technology, Institute of Primate Translational Medicine, Kunming, China

Study question: Molecular regulation and cell fate decision during human pre- and post-implantation development
Summary answer: We mapped the chromatin accessibility and transcriptome profiles for human pre- and post-implantation embryos.
What is known already: The human pre- and post-implantation development is a delicately balanced and orchestrated process that involves extensive changes in chromatin structure and transcriptional activity. However, a genome-wide survey of chromatin structure and its association with molecular regulation in this process have been impeded by the scarcity of the required materials.
Study design, size, duration: For pre-implantation development study, we adopted LiCAT-seq, a technique that allows simultaneous profiling of chromatin accessibility and gene expression with ultra-low input of cells, cell stages including oocytes, 1-cell, 2-cell, 4-cell, 8-cell, morula and blastocyst. For post-implantation development study, we generated single-cell RNA and single-cell ATAC-seq data of E6, E7, E8, E9, E10, E12, E13.5 cells isolated from an *in vitro* culture system.
Participants/materials, setting, methods: Here, by developing LiCAT-seq, we mapped the chromatin accessibility and transcriptome profiles for human pre-implantation embryos. In addition, combined with single-cell transcriptome and epigenome maps of human post-implantation *in vitro* culture system (before E14) allowed us to reveal the underlying regulatory mechanism of cell fate decision during this complex developmental time.
Main results and the role of chance: We mapped the chromatin accessibility and transcriptome profiles for human pre- and post-implantation embryos. Integrative analysis between the two omics layers revealed a strong association between the establishment of accessible chromatin and the related genes up-regulated during embryonic genome activation (EGA) and epiblast development. Furthermore, combined analysis of transcription factor accessibility identified putative novel transcription factors in regulating EGA and cell fate decision. In addition, we identified massively expressed endogenous retrovirus (ERVs) during EGA and epiblast disc.
Limitations, reasons for caution: Relatively small dataset.
Wider implications of the findings: Our results thus offer new mechanistic insights into the molecular events inherent to human pre- and post-implantation embryo development.
Trial registration number: none.

O-062 Heterozygous loci used for evaluation of sgRNA off-targeting

A. Koski[1], D. Liang[1], N. Marti Gutierrez[1], S.W. Park[2], H. Ma[1], H. Darby[1], Y. Lee[1], E. Kang[1], R. Ahmed[1], T. Hayama[1], C. Van Dyken[1], Y. Li[1], P. Amato[3], J.S. Kim[2], S. Mitalipov[1]

[1]Oregon Health & Science University, Center for Embryonic Cell and Gene Therapy, Portland, U.S.A.
[2]Institute for Basic Science, Center for Genome Engineering, Seoul, Korea- South
[3]Oregon Health & Science University, Division of Reproductive Endocrinology-Department of Obstetrics and Gynaecology, portland, U.S.A.

Study question: Can heterozygous loci be used for easy assessment of sgRNA off-targeting effects?
Summary answer: Targeting of heterozygous loci can be used to evaluate single guide RNA (sgRNA) specificity and provide simple informative data on off-targeting of opposite alleles.
What is known already: CRISPR/Cas9 is a powerful gene-editing tool; however, sgRNA mismatch tolerance and off-target mutations on homologous regions are serious safety concerns. Existing off-target screening approaches are based on extensive sequencing of most potential loci but can be expensive and time consuming. The results are cumbersome to analyze, mostly predictive and can contain false positives. Here we provide a simple and reliable method to assess the specificity of genome editing tools by targeting heterozygous loci.
Study design, size, duration: Human embryos carrying three different heterozygous loci were generated containing mutant (MT) and wildtype (WT) loci: *MYBPC3* 4-bp GAGT deletion (g.9836_9839 del., NC_000011.10), *MYH7* 1bp substitution (g.15819 C>T, NG_007884.1), and *LDLRAP1* 1bp substitution (g.24059 G>A, NG_008932.1). Multiple sgRNAs were designed and pre-tested in heterozygous iPSCs, one sgRNA for each locus with the highest indel rate on MT allele and lowest on WT allele were selected for embryo experiments. Indel mutations on alleles were compared.
Participants/materials, setting, methods: Three sperm and 12 oocyte donors' carriers of the *MYBPC3*, *MYH7* and *LDLRAP1* mutations were recruited and consented to provide gametes, skin and blood. Each blastomeres from injected embryos were isolated, whole genome amplified and evaluated by sequencing. The sgRNA and Cas9 protein were injected into heterozygous zygotes and on (MT) and off-target (WT) specificity were evaluated in cleaving day 3 embryos. Indel mutations were compared to assess targeting specificity of sgRNA.
Main results and the role of chance: The sgRNAs selected for *MYBPC3* and *MYH7* mutations exhibited exceptional fidelity as 55/55 and 91/91of analyzed blastomeres, for the each locus respectively, carried indels on MT allele but all WT alleles were intact. Targeting the *LDLRAP1* locus with the first selected sgRNA introduced indels on 56/74 (76%) of MT alleles. However, indels were also found in 18/74 (24%) of WT alleles; We designed, and selected another sgRNA that demonstrated a 43% (3/7) on-target and 57% (4/7) off-target indels. These results demonstrate that targeting heterozygous loci allows simple and reliable evaluation of sgRNA specificity.
Limitations, reasons for caution: Data presented is limited to the three loci and mutation types tested. Results suggest the nitrogenous base positions and nucleotide chain interactions may affect sgRNA specificity. Research into how nucleotide bases influence sgRNA specificity is needed.
Wider implications of the findings: Off-targeting effects of genome editing pose a concern for therapeutic applications. Heterozygous loci provide rapid and precise confirmation of specificity prior to conducting expensive next generation sequencing to search for genome wide off-targeting.
Trial registration number: not applicable

O-063 Treatment Factors and the Risk of Specific Congenital Heart Defects

M. Davies[1], A. Rumbold[1], K. Willson[1], R. Fernandez[1], W. Scheil[2], V. Moore[1]

[1]The University of Adelaide, The Robinson Institute, Adelaide, Australia
[2]South Australian Department of Health, Epidemiology, adelaide, Australia

Study question: Are there specific congenital heart (CH) defects associated with ART treatments?
Summary answer: Patent Ductus Arteriosus was associated with Fresh IVF cycles aOR=2.69, and frozen ICSI cycles aOR=4.59. Clomiphene citrate was associated with coarcation of the aorta aOR=5.90.
What is known already: CH defects are a leading cause of death in the first year of life and occur in around 8 per 1,000 births natural conceptions, but in 16 per 1,000 after ART. Approximately half of children diagnosed will require surgery, with more complex conditions often requiring lifelong medical care. As we and others have reported previously that certain ART is associated with an increased risk of cardiac defect, further reporting of specific defect types is an important step in identifying aetiologic pathways.
Study design, size, duration: Cohort study of all deliveries (n=302,811) and terminations of pregnancy in South Australia for the period Jan 1986-Dec 2002 that were linked to all cycles of ART (6,163 births) for the same time period. These data were linked to a State-wide birth defect registry.
Participants/materials, setting, methods: The South Australian Birth Cohort is based on all registrations of birth and terminations of pregnancy, linked to all cycles of ART, and to all congenital anomalies notified to the 5th birthday (ICD-9 British Paediatric Association codes). Logistic regression was used to investigate associations between parental factors, treatment modality and the presence of CH defects. Adjustment for multiple testing was not performed at this investigatory stage.
Main results and the role of chance: Compared to the fertile population, and after adjustment:

a) For IVF and ICSI combined, risk for Any cardiac defect (BPA 74500-74799) was increased aOR=1.42, 1.13-1.80; as was Congenital Aorta Valve Stenosis aOR=3.20;, 1.26-8.11; Patent Ductus Arteriosus aOR=1.88, 1.18-3.00.

b) Increased risk of Patent Ductus Arteriosus was associated with Fresh IVF cycles aOR=2.69, 1.32-5.48 and frozen ICSI cycles aOR=4.59, 1.84-11.44.

c) Ovulation induction with clomiphene citrate was associated with Coarctation Of Aorta aOR=5.90, 1.05-33.11.

d) Comparison of 4 culture medias revealed one with an increased risk of Patent Ductus Arteriosus for both fresh IVF aOR=5.56, 1.31-23.53, and for fresh ICSI aOR=5.57, 1.08-28.71

e) 'Spontaneous' conceptions to ART patients post-treatment were associated with Endocardial Cushion Defects aOR=4.06, 1.43-11.50.

f) A medical history of "infertility" with no IVF clinic contact was associated with Cardiac Septal Closure Anomalies aOR=1.90, 1.12-3.23; Atrial Septal Defect, 3.65, 1.88-7.12; Patent Ductus Arteriosus aOR=3.09, 1.26-7.56.

g) As there were no protective associations for any ART procedure for any cardiac defect, the distribution of multiple increased risks with ART is unlikely to be random.

Limitations, reasons for caution: Analyses were limited in statistical power for infrequent events. Increased power may reveal further associations that are boarder line in the present analysis. Replication of these findings elsewhere is important as some individual significant associations may not be robust.
Wider implications of the findings: Serious cardiac defects are associated with ovarian stimulation with clomiphene citrate, mode of fertilisation, cryopreservation with ICSI, and culture media. These observations can inform both mechanistic studies on cardiovascular development, and further targeted epidemiological research on specific clinical and pharmacological exposures and cardiac outcomes.
Trial registration number: N/A

O-064 Lipids are modulators of embryonic metabolism and stress response: insights from the diabetic rabbit model

M. Schindler[1], S. Pendzialek[1], K. Grybel[1], T. Seeling[1], D. Dannenberger[2], B. Fischer[1], A. Navarrete-Santos[1]

[1]Medical Faculty of Martin Luther University Halle-Wittenberg, Institute of Anatomy and Cell Biology, Halle Saale, Germany
[2]Leibniz Institute for Farm Animal Biology FBN, Institute of Muscle Biology and Growth- Lipid metabolism and muscular adaptation workgroup, Dummerstorf, Germany

Study question: Our aim was to analyse embryonic lipid metabolism in embryoblast and trophoblast, and to determine potential consequences for cellular stress adaptation in rabbit blastocysts.

Summary answer: Rabbit embryoblast and trophoblast cells handle hyperlipidaemic conditions in lineage-specific ways, leading in consequences to a different endoplasmatic and oxidative stress response.

What is known already: During preimplantation development embryos take up nutrients from the surrounding milieu. The uterine concentrations depend on maternal metabolism and can be affected by maternal diseases, such as diabetes mellitus. We have shown that an insulin-dependent diabetes mellitus leads to maternal hyperlipidaemia and to higher amounts of intracellular lipid vesicles in rabbit blastocysts, especially in embryoblast cells (doi:10.1210/en.2013-1760). Lipids and fatty acids are able to regulate central transcription factors, like PPARα and PPARγ. Alterations in PPARs signalling lead to changes in antioxidant defence and redox status.

Study design, size, duration: To study effects of a maternal diabetes mellitus on early embryo metabolism, we induced an insulin-dependent diabetes experimentally by alloxan in female rabbits. Blastocysts were collected on day 6 post coitum and separated into embryoblast and trophoblast for the metabolic profiling in vivo. To evaluate the effect of an increased lipid level more in detail, blastocysts from healthy rabbits were cultured for 6h in vitro with a specified lipid mixture (Gibco, *Chemically Defined Lipid Concentrate*).

Participants/materials, setting, methods: Expression of relevant marker molecules involved in lipid metabolism (PPARα, PPARγ, PGC1α, SREBP1c, FASN, CPT1, FATP4 and FABP4) and endoplasmatic and oxidative stress response (ATF4, NRF2 and SOD2) were analysed by qRT-PCR and Western Blot, separately in embryoblast and trophoblast. Intracellular lipid accumulation was visualised by Oil Red-O staining. Amount of the ketone body 3-hydroxybutyrylcarntine (BHBA) which is synthesised via the metabolism of fatty acids was analysed by Metabolon® analysis in the blastocysts' cavity fluid.

Main results and the role of chance: Maternal diabetes increased BHBA levels in the embryo almost 3-fold. Expression of genes encoding for fatty acid uptake (FATP4) and binding (FABP4) as well as for fatty acid metabolism (PGC1α, PPARα and PPARγ) and β-oxidation (CPT1) was increased in embryoblasts from diabetic rabbits. Trophoblastic genes encoding for fatty acid and lipid biosynthesis (SREBP1c) and PGC1a were elevated. CPT1 and fatty acid synthesis (FASN) were down-regulated in trophoblast cells from diabetic rabbits. Furthermore, only in the embryoblast from diabetic rabbits two markers for endoplasmatic (ATF4) and oxidative stress (NRF2) were increased. SOD2, a marker for cellular redox status, was again differentially regulated with a reduction in embryoblast and increase in trophoblast cells from diabetic rabbits. These results show that metabolic changes in a diabetic pregnancy are differently processed in embryoblast and trophoblast gastrulation. Consistently with our observation in the diabetic model, rabbit embryos cultured with a lipid mixture showed a higher amount of intracellular lipid droplets. The expression of PPARs and fatty acid transporters was increased in embryoblast and decreased for CPT1 and FASN in trophoblast cells. Lipid exposure induced the expression of NRF2, ATF4 and SOD2 in embryoblast cells, indicating that the embryoblast is more sensitive towards metabolic stress.

Limitations, reasons for caution: The embryogenesis of the rabbit reflects human development only during blastocyst formation. Therefore, statements are limited to the embryonic stages investigated.

Wider implications of the findings: The results of the current study provide further experimental evidence that in a diabetic pregnancy maternal lipids have an impact on metabolism of the preimplantation embryo. In addition, our study point out that especially the embryoblast is vulnerable to metabolic stress by dysregulation of endoplasmatic and oxidative stress response.

Trial registration number: not applicable

O-065 L-carnitine restores mitochondrial function of human embryos decreased with female donor age

S. Hashimoto[1], N. Morimoto[2], Y. Masaya[3], T. Nakano[4], M. Satou[4], Y. Nakaoka[2], Y. Morimoto[5]

[1] *Osaka City University Graduate School of Medicine, Reproductive Science Institute, Osaka, Japan*
[2] *IVF Namba Clinic, Medical office, Osaka, Japan*
[3] *IVF Namba Clinic, Research, Osaka, Japan*
[4] *IVF Namba Clinic, Embryologist, Osaka, Japan*
[5] *HORAC grand front Osaka clinic, Medical Office, Osaka, Japan*

Study question: Does L-carnitine restore an adverse effect of female donor age on the mitochondrial function of their embryos?

Summary answer: Mitochondrial function at morula stage of human embryos decreased with their female-donor age and L-carnitine restored the mitochondrial function and the development of human embryos.

What is known already: Although the rates of oxygen consumption (OCRs) of human embryos increases with their development, the relationship between female donor age and mitochondrial function of their embryos remains obscure. L-carnitine plays important roles in reducing the membranous toxicity of free fatty acids by forming acyl-carnitine and promoting beta-oxidation, leading to alleviation of cell damage. Recent studies have shown that L-carnitine also plays important roles in in vitro oocyte growth, oocyte maturation, and embryonic development. However, whether such beneficial effects of L-carnitine lead to an improvement of mitochondrial function remains unknown.

Study design, size, duration: Fourteen oocytes and 106 embryos were used to assess mitochondrial DNA (mtDNA) copy numbers and OCRs and to examine the effect of L-carnitine. All specimens were obtained between July 2004 and June 2016, and donated from couples after they had given informed consent. The development of 374 embryos was retrospectively analyzed to assess the effects of female donor age. The development of 1308 zygotes cultured in medium with or without L-carnitine was prospectively analyzed.

Participants/materials, setting, methods: Mature oocytes and developed embryos to 6-8 cell, morula and blastocyst stages were used to assess their OCRs and mtDNA copy number. The relationships between female donor age and OCRs, and female donor age and mtDNA copy number were analyzed. Effect of L-carnitine was also assessed similarly. Using clinical data, the developmental rate from morula to blastocyst was compared among 3 different age groups and effect of L-carnitine on the blastocyst development was examined.

Main results and the role of chance: Although there were no relationships between female donor age and mtDNA copy number in any stages, the OCRs of morulae decreased with female donor age ($r^2 = 0.45$, $P < 0.01$). An addition of l-carnitine increased the OCRs of morulae (1.18 fmol/sec) compared with their sibling embryos (1.08 fmol/sec, $P < 0.05$). In clinical data analysis, the developmental rate from morula to blastocyst decreased with female donor age ($P < 0.05$, < 35 yo: 75.6% vs. 35-40 yo: 70.4% vs. > 40 yo: 46.8%). An addition of L-carnitine into a culture medium significantly improved the morphologically-good blastocyst rate per fertilized ova ($P < 0.01$, 15.1%) compared with their sibling embryos (8.8%). Twenty healthy babies were born from blastocysts cultured in L-carnitine-supplemented medium after single blastocyst transfer.

Limitations, reasons for caution: Large-scale studies should be required to assess whether an addition of L-carnitine improves the development of embryos obtained from older women. Aneuploidy has not been assessed in accordance with clinical guideline of the Japan Society of Obstetrics and Gynecology.

Wider implications of the findings: The data of the present study revealed that mitochondrial function (OCRs) at morula stage of human embryos decreased with their female donor age. L-carnitine restored the mitochondrial function and the development of human embryos.

Trial registration number: This study was approved by the IRB of IVF Namba Clinic and registered by Japan Society of Obstetrics and Gynecology (Registry numbers 135 and 138).

O-066 Pregnancy and perinatal outcomes of 521 fresh and frozen cycles resulting in pregnancy: a secondary outcome of a RCT comparing GnRH antagonist and agonist protocols

C. Tomas[1,2], A. Pinborg[1], K. Løssl[1], J. Bogstad[1], L. Prætorius[3], A. Zedeler[3], T. Bryndorf[3], A. Nyboe Andersen[1], M. Toftager[3]

[1]The Fertility Clinic- Copenhagen University Hospital- Rigshospitalet, The Fertility Clinic- Copenhagen University Hospital- Rigshospitalet, Copenhagen, Denmark
[2]Center of Infertility and Medically Assisted Reproduction- Hospital Garcia de Orta., Center of Infertility and Medically Assisted Reproduction- Hospital Garcia de Orta, Lisbon, Portugal
[3]Department of Obstetrics & Gynaecology- Fertility Clinic- Copenhagen University Hospital Hvidovre, Department of Obstetrics & Gynaecology- Fertility Clinic- Copenhagen University Hospital Hvidovre-, Copenhagen, Denmark

Study question: Are pregnancy and perinatal outcomes different after treatment with the GnRH antagonist versus the long GnRH-agonist protocol for IVF?
Summary answer: Pregnancy and perinatal outcomes are similar after GnRH-antagonist or long GnRH-agonist protocols in IVF treatments.
What is known already: The goal of assisted reproductive technology (ART) is to achieve a healthy live born child with the least complications during pregnancy. However, several studies have shown that ART pregnancies are associated with higher risks of obstetric and perinatal complications compared to spontaneously conceived pregnancies.
Study design, size, duration: Pregnancy and perinatal outcome were secondary outcomes in a large phase IV, dual-centre, open-label, randomized controlled study, with the objective to compare the GnRH-antagonist and long GnRH-agonist protocols in an unselected population of women <40 years of age referred for their first ART treatment. Women (n=1050) were randomized in a ratio 1:1 from January 2009 to December 2013 and were followed until December 2016.
Participants/materials, setting, methods: All fresh and frozen embryo transfer (FET) cycles from one single oocyte aspiration, leading to pregnancy (hCG > 10 IU/L), were included (n=521). Data were analyzed to compare miscarriage, ongoing pregnancy, stillbirth and live birth rates. Preterm birth (<37 weeks), very preterm birth (VPTB) (<32 weeks), low birth weight (LBW) (<2500 grams) and very LBW (<1500 grams) rates were compared among singleton live births.
Main results and the role of chance: Similar pregnancy outcomes were found in the GnRH-antagonist and GnRH-agonist protocols in cycles with fresh embryo transfer: miscarriage (32.0% vs 34.3%; p=0.73), ongoing pregnancy (65.2% vs 64.5%; p=0.89), live birth (64.1% vs 63.9%; p=0.96) and stillbirth (1.1% vs 0.6%; p=0.61) rates. After fresh ET, the singleton mean gestational age at delivery was similar in antagonist and agonist protocol (39.1±2.49 vs 39.3±1.90; p=0.67). Very early PTB rates (0.95% vs 0 %; 95% CI (-0.086; 0.286); p=0.31) were also similar. Mean birth weight was 3264 ± 662g in the antagonist and 3341 ± 562g in the agonist group (p=0.37). LBW was found in 9.5% vs 6% (95%CI (-0.038; 0.108); p=0.35) and very LBW in 2.9% vs 1% (95% CI (-0.019; 0.056); p=0.34). For FET cycles, all pregnancy and perinatal outcomes were similar for antagonist vs. agonist protocol except that mean birth weight was significantly lower in the GnRH-antagonist protocol (3404g ± 642 vs 3641g ± 485; p=0.05).
Limitations, reasons for caution: Twins account for poor perinatal outcomes and were excluded from the analyses to avoid bias. Perinatal outcomes were secondary outcomes of an RCT and the study was not powered for these outcomes.
Wider implications of the findings: This is the first RCT comparing GnRH antagonist and agonist protocols reporting perinatal outcomes. It strengthens the importance of large follow-up studies on children after ART. In addition, the choice of GnRH-analogue for ART treatments should be based only on optimizing clinical aspects.
Trial registration number: EudraCT #: 2008-005452-24, ClinicalTrial.gov: NCT00756028.

O-067 Relationship between low ovarian reserve and p53 family members polymorphisms

A. Renzi[1], C.C. Petersen[1,2], A.L. Mauri[1], L.D. Vagnini[1], B. Petersen[1,2], M. Mattila[2], A. Nicoletti[2], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Paulista Centre for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[2]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil

Study question: Is low ovarian reserve (LOR) associated with polymorphisms in the p53 family members?
Summary answer: TP53C>T(rs1625895), TP63A>G(rs7619549) and TP73G>A(rs3765730) polymorphisms are associated with ovarian reserve. TP53-TT and TP73-GG genotypes increase, but TP63-AA decreases the likelihood of a woman presenting LOR.
What is known already: Knowledge regarding a patient's potential ovarian reserve may assist clinicians in adjusting medication dosages to reduce adverse effects. However, the ovarian reserve is a complex clinical phenomenon, influenced not only by age but also by environmental and genetic variables. The p53 family members are powerful transcription factors and small variations in their DNA structure can modify gene expression patterns. We know that the p53 family is involved in blastocyst implantation and female germ cell integrity, but we still do not understand its influence on ovarian function.
Study design, size, duration: All of the recruited women (n: 145) met the following inclusion criteria: age ≤37years, normal karyotype, ultrasound evidence of the two ovaries and no ovarian surgery, endometriosis, hydrosalpinx, infections or endocrine problems. The women were divided into two groups according to their Anti-Müllerian hormone/AMH (ng/ml) levels and antral follicle count/AFC (2-9mm), evaluated during the early follicular phase:
-Low ovarian reserve (LOR/n=86): AMH<1+AFC≤9
-Normal ovarian reserve (NOR/=59): AMH≥2+AFC≥15
Participants/materials, setting, methods: DNA was extracted from peripheral blood samples taken from LOR and NOR groups. DNA was sequenced on MiSeq(Illumina) to search for single nucleotide polymorphisms(SNPs) in the p53 family members (TP53/TP63/TP73). SNPs were identified using TruSeq Custom Amplicon (TSCA) Panel (DesignStudio Illumina). This design was performed in order to sequencing the exons, 3' and 5' *untranslated regions* (UTRs) and some intronic regions SNPs found by Next-Generation Sequencing were analysed to find a possible association with LOR
Main results and the role of chance: The TP53 C>T (rs1625895), TP73 G>A (rs3765730) and TP63 A>G (rs7619549) SNPs were identified. The results observed an association between TP53-TT genotype and TP73-GG genotypes with women presenting LOR and TP63-AA genotype with women presenting NOR(Table1). Logistic regression (Table 2) showed that patients with TP53-TT and TP73-GG genotypes had 4.0-fold and 2.5-fold (respectively) increase in the chance of being included in the LOR group. On the other hand, the presence of TP63-AA genotype was associated with an 81% decrease in the chance of being included in the LOR group.
Limitations, reasons for caution: Additional validation of the SNPs analysed would be important to provide more information about the relationship of theses polymorphisms and ovarian reserve, once sample size was limited despite recruiting all eligible participants during the study period. Differences in the genetic backgrounds of various ethnic populations should also be considered.
Wider implications of the findings: The SNPs identified might provide an additional tool to test ovarian reserve and help in the individualization of ovarian stimulation protocols. To the best of our knowledge, this is the first study associating these SNPs and ovarian reserve.
Trial registration number: Not applicable. The local ethics committee authorised the study. Merck Grant for Fertility Innovation (GFI-2014-16) supported this study.

O-068 Comparison of the ongoing pregnancy rate of immediate versus delayed frozen-thawed embryo transfer following a stimulated IVF cycle: a prospective randomized controlled trial

Table 2 Logistic regression. Genotypes X Chance of low ovarian reserve.

Genotypes	Odds Ratio	95% Confidence Interval	*P*
TP53:TT	4.0	1.78-9.01	0.0008
TP73:GG	2.5	1.25-4.85	0.009
TP63:AA	0.19	0.05-0.75	0.01

Study question: To compare the ongoing pregnancy rate of immediate versus delayed frozen-thawed embryo transfer (FET) following a stimulated (in-vitro fertilization) IVF cycle.

Summary answer: Immediate FET following a stimulated IVF cycle had a significantly higher ongoing pregnancy rate than delayed FET.

What is known already: FET has become an increasingly important part of IVF but there is still no good evidence to support when to perform FET following a stimulated IVF cycle. Since all published studies are retrospective and the findings are contradictory, a randomized study is needed to provide level 1 evidence to guide the clinical practice.

Study design, size, duration: This is a prospective randomized controlled trial of 724 women recruited between August 2017 and December 2018. The primary outcome is the ongoing pregnancy defined as a viable pregnancy beyond 12 weeks' gestation.

Participants/materials, setting, methods: Women aged ≤43 years having the first FET cycle after a failed stimulated IVF cycle or undertaking the freeze-all strategy were randomized to either: (1) the immediate FET group in which FET was performed in the first cycle following the stimulated IVF cycle, or 2) delayed FET group in which FET will be performed at least in the second cycle following the stimulated IVF cycle.

Main results and the role of chance: At the time of abstract submission, 687 women completed the study, 1 patient waiting pregnancy result and 36 women dropped out. We expect to have completed results by the time of the conference. The age of women was significantly younger in the immediate group than the delayed group (30.5±4.0 years vs 31.4±4.1 years respectively, p=0.004). No significant differences in other baseline characteristics were observed between the two groups. Intention to treat analysis showed the ongoing pregnancy rate was significantly higher in the immediate group [170/362, 47.0%] vs in the delayed FET group [142/362, 39.2%], odds ratio 0.729 (95% CI 0.543–0.979)]. Per protocol analysis showed similar results. The ongoing pregnancy rate was significantly higher in the immediate group [170/345, 49.3%] vs in the delayed FET group [142/342, 41.5%], odds ratio 0.731 (95% CI 0.541–

0.988)]. After a multivariable logistic regression, the ongoing pregnancy rate is still higher in the immediate group [adjusted odds ratio 0.721 (95% CI 0.529–0.983)]. The positive HCG and miscarriage rate are comparable between the two groups.

Limitations, reasons for caution: The researchers, doctors and the participants cannot be blinded to treatment allocation.

Wider implications of the findings: Immediate FET following a stimulated IVF cycle had a significantly higher ongoing pregnancy rate than delayed FET. The findings of the study support immediate FET after a failed fresh ET cycle or a freeze all cycle.

Trial registration number: NCT03201783

O-069 Freeze-all versus fresh embryo transfer in ART: A multicentre randomised controlled trial in normo-ovulatory women

S. Stormlund[1], N. Sopa[1], A. Zedeler[1], J. Bogstad[2], L. Prætorius[1], H.S. Nielsen[2], M.L. Kitlinski[3], S.O. Skouby[4], A.L. Mikkelsen[5], N.P. Polyzos[6], C. Bergh[7], P. Humaidan[8], A. Nyboe Andersen[2], K. Løssl[2], A. Pinborg[1]

[8]Skive Regional Hospital and Faculty of Health- Aarhus University, The Fertility Clinic, Aarhus, Denmark

Study question: Is the ongoing pregnancy rate in a freeze-all strategy involving GnRH agonist trigger superior to the ongoing pregnancy rate in conventional fresh embryo transfer strategy?

Summary answer: The ongoing pregnancy rate per randomised patient after the first single blastocyst transfer is comparable between freeze-all and fresh embryo transfer.

What is known already: In recent years, growing clinical evidence has emerged suggesting similar or even better pregnancy rates in elective frozen embryo transfer cycles compared to conventional fresh transfer, thus encouraging a further implementation of a freeze-all strategy as part of standard ART in patients at risk of ovarian hyperstimulation syndrome (OHSS) or where impaired endometrial receptivity is suspected. Importantly freeze-all including the use of GnRH agonist trigger has the potential to virtually eliminate the risk of OHSS alongside encouraging an eSET policy diminishing multiple birth rates overall improving safety aspects of ART care.

Study design, size, duration: Multicenter, randomised, double-blind trial including 460 women allocated 1:1 to either (1) GnRH agonist trigger and single vitrified-warmed blastocyst transfer in a subsequent natural cycle or (2) hCG trigger and single blastocyst transfer in the fresh cycle. Patients at risk of OHSS(>18 follicles >11mm)on trigger day had their embryo transfer postponed to a subsequent natural cycle. A computerized randomization program was used. Participants were enrolled over a two-year period from May 2016 to September 2018.

Participants/materials, setting, methods: A total of 460 normo-ovulatory women aged 18 to 39 referred to their first, second or third ART treatment in 8 clinics in Denmark, Sweden and Spain were included. Participants were randomised on the day of inclusion and blinded of the randomisation result until the day of ovulation trigger. After randomisation 23 patients were excluded from analyses on criteria of AMH and TSH. Ongoing pregnancy was determined by transvaginal ultrasonography at gestational weeks 8 –10.

Main results and the role of chance: All analyses were based on the ITT principle. In the primary endpoint, the ongoing pregnancy (OPR) per randomised patient after the first potential blastocyst transfer was 26.1 % (57/218) in the freeze-all group compared with 28.8 % (63/219) in the fresh transfer group (OR 0.88, 95% CI 0.58-1.34; p =0.54). OPR per transfer (only including patients who had a transfer) was 36.1% (57/158) in the freeze-all group compared with 36.8 % (63/171) in the fresh embryo transfer group (OR 0.97, 95% CI 0.62-1.52; p = 0.89). Positive hCG rate per randomised was 32.1% (70/128) vs. 38.4% (84/219) in freeze-all and fresh group, respectively (NS) and positive hCG per transfer was 44.3% (70/158) vs. 49.1% (84/171) in freeze-all vs. the fresh group (NS). In the fresh embryo transfer group, 25 participants were converted to freeze-all due to risk of OHSS. These patients were all included in the ITT analysis as part of the fresh embryo transfer group. One patient in the fresh embryo transfer group had an OHSS related hospital admission. Cancellation of transfer due to lack of blastocyst development occurred in 18.8% (n=41) and 15.1% (n=33) of patients per randomised in the freeze-all and fresh embryo transfer group, respectively.

Limitations, reasons for caution: In this design the effect of GnRH-agonist trigger and freeze-all cannot be separated, however aimed to compare an OHSS-free strategy with conventional fresh embryo transfer. The study is powered to detect a 12 % difference in OPR between the two groups, thus smaller differences may be overlooked.

Wider implications of the findings: Our findings give no support for a general freeze-all strategy in normo-ovulatory women but encourage further adaptation of a freeze-all strategy including GnRH agonist trigger in patients where this may be beneficial as part of individualised patient care. The results are in agreement with the latest meta-analysis on the area.

Trial registration number: Clinicaltrials.gov identifier: NCT02746562

O-070 Fresh versus elective frozen embryo transfer: The cumulative live birth rates for 7132 in vitro fertilization cycles

L.T.M. Chau[1], O.P. Thinh[2], D.V. Dung[2], N. Quoc[1], M. Roque[3]

[1]Tu Du OBGYN Hospital, Infertility Department, Hochiminh City, Vietnam

[2]University of Medicine and Pharmacy at Hochiminh City, Department of Medical Statistics, Hochiminh City, Vietnam

[3]ORIGEN - Center for Reproductive Medicine, Reproductive Medicine, Rio de Janeiro, Brazil

Study question: Is elective frozen embryo transfer, or the 'freeze-all' strategy, associated with better clinical outcomes compared to fresh embryo transfer in *in vitro* fertilization (IVF) cycles?

Summary answer: The freeze-all strategy is associated with improved cumulative live birth rates in normal and hyper-responders, but not in suboptimal and poor responders.

What is known already: Many questions have arisen regarding the adverse effects of controlled ovarian stimulation (COS) on the endometrium and its consequences on endometrial receptivity. Thus, many practitioners have advocated for the use of elective frozen embryo transfer (eFET) to overcome the potentially deleterious effects of COS while improving clinical outcomes during an IVF cycle. However, evidence in support of this approach is not unequivocal. Further, less is known about which groups of patients would benefit most from the freeze-all strategy, as most studies have not evaluated this approach in different subgroups of patients based on their ovarian response to COS.

Study design, size, duration: This is a retrospective analysis of 7132 IVF cycles that were followed by a fresh or elective frozen embryo transfer between 2012 and 2017. The patients were submitted to COS with a gonadotropin-releasing hormone (GnRH) antagonist protocol and cleavage-stage embryo transfer. Embryo cryopreservation was performed on day 3 by vitrification using an open system.

Participants/materials, setting, methods: We performed a comparison of cumulative outcomes between the eFET (n=3920 cycles) and fresh embryo transfer groups (n=3212 cycles). The analysis was performed in four groups of patients based on the number of retrieved oocytes: **Group 1**– poor responders (1–3 oocytes); **Group 2**– suboptimal responders (4–9 oocytes); **Group 3**– normal responders (10–15 oocytes); and **Group 4**– hyper-responders (>15 oocytes). The primary outcome was the cumulative live birth rate (CLBR) per stimulated cycle.

Main results and the role of chance: There was a total of 7132 IVF/intracytoplasmic sperm injection (ICSI) cycles and 10314 embryo transfers (n=5621 in the eFET group; n=4693 in the fresh group). In **Group 1**, there were 343

IVF cycles and 373 embryo transfers (ET) in total, and the CLBR was 16.5% and 17.9% (P=0.75) for the eFET and fresh group, respectively (relative risk [RR]=0.92; 95% confidence interval [CI]: 0.56–1.52). In **Group 2**, there were 1990 IVF cycles and 2398 ET in total, and the CLBR was 27.7% and 24.9% (P=0.16) in the eFET and fresh group, respectively (RR=1.11; 95% CI: 0.96–1.29). There was a significant difference in the CLBR in Groups 3 and 4, favoring the eFET strategy. In **Group 3**, 2211 IVF cycles and 3225 ET were performed. The CLBR was 43.4% in the eFET and 38.9% in the fresh group (P=0.03; RR=1.11; 95% CI: 1.01–1.23). In **Group 4**, there were 2588 IVF cycles and 4318 ET in total, and the CLBR was 54.6% and 49.8% (P=0.03) in the eFET and fresh group, respectively (RR=1.10; 95% CI: 1.01–1.19). The number needed to treat to achieve one additional live birth was 22.5 in Group 3 and 21.0 in Group 4.

Limitations, reasons for caution: The main limitation of this study was its retrospective design, which may be subject to bias.

Wider implications of the findings: This is the most extensive study comparing the CLBR between eFET and fresh cycles. Moreover, comparisons among different groups of patients based on ovarian response were conducted for the first time. The findings suggest that the freeze-all strategy should not be implemented for all patient groups given the clinical outcomes.

O-071 Germ cells synthesis of all-trans retinoic acid (ATRA) is dispensable for spermatogenesis but cooperates with Sertolian synthesis to initiate and propagate spermatogenic waves during puberty

M. Teletin[1,2], N. Vernet[2], M. Klopfenstein[2], B. Feret[2], M.A. Kane[3], N.B. Ghyselinck[2], M. Mark[1,2]

[1]CECOS, Hôpitaux Universitaires de Strasbourg, Strasbourg, France
[2]IGBMC, Functional genomics and cancer, Strasbourg, France
[3]School of Pharmacy- University of Maryland, Department of Pharmaceutical Sciences, Baltimore- MD 21201, U.S.A.

Study question: What is the role of germ cells or Sertoli cells-derived ATRA in spermatogenesis?

Summary answer: Sertoli cell (SC)-derived source of ATRA is sufficient to ensure a normal adult spermatogenesis while germ cells (GC)-derived ATRA is dispensable in steady-state conditions. Both sources are involved during puberty.

What is known already: In mammals, ATRA is instrumental to spermatogenesis. ATRA is synthesized by dedicated enzymes, RALDHs and binds to and activates nuclear ATRA receptors (RARA, RARB, and RARG) either within the ATRA-synthesizing cells or in the neighboring cells. We established previously that during the first, prepubertal, spermatogenic cycle RALDH-dependent synthesis of ATRA by Sertoli cells, the supporting cells of GC lineage, is indispensable to initiate differentiation of A aligned into A1 spermatogonia. Moreover, ATRA of SC origin is no longer necessary for the subsequent spermatogenic cycles but essential to spermiation.

Study design, size, duration: In order to determine the relative contributions the somatic, Sertoli, and germ cell sources of ATRA to spermatogenesis and spermiation, we have generated mutant mice lacking all RALDH activities in germ cells and compared their phenotype with that of mice lacking RALDH in Sertoli cells.

Participants/materials, setting, methods: To study the role of RALDH1 and RALDH1 in GC, mice expressing the Cre recombinase under the control of *Stra8* promoter were crossed with mice bearing loxP-flanked alleles for *Raldh1*, *Raldh1* and *Raldh3*. The Stra8-Cre transgene yields an efficient excision of loxP-flanked genes in GC.

Main results and the role of chance: We show that ATRA both sources cooperate to initiate and propagate spermatogenic waves at puberty. In homeostatic adult spermatogenesis, the GC and SC sources exert redundant functions and, against all expectations, the former does not perform any specific role. The production from SC, although representing the minor fraction of ATRA in the seminiferous epithelium, is sufficient to maintain, throughout life, the normal periodic expression of genes in these cells as well and the cycle and wave of the seminiferous epithelium which account for the constant and steady production of sperm. ATRA source of SC is also specifically required for spermiation. Altogether, these results suggest that during spermatogenesis key transitions in germ cells differentiation are regulated by distinct threshold values of ATRA concentrations.

Limitations, reasons for caution: These results were obtained in mice and therefore the relevance for human spermatogenesis remains to be demonstrated.

Wider implications of the findings: Pharmacological studies strongly support a role of the ATRA signaling pathway in human spermatogenesis. However, vitamin A deficiency, although common in developing countries, does not include male infertility among its clinical manifestations. Whether intratesticular impairment of ATRA (the active metabolite of vitamin A) synthesis might be a cause of azoospermia or oligozoospermia remains to be explored in clinical research.

Trial registration number: N.A.

O-072 Molecular profiling different stages of human sperm maturity based on transcriptome analysis and in situ hybridizations of testicular spermatozoa in comparison to mature ejaculated spermatozoa

T. Skutella[1], G. Bendner[2], I. Virant-Klun[3]

[1]Institut für Anatomie und Zellbiologie, Neuroanatomy, HEIDELBERG, Germany
[2]Institut für Anatomie/Zellbiologie III, Neuroanatomy, Heidelberg, Germany
[3]University Medical Centre Ljubljana, Department of Obstetrics and Gynecology, Ljubljana, Slovenia

Study question: The major objective of this study was to generate a transcriptomic profile of human sperm maturity by microarray analysis and in situ hybridization.

Summary answer: Gene expression profiles between testicular and ejaculated spermatozoa are provided as RNA-based marker panels for the distinct stages of sperm maturity in humans.

What is known already: Although the testicular spermatozoa of azoospermic men are successfully used for in vitro fertilization and newborns were produced by microinjection of testicular spermatozoa into oocytes, there is not much data available on human testicular spermatozoa, including their potentially different gene expression profile in comparison to mature, ejaculated spermatozoa. The fact that in all previous studies only transcriptomics of the whole human testicular tissue or ejaculate, consisting of different cell types, have been dissected, may represent a bias.

Study design, size, duration: In this study, we selected 100 single human testicular or ejaculated spermatozoa per sample using the micromanipulation system and analyzed them on gene expression profiles by microarrays. At least samples from 3 different patients per group were used for the in situ hybridizations.

Participants/materials, setting, methods: For the microarray samples from 3 different patients per group were provided and for the in situ hybridizations at least samples from three different patients per group were used.

Main results and the role of chance: The microarrays revealed different expression profiles related to different cellular components with various molecular and biological ontological functions. While molecular functions of testicular spermatozoa are locally restricted to cellular components of the nucleus and intracellular membrane-bound organelles, the molecular features of ejaculated spermatozoa are more limited to cytosolic large ribosomal subunits related to the synthesis of proteins. Some differentially expressed transcripts in testicular spermatozoa were closely connected to spermatogenesis, germinal lineage, transcription regulation, epigenetics, DNA repair and chromatin, development and differentiation. We further performed the comparison of testicular spermatozoa in situ (in testicular tubules) and ejaculated spermatozoa in humans by in situ hybridization (ISH) for the genes CRISP2, RCOR3, DDX57, and RAD23B.

Furthermore, we compared by ISH the expression of these proteins/genes in non-malignant ("healthy") tissue vs. malignant tissue (testicular cancer), and comparison of different cancerous tissues (testicular cancer): seminoma, non-seminoma, teratoma.

Limitations, reasons for caution: Technical limitations of microarray and in situ hybridization.

Wider implications of the findings: The results of this study might provide exciting varieties in gene expression profiles between testicular and ejaculated spermatozoa, which might serve as RNA-based marker panels for the distinct stages of sperm maturity in humans.

Trial registration number: none

O-073 Microarray analysis in human testis reveal the critical roles of long non-coding RNAs in non-obstructive azoospermia via immune signaling pathway.

X. Zhou[1], Y. Zhu[1], S. Quan[1]

[1]Nanfang Hospital- Southern Medical University, Reproductive Medicine Center-Department of Obstetrics and Gynecology-, Guangzhou, China

Study question: The function of long non-coding RNAs (lncRNA) in the underlying etiology of non-obstructive azoospermia (NOA) which are not systematically understood.

Summary answer: The significanty altered lncRNAs may lead to impaired spermatogenesis, paving the way for deciphering the pathogenesis of NOA.

What is known already: Spermatogenesis is an intricate yet highly sequential process, which involves three distinct phases: mitotic proliferation of spermatogonia, meiotic divisions of spermatocyte, and spermiogenesis. Damage to any link in the process may cause spermatogenic failure. NOA is one of the most severe male-related reproductive disorders, which results from spermatogenic failure, affecting approximately 10% of infertile men in the world. LncRNAs engaged in numerous important biological process. There is abundant evidence that lncRNAs were found to present highly specific expression in the testis by genome-wide transcriptome analyses. Furthermore, increasing evidence indicates that lncRNAs play pivotal roles in spermatogenesis.

Study design, size, duration: The study analyzed the expression profile of lncRNAs and mRNAs in NOA. Four pairs of NOA patients and obstructive azoospermia (OA) with normal spermatogenesis (controls) were screened by microarray. In details, adult human testis specimens were obtained from NOA and OA patients, voluntarily recruited from the Reproductive Medicine Center of Nanfang Hospital, Southern Medical University, from 2017 to 2018. Furthermore, all subjects were selected on the basis of comprehensive andrological testing.

Participants/materials, setting, methods:

1 Hematoxylin and Eosin Staining(H&E)

2 RNA extraction and qualification3 Microarray analysis

4 Quantitative real-time PCR (qPCR) validation

5 Gene Ontology (GO) analysis and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis

6 LncRNA and mRNA co-expression network

7 Statistical analysis

Main results and the role of chance: Our data showed that 2108 lncRNAs and 2021 mRNAs that were differentially expressed (fold change ≥2.0-, p value < 0.01) among NOA compared with controls. Several GO terms including spermatogenesis, male gamete generation, cell cycle, were enriched in gene lists, suggesting a potential correlation with NOA. Pathway analysis demonstrated that apoptosis pathway, lysosome and phagosome pathway play important roles in spermatogenesis. Through co-expression analysis, differently expressed transcripts were divided into unique modules, and lncRNA were functionally annotated. Furthermore, We analyzed all the differentially expressed lncRNAs and constructed three separate networks to show the connections of lncRNAs with GO annotations. The core biological process GO terms of each separate system were:GO:0000003, reproduction;GO:0007049, cell cycle; GO:0002376, immune system process. Referring to the results of GO annotations for differentially expressed mRNAs, the core GO terms for lncRNAs correctly reflect the biological process of NOA. Finally, three candidate lncRNAs were verified by qPCR and indentified for further study.

Limitations, reasons for caution:

1 The biological functions of the candidate lncRNAs need to be further validated by additional studies.

2 For the limit of ethics, testis samples from OA patients with normal spermatogenesis were used as controls, which could lead to minor variations as expected.

Wider implications of the findings: Our findings paved the way for elucidating the pathogenesis of NOA with unknown etiologies. Furthermore,the study provided clues for further diagnosis and investigation of male-related reproductive disorders.

Trial registration number: not applicable

O-074 In vitro Induction of different stages of spermatogenesis from immature mice by colony stimulating factor-1 using methylcellulose as a 3-dimension culture system

E. Lunenfeld[1], A. Sawaied[2], M. Huleihel[2]

[1]Faculty of Health Sciences Ben-Gurion University of the Negev- Beer-Sheva- Israel. and Soroka Medical Center, Department of Obstetrics and Gynecology, Beer - Sheva, Israel

[2]Ben-Gurion University of the Negev, The Shraga Segal Dep. of Microbiology-Immunology and Genetics-, Beer-Sheva, Israel

Study question: What is the effect of colony stimulating factor-1 (CSF-1) on the development of mouse spermatogonial cells in 3-dimension (3D) in vitro culture system?

Summary answer: CSF-1 induced the proliferation of spermatogonial cells (VASA positive stained cells) and their differentiation to BOULE and ACROSIN positive stained cells.

What is known already: CSF-1 is a hematopoietic growth factor that induce the development of macrophages from hematopoietic stem cells. It is produces by fibroblasts and by endothelial cells. In the testis it is mainly produced by Leydig cells. The receptor for CSF-1 (CSF-1R) is present on spermatogonial cells. It was shown that CSF-1 induced the proliferation of spermatogonial cells.

Study design, size, duration: Cells were enzymatically isolated from the seminiferous tubules of 7-day-old immature mice. Cells were cultured in methylcellulose (as a 3D in vitro culture system) that contained 10% KSR and GDNF, LIF and EGF with/without CSF-1 (0.1-100 ng/ml). After 4-6 weeks of culture, the developed cells were collected.

Participants/materials, setting, methods: The developed cells were evaluated by immunofluorescence staining using specific antibodies for VASA (a marker for premeiotic cells), BOULE (a marker for meiotic cells) and ACROSIN (a marker for meiotic/postmeiotic cells).

Main results and the role of chance: Isolated cells from seminiferous tubules that grow in methylcellulose that contained KSR and GDNF, LIF, EGF lead to development of colonies after 4-6 weeks (control). These cultures contained cells that expressed VASA, BOULE and ACROSIN positive cells. Addition of CSF-1 (0.1-100 ng/ml) to those cultures significantly increased the percentage of VASA positive cells (from 15% in the control to 25%) ($p<0.001$), in a dose-dependent manner compared to control. Furthermore, addition of CSF-1 to the cultures significantly increased the percentages of BOULE positive cells (from 17% in the control to 28%) ($p<0.001$) and ACROSINE positive cells (from 15% in the control to 27%) ($p<0.001$) compared to control.

Limitations, reasons for caution: The experiments were performed in vitro and need to be confirmed in vivo.

Wider implications of the findings: This is the first study to show a direct effect of CSF-1 on the differentiation of spermatogonial cells in vitro, in addition to its effect on their proliferation. These results may suggest the possible involvement of CSF-1 that is mainly produced by Leydig cells, in the microenvironment of spermatogonial cells.

Trial registration number: NA

O-075 The influence of AZF deletions on sperm retrieval rate (SRR) by TESE and ART results

M. Toya[1], T. Tai[1,2], H. Hattori[1], N. Aono[1,2], R. Obata[2], N. Okuyama[2], N. Oka[2], M. Tsunoda[2], E. Sagara[2], M. Takahashi[1], Y. Nakamura[1], N. Sugaya[1,2], H. Igarashi[1], T. Hashimoto[2], K. Kyono[1,2]

[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan

Study question: For men with AZFc deletion, sperm can be collected by TESE. Does AZFc deletion affect SRR and clinical outcome of ART?
Summary answer: SRR is significantly higher in the gr/gr and b2/b4 deletion groups. However, in b2/b4, clinical outcome of ART was extremely poor.
What is known already: AZF is used as a predictor of the possibility of sperm retrieval by TESE, and it is said that sperm can be collected for patients with AZFb partial deletion, AZFc deletion, and microdeletion. Since gr/gr deletion is a common deletion for Asians especially Japanese, it does not affect the sperm retrieval rate by TESE. Although there are many papers showing SRR according to the results of AZF deletion, there are few references to the clinical outcome of ART.
Study design, size, duration: From April 2014 to December 2017, a screening test for detecting AZF deletion was performed on 294 patients with azoospermia (AZO) or cryptozoospermia (CS). Among them, we surveyed 191 cases who had TESE. Patients were divided into obstructive azoospermia (OA) and non-occlusive azoospermia (NOA) by testicular size, medical history, serum hormone level, chromosome examination, and AZF test result before TESE.
Participants/materials, setting, methods: The relationships among AZF deletion type, sperm retrieval rate, and ART results-fertilization rate (FR), blastocyst rate (BR), good blastocyst rate (GBR), and pregnancy rate (PR)-were retrospectively studied in OA, NOA and CS.
Main results and the role of chance: Out of 294 cases, 249 with AZO and 45 with CS appeared. 118 cases had AZF deletion (40.1%): 89 gr/gr (30.3%), 12 b2/b4 (4.1%), 4 AZFb+c, 3 AZFa, 3 Ym-3, and 3 Y-chromosome long arm deletion, 2 indeterminate finding, 1 AZFb and 1 Y-chromosome complete deletion. 37 OA (No deletion (ND): 25, gr/gr: 12), 145 NOA (ND: 88, gr/gr: 51, b2/b4: 3, others: 3), and 10 CS (ND: 6, gr/gr:1, b2/b4:3) received TESE. In OA, sperm was retrieved in all cases. FR (ND vs gr/gr: 62.5% vs 62.2%), BR (49.6% vs 39.5%), GBR (26.1% vs 21.9%), and PR (49.0% vs 25.9%) showed no significant difference. In NOA, sperm was retrieved in ND, gr/gr, and b2/b4 (25.0% vs 39.2% vs 66.6%), and b2/b4 tended to be higher than others. No sperm was retrieved in the Ym-3 and indeterminate finding groups. FR (61.0% vs 58.5% vs 23.9%), BR (43.24% vs 44.17% vs 0.0%) and GBR (20.5% vs 20.8% vs 0.0%) were significantly lower in b2/b4. PR (46.2% vs 50.0% vs 0%) showed no significant deference in ND and gr/gr, but no pregnancy was achieved in b2/b4. In CS, FR of gr/gr was comparatively high at 53.1%, but GBR (11.8%) and FR (22.2%) tended to be lower.
Limitations, reasons for caution: In the CS group, the AZF test was performed because it was diagnosed as AZO in the first semen examination. In b2/b4, the number of cases is small, and statistical significance cannot be obtained in this study.
Wider implications of the findings: In b2/b4 of CS, FR was lower than ND but other factors saw no difference. In b2/b4 of NOA, although SRR was high, FR and embryogenesis rate were extremely low. It is suggested that the AZF test can predict not only SSR but also clinical outcome of ART.
Trial registration number: none

SELECTED ORAL COMMUNICATIONS
SESSION 21: INSIGHTS ON EMBRYO SELECTION AND PGT/IVF OUTCOMES
Monday 24 June 2019 Haydn 2 15:15–16:30

O-076 Selection of single euploid blastocysts for transfer with high resolution next-generation sequencing significantly improves live birth outcome for IVF patients: a prospective randomized study

Z. Yang[1], Y. Kuang[2], Y. Meng[3], X. Zhang[3], S. Zhang[4], J. Lin[1]

[1]Reproductive Fertility Center, Art, Irvine, U.S.A.
[2]Shanghai Ninth Hospital- Shanghai Jiao Tong University School of Medicine-, Art, Shanghai, China
[3]Second Affiliating Hospital- Kunming Medical University, Art, Kunming, China
[4]Sir Run Run Shaw Hospital- Zhe Jiang University School of Medicine-, Art, Hangzhou, China

Study question: Is selection of single euploid blastocysts for transfer with high resolution NGS (hrNGS) an efficient mean to improve live birth outcome for young IVF patients with good prognosis?
Summary answer: NGS has demonstrated an efficient and robust high-throughput technology for selecting single euploid blastocysts for transfer in patients with good prognosis to reduce multiple pregnancies.
What is known already: Early randomized clinical trials of preimplantation genetic testing for aneuploidy (PGT-A) with FISH detected a limited numbers of chromosomes and produced disappointing pregnancy and live birth outcomes. Recent studies on PGT-A with aCGH, SNP array and qPCR testing of 24 chromosomes have resulted in a significant increase in ongoing pregnancy and implantation rates for IVF patients. More recent advancement in high resolution next-generation sequencing has provided new method for PGT-A in IVF treatment. However, there is still limited information about the efficiency of hrNGS in selecting single blastocysts for transfer for IVF patients with good prognosis in a randomized study.
Study design, size, duration: A total of 267 IVF patients at mean age 32.4 ± 3.5 years who met the inclusion criteria (≤37 years old, presence of both ovaries and with normal uterine lining) were enrolled in this prospective, single-blind interventional study in our multiple IVF clinics from June 2015 to June 2017. The enrolled patients with good prognosis requested single embryo transfer (SET) and singed consents for selecting single blastocysts for transfer with hrNGS to reduce multiple pregnancies.
Participants/materials, setting, methods: The enrolled patients were randomized into either hrNGS plus morphology assessment (Group A, n=134) or morphological assessment alone (Group B, n=133). For both groups, all embryos were cultured to blastocyst stage and were vitrified after biopsy on day 5 (up to 10pm). Single blastocysts were selected for transfer to individual patients based on NGS results primarily in Group A or morphological assessment only in Group B. Live birth rates were compared between the two groups.
Main results and the role of chance: Data analysis revealed that there were no significant differences in female patient's mean age, day 3 FSH, AMH, E_2, antral follicle number between the two groups ($p > 0.05$). The fertilization (2PN) and blastocyst rates were comparable between the two groups ($p > 0.05$). Clinical pregnancy rate was significantly higher in Group A compared to Group B (72.1% vs. 51.9%, respectively, $p < 0.05$). The live birth rate in Group A was also higher than that of Group B (69.8% vs. 46.6%, respectively, $p < 0.05$). There was no significant difference in miscarriage rate between Group A and Group B (2.3% vs. 5.3%, respectively, $p > 0.05$) probably due to the limited numbers in this category. There were no twin or higher-order multiple pregnancies in Group A and Group B. While hrNGS has been recently introduced to IVF treatment, this is the first randomized study showing clinical benefits of hrNGS on selection of single euploid blastocysts for transfer in good prognosis patients in comparison to morphology assessment alone. With the resulting high clinical pregnancy and live birth rates, NGS has demonstrated an efficient and robust high-throughput technology for selection of single euploid blastocysts for transfer in IVF patients with good prognosis to reduce multiple pregnancies.
Limitations, reasons for caution: Although PGT-A with hrNGS brings distinct benefits for many IVF patients seeking single embryo transfer, the approach is not for all patients, especially for those with diminished ovarian reserve and/or poor responders. Further randomized clinical trials with a larger sample are required to confirm its clinical benefits for these patients.
Wider implications of the findings: With the observed high accuracy of 24-chromosome testing and the resulting high live birth rate, hrNGS has demonstrated an efficient and reliable technology for selecting single blastocysts for transfer. With high sensitivity and specificity, hrNGS may be used to detect embryonic aneuploidies, imbalance translocations and mosaicism in routine clinical practice.
Trial registration number: No applicable.

O-077 New evidence on mosaic developmental potential: two hundred mosaic embryos transferred prospectively in a single clinic

F. Spinella[1], A. Biricik[1], M.G. Minasi[2], E. Cotroneo[1], M. Baldi[1], M.T. Varricchio[2], P. Viganò[3], L. Corti[3], M. Surdo[1], E. Greco[2], F. Fiorentino[1]

[1]Genoma Group srl, Molecular Genetics Laboratories, Rome, Italy
[2]European Hospital, Reproductive Medicine-, Rome, Italy
[3]IRCCS San Raffaele Scientific Institute, Reproductive Sciences Laboratory- Division of Genetics and Cell Biology, Milan, Italy

Study question: Can chromosomal constitution of mosaic embryos influence the clinical outcome of in vitro fertilization treatments?
Summary answer: Mosaic monosomy embryos have significant higher chances to result in healthy babies born compared to mosaic trisomy, mosaic segmental and mosaic complex aneuploidy embryos.
What is known already: Chromosomal mosaic embryos are characterized by the presence of chromosomally different cell lines within the same embryo. In a recent published study, we have demonstrated that mosaic embryos hold the potential to implant and result in the birth of healthy babies. Therefore, the transfer of these embryos is now offered as an option for women who undergo in vitro fertilization (IVF) resulting in only mosaic embryos but no euploid embryos for transfer. However, there is still few data concerning the impact of mosaicism on viability, and the classification of such embryos in relation with their reproductive potential is unclear.
Study design, size, duration: The transfer of mosaic embryos was offered to 200 women for whom IVF had resulted in no euploid embryos between May 2016-May 2018. All embryos were cultured to blastocyst stage; trophectoderm (TE) biopsy was performed on Day-5 of development or Day6/7 for slow growing embryos. The clinical outcome obtained after transfer of mosaic embryos with different chromosomal constitution was compared with each other and with that obtained from a control group of 500 euploid blastocysts.
Participants/materials, setting, methods: Comprehensive chromosome screening PGT-A was performed using high resolution next generation sequencing (NGS) methodology. TE biopsies were classified as mosaic if they had 20%-80% abnormal cells. For statistical analysis mosaic embryos were divided in four groups based on chromosomal constitution: mosaic monosomy (single and double monosomies; MM), mosaic trisomy (single and double trisomies, MT), mosaic complex aneuploidy (more than two different aneuploidies; MC) and mosaic segmental aneuploidy (single and double deletion or insertion >5Mb, MS).
Main results and the role of chance: MM showed significant higher birth rate compared to MT (46% vs 24% p=0.02), MC (46% vs 23% p=0.03) and MS (46% vs 22% p=0.02). No significant difference was observed in clinical outcome between the groups MT, MC and MS. A comparison of the clinical outcomes with control euploid group showed no significant difference between euploid control and MM, while a significant low implantation rate (55.4% vs 37% MT, vs 31% MC, vs 23% MS, $p<0.05$) and live birth rate (48.4% vs 24% MT, 23% MC, vs 22% MS, $p<0.05$) between the euploid control and rest of mosaic groups was observed (Table). The highest biochemical pregnancy rate (31%) and early abortion rate (13%) was observed in MS, and MT, respectively.
Limitations, reasons for caution: Additional clinical data must be obtained to evaluate the contribution of different chromosomal constitution before this approach can be evaluated as an additional tool to choose mosaic embryos for transfer.
Wider implications of the findings: The study demonstrated that embryos with MT, MS and MC aneuploidies have lower chances of resulting with birth of healthy babies compared to embryos with MM. More interestingly, no difference has been find in clinical results between MM and euploid control group. These findings should be considered for genetic counseling.
Trial registration number: not applicable.

O-078 Preimplantation genetic testing is not associated with adverse perinatal and obstetric outcomes in singletons

M. Cavagnoli[1], M. Roque[2], M.B. Chehin[3], C. Gomes[4], A.R. Lorenzon[5], J.R. Alegretti[6], P. Serafini[7], E.L.A. Motta[8]

[1]Huntington Medicina Reprodutiva, Clinical Medicine Department, São Paulo, Brazil
[2]Clinica Origen, Scientific Director, Rio de Janeiro, Brazil
[3]Huntington Medicina Reprodutiva, Clinical Coordinator, São Paulo, Brazil
[4]Huntington Medicina Reprodutiva, Clinical Director, São Paulo, Brazil
[5]Huntington Medicina Reprodutiva, Scientific Coordinator, São Paulo, Brazil
[6]Huntington Medicina Reprodutiva, Embryology Director, São Paulo, Brazil
[7]Huntington Medicina Reprodutiva/University of São Paulo, Clinical Director / Department of Gynecology and Obstetrics, São Paulo, Brazil
[8]Huntington Medicina Reprodutiva/Federal University of São Paulo, Clinical Director/Department of Gynecology, São Paulo, Brazil

Study question: Does the embryo biopsy for preimplantation genetic testing (PGT) is associated with adverse obstetric and perinatal outcomes IVF/ICSI cycles singletons?
Summary answer: The PGT in blastocyst stage in GnRH antagonist protocol ICSI cycles is not associated with increased risk of adverse obstetric and perinatal outcomes.
What is known already: Pregnancies arisen from IVF/ICSI treatments are associated with a higher risk of adverse perinatal and obstetric outcomes when compared to naturally conceived. It has been suggested that the manipulation and culture of gametes and embryos would be one of the factors leading to increase risks of adverse outcomes. PGT during IVF/ICSI treatments is increasing worldwide due to advanced maternal age and for embryo selection that may improve live birth per embryo transfer. However, there are few data available evaluating if embryo manipulation associated with PGT cycles may add risk to obstetric and perinatal complications when compared to cycles without PGT.
Study design, size, duration: This is a cohort study evaluating singletons born following ICSI cycles with and without PGT in a private center between 2011 and 2015. Data were collected from 996 newborns following fresh (n= 490 singletons) and frozen-thawed (FET) (n=506). All the embryo transfers and biopsies were performed in the blastocyst stage. The cycles were performed in GnRH antagonist protocols and the FET following a hormonal replacement endometrium priming.
Participants/materials, setting, methods: Outcomes measure were: low birthweight (LBW), small-for-gestational-age (SGA), large-for-gestational-age (LGA), preterm birth, congenital anomalies, preeclampsia, gestational diabetes, and perinatal mortality. Multiple logistic regression analysis was performed to evaluate the association of the number of the oocytes retrieved with the outcomes mentioned above. Adjusted odds ratio (aOR) was obtained for each outcome after adjusting for confounding factors such as female age and BMI, infertility cause, number of oocytes retrieved.
Main results and the role of chance: The singletons from a fresh embryo transfer with PGT (n=113) vs. no-PGT (n=377) presented no differences in the obstetric and perinatal outcomes. After fresh embryo transfer, the singletons mean birthweight was 2971.97±501.16 and 3016.41±546.69 grams (P=0.4382), in PGT and no-PGT cycles, respectively. The mean gestational age was 37.55±1.95 and 37.79±2.15 weeks (P=0.2848) following PGT and no-PGT cycles, respectively. There were no statistical differences in the aOR of LBW, SGA, LGA, preterm birth, congenital anomalies, preeclampsia, gestational diabetes, and perinatal mortality when comparing PGT to no-PGT cycles with fresh embryo transfers. In singletons following FET with (n=127) and without (n=379) PGT, no differences were found. The singletons mean birthweight was 3109.26±528.44 and 3080.23±542.67 grams (P=0.4801) in PGT and no-PGT cycles, respectively. The mean gestational age was 38.37±2.13 and 37.98±2.27 weeks (P=0.0807) following PGT and no-PGT cycles, respectively. The aOR of all the other outcomes were not statistical different in FET cycles with and without PGT.
Limitations, reasons for caution: As this is a cohort study, although the outcomes were adjusted for confounding factors, some unknown confounders may affect the outcomes.
Wider implications of the findings: For the first time, this study compared the obstetric and perinatal outcomes among singletons with and without PGT after blastocyst embryo transfer during a GnRH antagonist protocol in fresh and FET cycle with hormonal replacement therapy for endometrial priming.
Trial registration number: Not applicable.

O-079 Predictors of poor prognosis in preimplantation genetic testing for monogenic disorders (PGT-M)

W. Verpoest[1], P. Verdyck[2], A. De Vos[1], M. De Rycke[2], I. Liebaers[2], C. Blockeel[1], V. Berckmoes[2], P. De Becker[2], M. De Vos[1], K. Keymolen[2], S. Santos-Ribeiro[1]
[1]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium ; [2]UZ Brussel, Centre for Medical Genetics, Jette- Brussels, Belgium

Study question: How many oocytes are needed for a single PGT-M treatment cycle to achieve a sufficient cumulative live birth rate (CLBR).
Summary answer: When assessing both age and number of oocytes together the predicted CLBR remained >10% whenever female age was ≤40 and the number of oocytes ≥7.
What is known already: The number of oocytes is an important contributory factor in the prognosis of PGT in order to obtain a sufficient number of embryos. PGT treatment is more likely to bear the negative effects of suboptimal ovarian stimulation, fertilisation and embryo culture than conventional IVF. A part of the obtained embryos will be affected by the disease tested, a part of the embryos will fail to have a genetic diagnosis; these embryos may not be used for embryo transfer. The loss of embryos available for embryo transfer as a result of PGT varies between 25-81% according to the indication for PGT.
Study design, size, duration: This was a single centre retrospective comparative cohort study. The principal outcome measure were predictors of poor CLBR (predicted CLBR<10%) in patients undergoing PGT-M. The secondary outcome measure was to compare these predictors of poor prognosis to non-PGT women undergoing ART. 2265 PGT-M treatment cycles were compared to 2833 conventional ICSI cycles from January 2011 to December 2015. Treatment without known live birth outcome were considered negative. IVM and donor treatment cycles were excluded.
Participants/materials, setting, methods: Multivariable regression analysis was applied to account for the following potential confounding factors: female age, rank, oocytes, embryos analysed and dose of ovarian stimulation. Post-hoc power calculations (alpha of 0.05, power of 0.80) indicated that our study was powered adequately to demonstrate significant difference of 3.8% in CLBR per retrieval.
Main results and the role of chance: Main demographic characteristics (female age, cycle rank) and ICSI treatment characteristics (total gonadotrophins, oocytes retrieved, embryos available for PGT-M, blastocyst development) were not significantly different between both groups. In the PGT group the CLBR of 10% was surpassed from 2 oocytes retrieved or 1 embryo available per single treatment cycle. Both the crude and predicted CLBR reached a maximum at the age of 27 and decreased thereafter with increasing age. Relative to the number of oocytes in the PGT group the CLBR reached 30% at 11 oocytes and increased to a maximum of 47%. When assessing both age and number of oocytes retrieved together, the predicted CLBR remained >10% whenever female age was ≤40 and the number of oocytes ≥7. Neither the crude nor calculated cumulative live birth delivery rate changed substantially with increasing rank of treatment. CLBRs following PGT were significantly lower than without PGT (29.4% vs 35.0%, respectively; p<0.001) even following confounder adjustment. Both in the PGT and the non PGT group the CLBR increased with increasing numbers of oocytes retrieved, leveling off in both groups from 14 oocytes. The CLBR leveled off beyond 4 PGT useable embryos and beyond 6 useable embryos in the non PGT group.
Limitations, reasons for caution: Despite the large sample size, the findings are confined by limited confounder adjustment and lack of specific PGT comparators.
Wider implications of the findings: In a PGT-M programme patients need to be informed on the limited prognosis if ovarian response is low. Nevertheless, two or more oocytes retrieved per single treatment cycle offer a mean CLBR of over 10%. The results diagram produced from this study is a useful tool in counseling PGT patients.
Trial registration number: not applicable

O-080 miRNAs as novel biomarkers of mucous membrane permeability associated to infertility

M.A. Azpiroz[1], M.B. Azpiroz[1], M.A. Molina[1], L. Orguilia[2], G. Gutierrez[2]
[1]ABM Laboratorios Tandil, Fertility, Tandil, Argentina
[2]Inmunogenesis/CONICET, Reproductive Immunology, Buenos Aires, Argentina

Study question: Is there any biochemical parameter that allows us to identify microbiota dysbiosis related to immunological disbalance in women with unexplained infertility and implantation failure?
Summary answer: Aberrant expression of miRNAs regulating macrophages and mucosal tight junctions could be associated to microbiota disbiosis, increased mucous permeability, recurrent candidiasis and autoimmunity.
What is known already: Autoimmunity is associated to an increase in intestinal permeability as well as reproductive failure. Mucous membranes (gut, endometrium, reproductive tract) contain commensal bacteria that modulate physiological host functions. Dysbiosis of commensal bacteria triggers dysfunction of the intestinal epithelial barrier, leading to the induction or aggravation of intestinal inflammation. In addition increased tight junction (TJ) barrier permeability may lead to the defects in TJ barrier and subsequent development of inflammation. Recent evidence suggests that different miRNAs are implicated in inflammatory diseases. However, the physiological role of miRNAs in infertility remains elusive.
Study design, size, duration: Diagnostic test study. Analytical, prospective, experimental. microARN transcriptional vaginal test were performed in 17 fertile women and 21 unexplained primary infertility (UI) patients between March and December 2018. We investigated whether the single or combined expression of miR21, miR155, miR193b, and miR141 was able to identify infertile patients with increased risk of mucosal immune system deficiency, increased intestinal permeability, recurrent candidiasis and autoimmunity.
Participants/materials, setting, methods: Vaginal swab and peripheral blood samples were collected from 38 women between the ages of 25 and 39. MiRNAs (miR21, miR155, miR193b, miR141) were determined with specific TaqMan probes by real time PCR. Quantification of thyroid antibodies, gastrointestinal autoantibodies, antiphospholipid syndrome and anti-nuclear antibodies where determined together with insulin and glucose blood levels by standard protocols.
Main results and the role of chance: MiR-21 which is associated to tight junctions disruption, was up regulated (*p=0.0030) in infertile patients showing altered integrity and functionality of mucous membranes. Moreover, miR-155, which is strongly associated with inflammation, positively correlate with miR21 level in those patients (*p<0,0001). Receiver-operator characteristic (ROC) curve analyses suggest that these serum miRNAs may be useful markers for discriminating patients with gastrointestinal autoimmunity and infertility. ROC curve areas for miR-21, and miR-155 were 0.844 (95% CI: 0.773–0.947; *p<0.001), and 0.838 (95% CI: 0.765–0.944, *p<0.001), respectively.

According to the selected cutoff values , sensitivity and specificity were 81% and 92%, and 81% and 83%, respectively.
Limitations, reasons for caution: Sample size should be increased and the analysis of local microbiota by NGS which is ongoing at this moment should be include in order to correlate with miRNAs biomarkers.
Wider implications of the findings: miRNAs should be considered as new innovative not invasive diagnostic test in UI. Improving knowledge in maternal microbiome could inform future research about modifications to the individual's microbiome as a potential strategy to prevent adverse outcomes and to develop a healthy microbiome in the mother and their offspring.
Trial registration number: Not apply.

O-081 Too little, too late: A Systematic Review of Clinical Practice Guidelines Informing Counselling on Female Age-Related Fertility Decline

E. Trawick[1], J. Pecoriello[1], G. Quinn[1], K. Goldman[2]

[1]*NYU School of Medicine, Department of Obstetrics and Gynecology, New York, U.S.A.*
[2]*Northwestern University Feinberg School of Medicine, Department of Obstetrics and Gynecology- Division of Reproductive Endocrinology and Infertility, Chicago, U.S.A.*

Study question: What are the high-quality clinical practice guidelines (CPGs) informing patient counselling on female age-related fertility decline, and what is their content?
Summary answer: Few high-quality guidelines address counselling on female age-related fertility decline, and existing guidance is both inconsistent and incomplete.
What is known already: Natural fertility declines with increasing female age, with fecundity significantly diminished by age 40; however, women often underestimate the effects of age-related fertility decline. As women delay childbearing, this misunderstanding may lead to unintended childlessness. Providers do not routinely counsel patients on the effects of reproductive aging and may lack accurate knowledge of female age-related fertility decline and how to counsel. Healthcare providers rely on guidelines to inform care, and poor quality or insufficient recommendations may contribute to inconsistent counselling and a knowledge gap among healthcare professionals.
Study design, size, duration: A systematic review was performed of professional organization guidelines published in English between 2006 and 2018 addressing patient counselling on age-specific content relating to preconception, fertility decline, or reproductive life planning. Guidelines were assessed for quality and bias using the AGREE II guideline appraisal instrument and were considered high-quality if $\geq$3 domains had a composite score $\geq$60%.
Participants/materials, setting, methods: We identified 2036 records through a systematic database search and 872 records through a hand-search of professional organizations. We identified 18 of those records as guidelines addressing age-related fertility decline counselling. The content of each guideline was evaluated and compared.
Main results and the role of chance: Of the 18 guidelines identified, 6 focused on reproductive aging, and 12 covered related topics of contraception, preconception, infertility, and general women's healthcare. Only 11 (61%) met our criteria for high-quality, and all of these high-quality CPGs scored >60% in the AGREE II domain assessing rigor of development. Among the 11 high-quality guidelines, 9/11 targeted primary providers. Though 10/11 explicitly stated an age when female fertility declines, that age varied across guidelines from 30-"late 30s." Only one guideline recommended an age at which patients should be counselled, and 4/11 loosely advised counselling prior to onset of fertility decline. Nearly half (5/11) of the high-quality guidelines did not address the risks of advanced maternal age.
Limitations, reasons for caution: AGREE II does not endorse a specific threshold for considering a guideline high-quality, thus our criteria for high-quality guidelines is not validated. Inconsistent and limited guidance could be related to a lack of clear evidence regarding the benefits of counselling on patient knowledge and reproductive decision-making.
Wider implications of the findings: Recommendations vary regarding who and when to counsel about age-related fertility decline, and guidelines present conflicting ages at which fertility is compromised. Weak and inconsistent guidelines may contribute to insufficient counselling, leading to inconsistent care. Improvement in CPGs, including incorporation of age-specific recommendations, may lead to improved patient anticipatory guidance.
Trial registration number: N/A

O-082 Concerns on future fertility among users and non-users of combined oral contraceptives

S. Landersø[1], K.B. Petersen[2], D. Vassard[3], E.C. Larsen[4], H.S. Nielsen[1], A.N. Andersen[1], L. Schmidt[3]

[1]*Copenhagen University Hospital, The Fertility Clinic, Copenhagen, Denmark*
[2]*Zealand University Hospital- Køge, The Fertility Clinic, Køge, Denmark*
[3]*University of Copenhagen, Department of Public Health, Copenhagen, Denmark*
[4]*Danish Fertility Clinic, Danish Fertility Clinic, Copenhagen, Denmark*

Study question: To what extent are current users and non-users of combined oral contraceptives (COC) concerned about effects of COC usage on future fertility?
Summary answer: Overall, 28% of COC-users vs. 19% among non-users believed COC could impair ovarian reserve, and COC-users expressed considerable concerns about impact on future fertility.
What is known already: The COC-pill is one of the most commonly used contraceptive methods in the Western world; approx. 45% of Danish women use COC during their fertile life. To our knowledge no previous studies have explored the thoughts and concerns on future fertility among COC-users. Due to the frequent use of COC and increasing use of fertility assessment and counselling it is important to uncover concerns, well-founded or not, to optimize fertility counselling. Therefore, we conducted this large-scale study to investigate the extent of thoughts and myths about fertility among women of reproductive age, including 1332 current COC users.
Study design, size, duration: The study was performed as a population-based on-line questionnaire during the period from 2016 to 2018. Eligible women were between 18 to 41 years either with or without a current use of COC. Non-users (prior users and never users) constituted a comparison group. In total, 2534 women completed the electronic questionnaire. The analyses comprised 1332 current users of COC and 1202 non-users.
Participants/materials, setting, methods: Respondents (users and non-users) were recruited either from the Fertility Assessment and Counselling (FAC) Clinics in Copenhagen, Denmark (Hvidman et al. 2015), (n=1,075) or via an internet-based survey addressing women with interest in the FAC-Clinics webpages (n=1,410). The respondents were asked about contraceptive history and thoughts/concerns on various aspects on future fertility. Data were analyzed using age-adjusted logistic regression analyses to identify potential differences between current COC-users and non-users (non-users being the reference group).
Main results and the role of chance: Mean age of COC-users were 24.8 years vs. 30.8 among non-users ($p<0.0001$). Due to the age-difference all analyses were age-adjusted. The duration of COC-use spanned from 1-20 years among COC-users; 52% had used COC between 6-10 years. A total of 65.6% of COC-users reported having thoughts about whether COC-use could affect future fertility versus 52.1 among non-users (OR=1.6, 95%-CI 1.3-1.9). Overall, 27.9% of COC-users vs. 19% among non-users believed COC could impair the ovarian reserve (OR=1.2, 95%-CI 0.96-1.52). Oppositely, 14.1 % of COC-users and 10.5% in the non-COC group thought that lack of ovulation could "save" the eggs (OR=0.9, 95% CI 0.7-1.3). Nearly half of both groups thought that COC-use could make it more difficult to become pregnant after discontinuation (45.5% among COC-users, 53.3% among non-users, OR=0.7 (0.6-0.8). Two thirds of both groups were concerned it could be harmful to disturb the natural hormonal balance. Primary reasons for non-use were concerns on disturbance of the natural hormone-system (36.2%), and concerns on future fertility (26.4%). In conclusion, the results clearly show a

need for information on risks as well as "non-risks" when prescribing COC pills. The large sample size means that it is unlikely that the results is caused by chance.
Limitations, reasons for caution: There is a risk for recall bias regarding contraceptive and reproductive history. It cannot be excluded that questions on potential harmful effects of COC use could induce these concerns. However, comments from respondents suggest that many had pre-existing concerns.
Wider implications of the findings: Health care professionals prescribing contraception must be aware of concerns and myths on future fertility from COC usage to perform better counselling of these women, especially since this is one of the most widely used contraceptive methods in the Western world.
Trial registration number: Not applicable.

O-083 Does watching an educational video increase Fertility Awareness (FA)? Results from a randomised controlled trial with partnered people desiring to become parents

J. Pedro[1,2], J. Fernandes[1], A. Barros[3,4], P. Xavier[4,5], C. Oliveira[4], L. Schmidt[6], M.E. Costa[1,2], M.V. Martins[1,2]

[1]University of Porto, Faculty of Psychology and Educational Sciences, Porto, Portugal
[2]Centre for Psychology at University of Porto, University of Porto, Porto, Portugal
[3]University of Porto, Department of Genetics- Faculty of Medicine. Institute of Health Research and Innovation I3S, Porto, Portugal
[4]Centre for Reproductive Genetics A. Barros, Porto, Portugal
[5]University of Porto, São João Hospital, Porto, Portugal
[6]University of Copenhagen, Department of Public Health, Copenhagen, Denmark

Study question: What are the short and long-term effects of a video aiming to increase fertility awareness (FA) among partnered people desiring to become parents?
Summary answer: The video intervention increased FA levels 1-month later and the effects were maintained 1-year later for almost all variables.
What is known already: FA interventions have been shown to be effective on increasing FA in short-term. However, these studies had been using heterogeneous samples regardless of their age, marital status, parity, and desire to have children. Less is known about the long-term effectiveness of these educational interventions on childless and presumably fertile people who are already committed in a heterosexual relationship and who express the desire to have children in a near future.
Study design, size, duration: A double-blind randomised controlled trial was initiated in October of 2016. Participants were randomly allocated into the intervention group (IG) and control group (CG) and answered to an online questionnaire before(T0), 1-month(T1), 6-months(T2) and 1-year(T3) after the intervention. Seven questions assessed FA about infertility definition, risk factors, chance of pregnancy if the woman is 25-30, 35-40 years old and the chance of pregnancy with fertility treatment if the woman is 35, 40, 45 years old.
Participants/materials, setting, methods: 369 participants (243 women) were invited in gynaecology/fertility clinics, religious pre-marital courses and through social media. IG participants (n=189) were exposed to a 5-min video delivering information on age-related fertility decline, infertility risk factors and pregnancy chances according to women's age and conception mode after answered the T0 questionnaire; participants in CG (n=180) received no stimulus. Mixed Anovas using conservative F-tests were performed to test the interaction between time and group on FA variables.
Main results and the role of chance: Participants were aged 29 years old and were partnered for 6 years, on average. Attrition analyses didn't reveal significant differences between those who had answered and those lost to follow-up in T1 (n=217) regarding age, gender, relationship length, education, reproductive status (being trying to conceive or not) and belonging to IG or CG. Participants at T2 (n=111) and T3 (n=102) were older and T3 participants desired to have children in a shorter time. Significant interaction between group and time were found for infertility definition, lifestyle risk factors, chance of spontaneous pregnancy (if the woman is 25-30 and 35-40 years old) and treatment pregnancy if the woman is 35 and 40 years old ($p<.005$), demonstrating an increase in six of the seven FA variables in IG participants from T0 to T1. When looking at follow-ups times (T2,T3), significant interaction effects between group and time were found for the chance of spontaneous pregnancy if the woman is 25-30 and 35-40 years old and treatment pregnancy if the woman is 35 and 40 years old ($p<.005$). No significant interaction effects were found for intentions to adopt fertility-optimizing behaviours, intended time to start trying to conceive and desired age of first and last child.
Limitations, reasons for caution: Although we had randomly allocated people to CG and IG, the high attrition rate may limit the generalization of our results. Future studies should include larger samples to account for this. Some bias might have occurred due to high education level and volunteer participation since younger participants withdrawer more often.
Wider implications of the findings: This video might be a cost-effective and easy to access tool to raise FA among reproductive-age people in short and long-term. Information regarding fertility should be more easily spread (using videos, text messages, online tools) and presented in different contexts (health services, personalized appointments) in order to improve FA levels.
Trial registration number: NCT02813993

O-084 Women's perceptions of fertility assessment and counselling six years after attending the Fertility Assessment and Counselling clinic

E. Koert[1], R. Sylvest[2], I. Vittrup[3], H.W. Hvidman[1], K. Birch Petersen[4], J. Boivin[5], A. Nyboe Andersen[1], L. Schmidt[6]

[1]Copenhagen University Hospital- Rigshospitalet, Fertility Clinic, Copenhagen, Denmark
[2]Copenhagen University Hospital - Hvidovre Hospital, Department of Obstetrics and Gynecology, Hvidovre, Denmark
[3]Copenhagen University Hospital - Gentofte Hospital, Department of Skin and Allergy, Hellerup, Denmark
[4]Zealand University Hospital - Fertility Clinic, Department of Obstetrics and Gynecology, Køge, Denmark
[5]Cardiff University, School of Psychology, Cardiff, United Kingdom
[6]University of Copenhagen, Department of Public Health- Section of Social Medicine, Copenhagen, Denmark

Study question: What are women's perceptions of fertility assessment and counselling six years after attending the Fertility Assessment and Counselling (FAC) clinic?
Summary answer: Personalized fertility knowledge and advice were viewed as important aids to decision-making but the findings emphasize the need for guidance related to desired family size.
What is known already: Many young people wish to become parents in the future and desire an average of two children. There is a need for fertility awareness in women and men to increase fertility knowledge and support informed fertility decision-making to achieve parenthood and family size goals. The FAC clinic in Copenhagen, Denmark is a personalized fertility awareness intervention based on clinical examination and evaluation of individual risk factors (Hvidman et al., 2015). It opened at the end of 2011. Available qualitative research showed that attending the FAC clinic increased fertility awareness and served as a catalyst for change in women one-year post-consultation.
Study design, size, duration: A six-year follow-up qualitative study of 24 women who attended the FAC clinic between January and June 2012. All women were interviewed during a two-month period from February to March 2018 at Rigshospitalet, Copenhagen, Denmark. Interviews were held in English and ranged between 60 and 94 minutes (average 73 minutes).
Participants/materials, setting, methods: Invitations to participate in an interview-based follow-up study were sent to 120 women who attended the FAC clinic in 2012. In total 95 women read the invitation, 35 confirmed interest in participating and 16 declined to participate. Twenty-five interviews were booked and 24 interviews held. Interviews followed a semi-structured format regarding reasons for attending the FAC clinic, if/how their needs were met, and perceptions of fertility assessment and counselling. Data was analyzed using thematic analysis.
Main results and the role of chance: At the present interview, women were on average 38 years old. In total, 10 were currently single or dating and 14 were married/common-law. All were childless when they attended the FAC clinic. At the interview, 21 women were parents (14 women with 1 child; 6 with 2; 1 with 3) and 3 women intended to have children in the future. The most common reason for originally attending the FAC clinic was to determine how long they could delay childbearing. The majority of women now believed their needs had been met by attending the FAC clinic. Those who were

dissatisfied cited a desire for concrete information as to their remaining years of fertility, although acknowledged that this was likely not realistic. Women stated that they had felt reassured as to their fertility status after attending the FAC clinic whilst receiving the message that they could not delay childbearing "too long". Women viewed personalized fertility knowledge as an important aid to decision-making but cautioned about developing a false sense of security based on the results. Although many had achieved their goal of becoming a parent, several had not achieved their family size goal due to starting their family at an advanced age.

Limitations, reasons for caution: Participants were self-selected and interviews were conducted in English, which could have introduced a selection bias. Importantly, the study group included a broad spectrum of women who achieved parenthood through different means (heterosexual/lesbian relationship, single parent with donor, co-parent) with various family sizes, and women who were currently childless.

Wider implications of the findings: The findings suggest that women who attended the FAC clinic are generally satisfied with their experience and achieved their goal of becoming a parent. Information regarding timing of parenthood in terms of desired number of children should be emphasized in future consultations to support achievement of family-size goals.

Trial registration number: N/A.

O-085 Women's decision-making process about the use of fertility preservation (FP) to prevent age-related fertility decline: a two-year prospective study

M. Sousa Leite[1], B. Figueiredo[1], A. Ter Keurst[2], J. Boivin[3], S. Gameiro[3]

[1]University of Minho, Department of Psychology, Braga, Portugal
[2]Rijnstate hospital, Department of Medicine, Arnhem, The Netherlands
[3]Cardiff University, Department of Psychology, Cardiff, United Kingdom

Study question: How does decision-making about the use of FP in childless women aged between 28 and 35 years unfold over a two-year period?

Summary answer: Few women show evidence of progressing in their FP decision-making process with only 14% reaching a decision; all of which deciding not to use FP.

What is known already: During the last decade (2010-16), women's use of egg freezing increased by 460%. The optimal age-range to freeze oocytes is between 28 and 35 years, but around 30% of the women do it at 38 years or later, therefore compromising their reproductive goals. Additionally, although a considerable number of women consider its use (31.5-34.5%) only a minority (4%) actually use it, and evidence shows that this decision-making process takes on average two years. Thereby, it is critical to understand how this FP decision-making process changes over time, in order to better advise women about if and when to use FP.

Study design, size, duration: A theoretically informed online survey was conducted in 2014, to investigate the factors associated with women's intentions to use FP (Health Belief Model, HBM) and their stage of decision-making (Transtheoretical Model, TTM). The present study is the two-year follow-up to investigate how women's intentions and stage of decision-making changed over time. 257 women participated in the initial survey, among which 214 consented to be contacted for future research.

Participants/materials, setting, methods: The original inclusion criteria were being childless, aged 28-35 years, having a child-wish and not being/trying to get pregnant. The questionnaire used in the follow-up study assessed sociodemographic factors, parenthood goals (intention and desire to have a child, number of children wanted), fertility knowledge; HBM variables (perceived susceptibility, severity, barriers and benefits); FP intentions (Likert-scale from 1=*strongly disagree* to 7=*strongly agree*); FP decisional stage and steps regarding behavioural engagement (according to the TTM); and decision.

Main results and the role of chance: 115 women completed the questionnaire (53.74% response rate). Women were on average 32 years, the majority were living with their partner, were heterosexual, employed, resident in UK and had university education. Since the baseline assessment, 16% (n=17) of women delivered a baby or were pregnant and 7% (n=7) were trying to achieve pregnancy, without FP. Inferential statistical ($p<.05$) showed that women's intention and desire to have a child and number of desired children significantly decreased over time. Compared to baseline, fertility knowledge and perceived susceptibility to infertility significantly increased, perceived severity of infertility significantly decreased and perceived barriers/benefits toward FP did not change. Women's intentions to use FP remained low (around three). Most women (n=81, 77.14%) stayed in the first decisional stage of the TTM (pre-contemplation of whether or not to use FP), 10% (n=10) progressed through the stages, with 14% (n=15) reaching a decision, all of which deciding not to use FP. Around 40% (n=44) of women discussed FP, mostly with friends/partner, 30% (n=32) actively sought information about FP, with google being the most used source, and 3% (n=3) sought specialised advice. Women's baseline intentions to use FP did not significantly predict their decision at follow-up (β=-.12, p=.26).

Limitations, reasons for caution: This was a self-selected sample of childless women with parenting desire who may have been prompted to engage in FP decision-making by being invited to participate. Therefore, FP intentions and progression through FP stages may be overestimated. The sample size might have constrained the power to detect small effect sizes.

Wider implications of the findings: Women at the optimal age-range to freeze oocytes do not actively engage in decision-making about it. This lack of engagement could be related with achieving parenthood goals; downwards revision of desired number of children that could reduce required period of childbearing; and/or less appraisal that infertility is a threat.

Trial registration number: not applicable.

O-086 A Genome-wide Association Study of Endometriosis: Data from the UK Biobank

L. MAnning[1]

[1]Royal Devon and Exeter Hospital, Obstetrics- Gynaecology and Reproductive Medicine, Exeter, United Kingdom

Study question: *Study Aim* To perform a genome-wide association study in a population of European ancestry to investigate genetic factors contributing to endometriosis and to explore existing endometriosis-associated variants in the literature.

Summary answer: Identified variants implicate genes involving steroidogenesis, ovarian follicular development, cell signalling, maintenance of cell morphology, angiogenesis, regulation of sex hormone levels in development of endometriosis.

What is known already: The risk loci that have been identified from published GWAS so far implicate certain WNT protein signalling, cell adhesion, cell migration, angiogenesis and inflammatory and hormone-metabolism pathways as significant in the pathogenesis of endometriosis.

Study design, size, duration: A genome-wide association study using data from the UK Biobank including 3820 endometriosis cases and 240731 controls. Genotyping was performed using the Applied Biosystems™ UK BiLEVE Axiom™ Array by Affymetrix and the Applied Biosystems™ UK Biobank Axiom™ Array, covering 807,411 and 825,927 markers respectively, in GRCh37 coordinates.

Participants/materials, setting, methods: Data from the UK Biobank including 3820 endometriosis cases and 240731 controls were analysed in the GWAS using genotypes imputed from the 1000 Genomes reference panel and BOLT-LMM v2.3 software. Multivariate logistic regression analysis was performed in 12 top signals identified.

Main results and the role of chance: One novel variant and two previously published endometriosis signals reached genome-wide significance: Chr4:55998379_TAA_T deletion (p=2.90x10-8), rs11031005 (p= 1.7x10-9) and rs61768001(p= 8.1x10-10). A variant rs58415480 was also moderately associated with endometriosis (p= 2.9x10-6). Genes related to these loci include KDR, WNT4, SYNE1, ESR1, and FSHB. Association with previously

published endometriosis SNPs (rs1250241, rs1537377, rs10167914, rs6546324 and rs11674184) was replicated.
Limitations, reasons for caution: Further research to assess the functional impact of these variants is required. The process by which phenotype data was collected in the UK Biobank study for this condition risks reporting bias. Conditional analysis assessing rs1903068 and chr4:55998379 is required to ascertain if this is a truly novel variant.
Wider implications of the findings: Insight into the genomic pathways leading to endometriosis will potentially advance the development of treatments better targeted to processes underlying the condition, and the identification of markers that can be used to facilitate clinical diagnosis of the condition - possibly avoiding resort to surgery and the risks associated with this.
Trial registration number: not applicable.

O-087 Excess germline mutations in four genes in unrelated women with surgical endometriosis

K. Ward[1], R. Chettier[2], A. Hans[2]

[1]*Juneau Biosciences- LLC, Administration, Salt Lake City, U.S.A.*
[2]*Juneau Biosciences- LLC, Research and Development, Salt Lake City, U.S.A.*

Study question: To identify any genes with a large burden of mutations in subjects with endometriosis compared to normal population controls.
Summary answer: Four genes (ZNF586, LUZP4, POP4 and UNC5CL) show significant mutational burden associated with endometriosis.
What is known already: Genome-wide association studies in endometriosis have implicated several genomic regions, and whole exome sequencing studies have identified coding variants associated with endometriosis. Although some mutations have segregated with the disease in familial endometriosis, studies to date have not identified genes with significant mutational burden in unrelated patients with endometriosis.
Study design, size, duration: DNA was extracted from blood or saliva collected from 2,596 unrelated women with surgically-confirmed endometriosis using standard methods. Whole Exome Sequencing was performed using Ion Proton platform.
Participants/materials, setting, methods: Variants were called using Torrent Variant Caller (ThermoFisher). We calculated the cumulative genetic burden for each gene by adding the minor allele frequencies for all the rare coding variants identified in cases (frequency <0.01 in the gnomAD database). We used Fisher's Exact Test to determine excess burden in endometriosis subjects compared to the Non-Finnish European cohort (n=64,000) in gnomAD database.
Main results and the role of chance: We identified 4 genes (ZNF586, LUZP4, POP4 and UNC5CL) with significant gene burden in subjects with endometriosis ($p<5 \times 10^{-8}$). One in four women with endometriosis carry a mutation while the population prevalence is only 8%. 141 different coding mutations were observed in these 4 genes; the G518T mutation in the POP4 gene was seen in 2.9% of the endometriosis subjects. None of the protein encoded by these genes have a known role in endometriosis.
Limitations, reasons for caution: Replication of these results in additional cohorts is warranted.
Wider implications of the findings: Discovery of gene mutations underlying endometriosis may lead to new pathophysiology insights, improved diagnostics, and novel treatment approaches.
Trial registration number: N/A

O-088 Do women with endometriosis have an increased risk for immunological diseases? A systematic review of the literature and study of 273,404 women from UK Biobank

Study question: Are women with endometriosis more susceptible to have immunological diseases, and how robust is the evidence with regards to temporality, confounders, effect mediators and disease ascertainment?
Summary answer: Preliminary analysis results among 273,404 women from UK Biobank suggest that women with endometriosis are more likely to develop certain immunological diseases than those without.
What is known already: Aberrations in the immune system of endometriosis patients have been proposed, preventing clearance of ectopic endometrial cells and allowing for their implantation, survival and maintenance outside the uterus. Also, an association between endometriosis and immunological diseases at population level has been observed by several epidemiological studies, though the robustness of the evidence is uncertain. We investigate the association between endometriosis and 29 immunological diseases identified from UK Biobank including 9 autoinflammatory diseases, 16 classic autoimmune diseases and 4 mixed-pattern immunological diseases.
Study design, size, duration: The UK Biobank includes 273,404 women aged ≥40 years old at recruitment, linked to hospital records, of whom 8,223 are diagnosed with endometriosis and 64,620 with immunological diseases (52,027 autoinflammatory; 14,764 classic autoimmune; 4,379 mixed-pattern diseases).We investigate the association between endometriosis and immunological diseases through: 1) A systematic review of published population-based studies; 2) epidemiological analysis of UK Biobank data using both a nested case-control and a retrospective cohort study designs.
Participants/materials, setting, methods: The systematic review included 26 population-based studies (6 cross-sectional, 14 case-control, 6 cohort); fixed-/random-effect meta-analysis was employed for 5 endometriosis-immunological disease associations. The nested case-control study of UK Biobank data will be stratified by disease ascertainment and ethnicity, and accounting for confounders such as age, lifestyle or hormonal factors using logistic regression modelling. The retrospective cohort analysis will be conducted using Cox proportional hazards regression models of incident immunological diseases in association with endometriosis history.
Main results and the role of chance: The systematic review and meta-analysis suggested endometriosis to be significantly associated with systemic lupus erythematosus, Sjögren's syndrome, rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease and coeliac disease. However, quality of the evidence was generally poor due to study design issues such as self-reported outcomes, small sample size, unrepresentativeness of the control group or whole study population, limited or no adjustment of confounding factors, and reporting no confidence intervals for risk estimates. Preliminary analysis results of the UK Biobank data suggested a significantly increased risk among women with endometriosis of: systemic lupus erythematosus (odds ratio (OR):1.56,95% confidence interval (CI):1.10-2.15;P=0.009), multiple sclerosis (OR:1.31,95%CI:1.00-1.67;P=0.042), inflammatory bowel disease (OR:1.23,95%CI:1.02-1.46;P=0.023), coeliac disease (OR:1.26,95%CI:0.99-1.58;P=0.048), myasthenia gravis (OR:2.19,95%CI:1.12-3.85;P=0.012) and Behcet's syndrome (OR:9.22,95%CI:3.38-21.51;P<0.001). A 9% (OR:1.09, 95%CI:1.03-1.14;P=0.002) significantly increased risk is found for all immunological diseases combined; 6% (OR:1.06,95%CI:1.00-1.12;P=0.037) for autoinflammatory diseases; 15% (OR:1.15,95%CI:1.05-1.26;P=0.003) for classic autoimmune diseases; and 19% (OR:1.19,95%CI:1.01-1.40;P=0.031) for mixed-pattern diseases in association with endometriosis. Further analyses of UK Biobank data to test for the robustness of these associations with adjustment for confounders, stratification on effect modifiers and consideration of temporality are underway and will be presented.

Limitations, reasons for caution: While endometriosis ascertainment is most reliable by hospital diagnosis/surgeries, 3,197(38.88%) out of the 8,223 UK Biobank endometriosis cases were identified by self-reports; 3,982(48.43%) by hospital diagnosis; 1,044(12.70%) by both self-reports and hospital diagnosis. Although sensitivity analysis by diagnostic ascertainment, separate analyses highlight the validity of self-reported diagnosis will be presented.
Wider implications of the findings: The potential association between endometriosis and immunological disease will help to understand the causes and consequences of both disorders to provide reference for clinical and research practice, and opens up the opportunity for novel diagnosis or treatment methods for endometriosis.
Trial registration number: not applicable.

O-089 The Hippo pathway transcription coactivator Yes-associated protein 1 inhibits endometriosis stromal cell invasion through repression of estrogen receptor β

Q. Xue[1], C. Zeng[1], P. Wu[1], Z. Dong[1], X. Li[1], Y. Zhou[1]

[1]*Peking University First Hospital, Department of Obstetrics and Gynecology, Beijing, China*

Study question: The aim of this study was to investigate the regulatory mechanism of YAP1 in terms of ERβ and YAP1 regulation of ESC invasion in endometriosis.
Summary answer: Decreased levels of YAP1 in endometriotic tissues enhance ERβ expression via a YAP1-NuRD complex, which further binds to ESR2 promoters. Furthermore, YAP1 inhibits ESC invasion.
What is known already: Endometriosis is an estrogen-dependent disease, and estrogen receptor β (ERβ) plays a critical role in the pathogenesis of endometriosis by promoting cell invasion. Yes-associated protein 1 (YAP1) plays suppressive roles in several types of tumors. The relationship between YAP1 and ERβ is not fully understood.
Study design, size, duration: In vitro experiment.
Participants/materials, setting, methods: Paired ectopic endometrium (EC) and eutopic endometrium (EU) from patients with endometriosis and primary cultured paired ESCs were used. RT-PCR and western blotting were used to quantify gene expression. SiRNA-targeted knockdown of gene expression and YAP1 overexpression by plasmid transfection were performed. Chromatin immunoprecipitation was used to determine whether YAP1 binds to the ERβ promoter. The association between proteins was assessed by coimmunoprecipitation (Co-IP). Transwell analysis was carried out to observe cell invasion.
Main results and the role of chance: YAP1 mRNA and protein levels in EU tissues were higher than that in paired EC tissues. ESCs transfected with siYAP1 exhibited a significant increase in both ESR2 mRNA levels and ERβ protein expression. Simultaneously, YAP1 overexpression in ESCs exhibited the opposite results. Co-IP assays demonstrated YAP1-NuRD complex formation by YAP1, CHD4 and MTA1 in ESCs. YAP1 bound to two sites (-539, -533 and -158, -152) upstream of the ERβ transcription initiation site. YAP1 binding to the two sites of the ESR2 promoter in ESCs was significantly lower than that in EMs. ESCs transfected with siYAP1 exhibited profoundly increased invasion activity, while ESCs transfected with siERβ showed marked inhibition of invasion. However, transfection with siYAP1 and siERβ together decreased the number of invading cells compared with transfection with siYAP1 alone.
Limitations, reasons for caution: only in vitro.
Wider implications of the findings: new mechanisms in endometriosis
Trial registration number: not applicable.

O-090 A multi-methodological approach defines sub-populations in human endometrial epithelium

A. Maclean[1], J. Bhullar[1], O. Vaseiva[2], A. Valentijn[3], J. Drury[1], N. Tempest[1], C. De Lelis Medeiros-de-morais[4], F. Martin[4], S. Miwa[5], T. Von Zglinicki[5], D. Hapangama[1]

[4]*University of Central Lancashire, School of Pharmacy and Biomedical Sciences, Preston, United Kingdom*
[5]*Institute for Cell and Molecular Biosciences- Newcastle University, Ageing Research Laboratories- Campus for Ageing and Vitality, Newcastle, United Kingdom*

Study question: Can endometrial epithelial cell sub-populations be characterised using a multi-methodological approach?
Summary answer: Key differences in expression of hormone metabolizing enzymes provides evidence for the existence of endometrial epithelial sub-populations, and novel techniques offer opportunities for further characterisation.
What is known already: The human endometrium has the remarkable capacity to regenerate after menstruation. It is composed of epithelial and stromal cells, which are organised into functionally distinct layers; the luminal epithelium, the superficial functionalis, and deeper basalis. Endometrial epithelial cells (EEC's) are the defining cell type of the endometrium, and EEC's from the three compartments are known to respond differently to the same ovarian hormones, suggesting the existence of sub-types. We have previously shown that SSEA1 isolates basalis EEC's that have regenerative ability. This study aimed to optimise novel methods to contribute to the characterisation of EEC's.
Study design, size, duration: A prospective observational study, analysing full-thickness human endometrial biopsies from 30 healthy women undergoing hysterectomy for benign conditions, including 20 samples from premenopausal women, and 10 from postmenopausal women. Full thickness samples were obtained to enable investigation of the three endometrial compartments: the luminal epithelium, the functionalis, and the basalis. *In silico* study analysing all published whole endometrial microarray datasets (n=16) identified a list of hormone metabolising enzymes (HME's) likely to reflect cyclical hormone responsiveness.
Participants/materials, setting, methods: Transcriptional profiling of purified freshly sorted SSEA1-enriched and depleted EECs from full-thickness endometrium (n=8) identified differentially regulated HMEs. The expression of AKR1C3 and 17βHDS2 was investigated with immunohistochemistry (n=30), and corroborated by RT-qPCR in region specific EEC's isolated by laser capture microdissection (LCM) (n=3). Raman microspectroscopy investigated structural differences between EEC's (n=1). Hyperion^{TM} Imaging was used for the first time in endometrium (n=6) to identify and compare a panel of markers of cellular differentiation.
Main results and the role of chance: Analysis of published microarray data identified 1539 differentially expressed genes in SSEA-1 enriched basalis EEC's, including the HME's AKR1C3, which was upregulated, and 17βHSD2 which was down-regulated. This expression pattern was confirmed both at transcript and protein level in the endometrium. We observed significantly stronger AKR1C3 immunostaining in the basalis than the functionalis ($P<0.05$) and increased mRNA expression in the secretory phase basalis EEC's isolated by LCM. 17βHSD2 immunostaining was stronger in the functionalis than the basalis ($P<0.05$), and mRNA expression was absent in basalis, but present in functionalis. Computational analysis of the obtained Raman spectra identified key structural differences between functionalis and basalis endometrium. MatLab analytical models applied accurately distinguished between the basalis and the functionalis (AUC 98%, sensitivity 0.97, specificity 0.95 and AUC 94%, sensitivity 0.95, specificity 0.97, respectively). Key biomarkers of differentiation were identified by Raman spectra. Mass cytometry using CyTOF technology and Hyperion imaging was optimised for the first time in the human endometrium, providing comprehensive analysis of the expression profile of cell differentiation markers (SSEA1, N-cadherin). This identified significant differences between region specific EEC's.
Limitations, reasons for caution: This is a descriptive study focusing on the optimisation of novel methodology.
Wider implications of the findings: This study has confirmed that the above techniques are feasible adjuncts to improve our understanding of endometrial epithelial cell biology, and identified epithelial cell specific markers at protein level that discern the diversity of epithelial cell sub-populations, which contributes to identification of EEC sub-population specific abnormalities in endometrial disease.
Trial registration number: This work was funded by the Wellbeing of Women project grant RG1073, and Entry-Level Scholarship FTR706.

INVITED SESSION

SESSION 24: ARE IVF CHILDREN DIFFERENT?

Monday 24 June 2019 Haydn 1 17:00–18:00

O-091 Alarming findings when using administrative databases and national registries

O-092 ART children-long term reassurance?

C. Bergh[1]

[1] *Sahlgrenska University Hospital, Department of Obstetrics and Gynaecology, Göteborg, Sweden*

Abstract text

ART children-long term reassurance? IVF is an ever increasing strategy to help childless people to get an own child with now more than 8 million children born worldwide. New and more advanced techniques are steadily developed and brought into clinical practice. Children follow-up studies have so far showed that a majority of children born after ART are healthy even though some adverse outcomes are found in comparison to children born after spontaneous conception. While international registries, such as EIM and ICMART on ART only monitor pregnancy and delivery rates, child morbidity is best caught by large national/international registry studies where possibilities exist to crosslink registries on ART children with other health registries and perform comparison with children born after spontaneous conception. The main risk for adverse perinatal outcomes in ART, which includes ICSI and conventional IVF techniques, are associated with ART's higher rates of multiple pregnancies. In ART singletons, the rate of very preterm birth and very low birth weight is about two to three times higher than in the general population. These increased risks exist for conventional IVF as well as for ICSI, even though it seems some lower for the ICSI techniques. For children born after cryo preservation, a technique which is increasing worldwide, due to better freezing methods, more recent studies have found a lower risk for low birth weight and preterm deliveries compared to fresh IVF while higher rates of large for gestational age and macrosomia have been detected, both in comparison to fresh IVF and compared to singletons born after spontaneous conception. Another important neonatal outcome that has been in focus for studies are birth defects where a higher overall risk has been detected for ART, being between 30-70%. Turning to long-term effects of ART on children outcomes, much fewer studies of high quality exist. Studies of growth and physical health are few and limited to childhood where general physical health including hospitalizations, childhood illnesses, surgical interventions and medical therapies, are similar for age and gender-matched controls in the general population. For childhood cancer, the two largest studies, one from UK and one the Nordic countries, both including around 100 000 ART children do not show any increase in childhood cancer in ART children compared to children born after spontaneous conception and after adjustment for relevant confounders. Most studies on neurocognitive development, autism and autistic disorders show no increased risks if adjusted for multiple birth. In addition, school performances of 15-16 year old adolescents have been investigated in two large registry studies from Denmark and Sweden. Both studies showed better school performance for ART children in crude analyses but after adjustment for relevant confounders, particularly parental education, no differences of clinical importance were observed. There are some recent concern regarding cardiovascular parameters. Case-control studies have detected altered blood vessel structure and increased blood pressure, both systolic and diastolic in ART singletons compared to matched controls and further that these differences remain in adolescence. For diabetes type 1, very limited data exist but large studies are ongoing. A few longitudinal reports on reproductive health in adolescents and young adults have been published. While onset of puberty and pubertal development were similar for ICSI and spontaneously conceived boys and girls, ICSI-conceived men seemed to have lower sperm concentrations and total sperm counts than age-matched, spontaneously conceived controls. Further studies on long-term health of ART children are needed, both in view of the widespread use of ART and that new and advanced technique are rapidly implemented in this arena.

INVITED SESSION

SESSION 25: NAVIGATING BETWEEN HOPE AND HYPE IN SCIENCE COMMUNICATION: ETHICAL ISSUES IN PUBLICISING RESEARCH

Monday 24 June 2019 Haydn 3 17:00–18:00

O-093 The problem of science hype and what to do about it

T. Caulfield[1]

[1] *University of Alberta, Health Law Institute, Edmonton, Canada*

Abstract text

This presentation will explore the evidence that suggests both the existence and source of exaggerated claims about scientific advances and benefits. I will map the sources of hype to explore how they influence the representation of science in laboratory, the research institutions and, finally, in the popular press. While science hype is not a new phenomenon, it is arguably becoming both more common and more problematic. At a minimum, it adds an element of inefficiency to the corrective tendencies of the scientific process. Worse, it may facilitate the premature implementation of technology, have an adverse impact on the distribution of research resources and erode public trust.

O-094 Research finding, hype and public policy: Presenting evidence to policy makers

S. Norcross[1]

[1] *Progress Educational Trust, London, United Kingdom*

Abstract text

Title: Hype, Hope and Headlines: The Impact Factor Subject: The influence of 'impact' on patients, the public and policy in relation to ART Making an impact is important to everyone involved in research, whether in academia or in the clinical setting. But the significance of impact is wider than this – it involves clinics, patient support groups, charities (including the Progress Educational Trust - PET) and both the lay and specialist media (including BioNews). Institutions, companies, publications and broadcasters compete for profile, to attract funding and to increase their market share. The impact factor (IF) is making an impact, and like it or not it is here to stay. In a research context, IF is a measure of the frequency with which the average article in a journal has been cited in a particular year. It is used to measure the importance or rank of a journal, by calculating the number of times its articles are cited. IF is frequently used to rank the relative importance of a journal within its field. Journals with higher impact factors are often deemed to be more important than those with lower ones. Journals, keen to have a better IF than their rivals, use print and digital media – including social media – to promote papers. This promotion maybe coordinated with the authors' academic institution, but tensions can arise. In the UK, the Research Excellence Framework (REF) is the system for assessing the excellence of research in higher education institutions. Two of the elements assessed are quality of outputs (including publications and IF in its formal sense) and the impact of these outputs beyond academia (including IF in a more general and informal sense). Outside academia, news websites gather real-time data on their traffic, writing copy and using images to give readers what they want (or think they want) and encouraging them to click through and be exposed to advertising. The longer people spend on websites, the more those websites can charge for their advertising space. Attention-grabbing, sensational headlines can entice people to buy a print publication or click on a link. Headlines are often necessarily brief and lacking in nuance, and may promise more than the article below will deliver. Clinics and charities take to social media, issue statements and write blogs to attract attention. Of course, this is done to provide information to patients. But it is also often done with one eye on attracting paying clients and/or donors, and this means that hype can creep in. Over the years, many so-called IVF 'add-on' treatments have been reported uncritically in the media, giving patients what some have criticised as false hope. PET has been critical of this trend, and held two key events highlighting the issue in 2014, 2015 and 2017. Several media outlets have conducted undercover investigations into 'add-ons',

until in 2019 the UK's fertility regulator – together with leading professional bodies, including ESHRE – published a consensus statement advising that IVF clinics should not charge patients for add-on treatments that are not proven effective by clinical trials.Sometimes however, academics, clinicians, the media and charities work together to make a positive impact. A good example of this is the long-running and ultimately successful campaign to change UK law to permit the clinical use of mitochondrial donation. Concerted efforts were made throughout the campaign not to overpromise, and not to push for use of the relevant techniques outside a clearly and narrowly defined purpose.

What responsibilities fall upon all the actors who seek to make in impact, on professional audiences and on the wider public, in relation to ART?

INVITED SESSION

SESSION 26: DONOR IDENTITY - WHO IS TELLING WHO?

Monday 24 June 2019 Haydn 2 17:00–18:00

O-095 Lessons from three decades of non-anonymity

C. Lampic[1]

[1]*Reproductive Health, Women's and Children's Health, Stockholm, Sweden*

Abstract text

Lessons from three decades of non-anonymity

More than three decades ago, in 1985, Sweden was the first country in the world to abolish anonymous gamete donation. This initiative was met with some resistance by clinicians who feared a drop of sperm donors, but these concerns have been largely refuted. Initially, sperm donation was available only for heterosexual couples but in the past 15 years also oocyte donation, as well as sperm donation for lesbian couples and single women, has been permitted. In general, the donor is totally anonymous to the recipient couple or woman, and the adult offspring is the sole person who has the right to access the donor's identity. Donation treatment is only provided to recipients who plan to share information about the donor conception with the child, and they are encouraged to start the disclosure process from an early age. The child's conception with donor gametes is not visible in any official records and the parents have the full responsibility to share this information with the child. The psychosocial aspects of gamete donation are investigated in the multicenter longitudinal 'Swedish Study on Gamete Donation' that recruited large groups of recipient couples as well as oocyte and sperm donors in 2005-2008. Overall, the results indicate that couples want to be honest with their children and intend to share information about the donor conception with their offspring. In compliance with professional advice provided at the clinics, a majority of couples had already started the disclosure process when their children had reached school age. Similarly, oocyte and sperm donors were found to have neutral or positive attitudes towards potential contact by offspring from their donation. Half of the donors would prefer to receive notification when an offspring from their donation requests information about them, which is a service not routinely provided by the clinics. Since 1985 approximately 5000 children have been born following oocyte or sperm donation in Sweden. Among these, more than 700 offspring following sperm donation to heterosexual couples have now reached adult age, and thus have the legal right to obtain identifying information about their donor. However, the number of donor conceived persons who have come forward to request this information is surprisingly low. Preliminary results from an ongoing interview study with these adult offspring and their parents indicate a wide variety of experiences regarding both the disclosure process and the situation when the donor conceived person requested donor information. In some families, information about the donor conception was shared with the child from an early age, while the disclosure in other families was prompted by biology lessons at school or by adult offspring who used DNA-tests to find out about their genealogy. A majority of the offspring had contacted the donor and several were in regular contact with him and/or genetic half-siblings. While parents who received donation treatment in recent years appear to be open with their child , there is reason to believe that many of the persons conceived in the late 1980s and 1990s are unaware of their conception with donor sperm. It is also likely that parents are concerned about the risk of accidental revelation, e.g. through available resources to search for genetic linkage. In conclusion, introducing legislation that abolishes donor anonymity and informing recipients about the importance of early disclosure does not seem to be sufficient to ensure that donor conceived persons have access to information about their genetic origin. Sweden, which was a pioneering country in terms of legislation, could today learn from international initiatives to provide targeted resources and support to families following donor conception, as well as to donors.

O-096 Donor detectives

A. Indekeu[1]

[1]*Fiom- Expert Center for Ancestry and University of Leuven, Department of Sociology, Hasselt, Belgium*

Abstract text

"Donor detectives": The exchange of information/ contact between donor-offspring and their donor Already a longer time donor-conceived individuals have shown an interest in information about their donor and/or started searching for them. Two social developments have facilitated this request: the increasing removal of donor anonymity and the rise of online genetic testing sites. The first development concerns a social-legal movement in which more and more countries in the last two decades have abolished donor anonymity and have given donor-conceived people the child access to identifying information about their donor at a certain age or at maturity. This change demonstrates a growing recognition of donor-conceived peoples' interest in learning more about their donor(s). A second development relates to the technological advancement and establishment of online commercial 'direct-to-consumer' (DTC) genetic testing, (such as 23andMe DNA and FamilyTReeDNA), which enables to find genetic relatives. Increasing numbers of donor-conceived individuals (and/or parents) are seeking individuals genetically related through donor conception and one route they use is DTC DNA testing. The availability of DTC and the opportunities created by the internet are reshaping the field of assisted reproduction. Interest in the exchange of information/contact between donor-offspring and their donor have raised many concerns: What kind of information is searched for? What kind of expectations do people have from these searches and possible contact and what are the experiences? Do donor-offspring, donors and parents want exchange of information? What are the consequences of these searches and exchanges for donors, donor-offspring and parents themselves and their (wider) relationships? How should this exchange of information and possible contact be organised? This presentation reviews the existing empirical data, addressing differences and similarities between exchange for information and possible contact within the context of anonymous and identifiable, sperm, egg, or embryo donation and hetero-sexual, lesbian, or single mother families. It will also address how exchange of information is organised in practice and the legal, ethical, social challenges that arise from this new development.

INVITED SESSION

SESSION 27: PGT DATA REPORTING

Monday 24 June 2019 Haydn 4 17:00–18:00

O-097 PGT Data reporting
O-098 Recommendations for good practice in PGT : What's new

M. De Rycke[1]

[1]*UZ Brussel, Centre for Medical Genetics, Jette- Brussels, Belgium*

Abstract text

The field of PGT is evolving fast. PGT began as an experimental procedure in 1990 with PCR-based methods used for the detection of monogenic diseases. Interphase fluorescence in situ hybridization (FISH) was introduced a few years later and became the standard method for sexing embryos and for detecting chromosomal numerical and structural aberrations. Genome-wide technologies began to replace the gold standard methods of FISH and PCR over the last decade and this trend was most apparent for PGT-A. Based on the pace of development, up-to-date best practice advise is essential for

regulation and standardisation of diagnostic testing. The previous guidelines on best practice for PGT, published in 2005 and 2011, are considered outdated and the development of new series of papers outlining recommendations for good practice in PGT was necessary. Under supervision of the PGT consortium steering committee, four recommendations papers were prepared. Working groups were composed of people with relevant and hands-on experience. Based on the previous guideline papers and after several online discussions, recommendation papers were prepared by the working groups, consistency of the papers was checked, and stakeholder review organised. The final series of 4 papers will be published shortly. The series includes a paper on the organisation of PGT covering aspects of patient selection and counselling, basic requirements for PGT, quality management, pregnancy and children follow-up and transport PGT. Complementary to this paper on organisation of PGT, 3 technical papers provide recommendations on technical aspects of (1) polar body and embryo biopsy for PGT, (2) detection of structural and numerical chromosomal aberrations, and (3) detection of monogenic disorders. These technical papers provide general recommendations on training of staff, laboratory infrastructure, equipment and materials, and preclinical work-up, validation and (post) examination process, before providing specific recommendations for the different techniques or testing strategies. Together, the 4 recommendations papers provide best practice recommendations for organisational and technical aspects of a PGT service, based on experience and available evidence. The overall aim of the series is to take PGT to the same high-quality level as routine genetic testing.

SESSION 28: NURSING AND MIDWIFERY

Monday 24 June 2019 Strauss 1+2 17:00–18:00

O-099 Through women's eyes: The female experience of infertility following a recent diagnosis of severe male factor infertility

E. Stevenson[1], K. McEleny[2], E. Moody[2], D. Bailey[1]

[1]*Duke University, School of Nursing, Durham, U.S.A.*
[2]*Centre for Life, Newcastle Fertility Centre, Newcastle-upon-Tyne, United Kingdom*

Study question: How do the partners of men who have recently been diagnosed with severe male factor infertility (MFI) manage during diagnosis and treatment?
Summary answer: Partners perceive men with MFI experience psychological distress about the diagnosis. Partners use intentional strategies to help partners cope. The relationship is affected during treatment.
What is known already: Men with MFI experience psychosocial and informational challenges during diagnosis and treatment. They also experience higher incidences of problems that can impact upon their well-being, such as depression and sexual dysfunction. While the female experience of female factor infertility is well documented and understood, little is known about women's experiences of infertility following a partner's diagnosis of severe MFI. There is very limited understanding of how they perceive their partner's experience, how they support their partner during fertility evaluation/treatment, and the impact of the process upon the functioning of their relationship.
Study design, size, duration: This was a prospective qualitative study among female partners of American and British men with severe MFI (azoospermia, or sperm concentration < 5Million/ml) seeking care from a U.S. or U.K. Urologist for family building, between December 2015 and April 2017. Individual in-depth qualitative interviews were conducted 3 and 6 months after a MFI urology consultation. Each interview lasted between 35 and 60 minutes and was digitally recorded and transcribed verbatim.
Participants/materials, setting, methods: Inclusion criteria were the female partners (married or co-habitating) of men recently diagnosed with severe MFI and 40 years or younger. Exclusion criteria included (living) biological or adopted children, or a partner with a history of vasectomy. Eleven (7 U.S., 4 U.K.) participants were recruited immediately after their urology consultation for MFI. Interviews were conducted via phone. Data were analyzed using content analysis.
Main results and the role of chance: The analysis resulted in three major themes: 1) Women reported that the men's emotional response to receiving the diagnosis included a variety of negative responses (shock, disappointment, internalization/non- disclosure to social network); 2) Women employed intentional strategies to help their partner cope with the diagnosis and treatment, such as the use of prayer/humor, by offering reassurance, support, love, and by active management to reduce negative male feelings; and 3) Women reported that fertility assessment/treatment had an impact on their relationship quality: For those who offered reassurance to partners of their love/support, women perceived their relationship as stronger. For those who worked to reduce men's negative impact on their feelings/ego, women perceived their relationship as strained. Women who perceived infertility as a shared experience reported improved relationship quality. The results demonstrate that while men faced negative emotional challenges throughout the process, their partners worked to manage these emotional experiences, and the strategy employed, may have impacted upon their perception of the quality of their relationship.
Limitations, reasons for caution: The majority of the women lived in the same two areas (a small metropolitan area of the U.S. South and a city in Northern U.K.). As the results are based on qualitative data from 11 partners of men with MFI, the results cannot readily be generalized to larger populations.
Wider implications of the findings: This is the first study seeking to understand the psychosocial impact of MFI from the partner's perspective. The findings highlight a connection between partner's perception and active management to help men cope. More research is needed to understand the dyadic impact on psychological functioning of men during diagnosis and treatment.
Trial registration number: not applicable.

O-100 Cross-border reproductive care: A quantitative study of patients' experiences of care in the Netherlands and the motivation for treatment at a Belgian University Hospital

A. Jongbloet[1], S. Somers[1], M. Schoonenberg[2], A. Geril[1], D. Braat[3], P. De Sutter[1]

[1]*Ghent University Hospital, Department of Reproductive Medicine, Gent, Belgium*
[2]*Nij Geertgen Fertility Center, Fertility Center, Nijmegen, The Netherlands*
[3]*Radboud University Medical Center, Department of Obstetrics and gynaecology, Nijmegen, The Netherlands*

Study question: How do Dutch patients experience the quality of reproductive care in their own country? What is their motivation for treatment at a Belgian University Hospital?
Summary answer: The reason why Dutch patients opted for fertility treatment at a Belgian University Hospital was a combination of emotional factors and real differences in care.
What is known already: Over the years, we saw an increase in the number of Dutch patients going to Belgium for fertility care. Previous research showed that Dutch patients think treatment in the Netherlands is highly protocol-oriented (Van Hoof et al., 2014). An experienced lack of patient orientation would be the main reason for patients to change hospitals (van Empel et al., 2011). Also, patient-oriented care is associated with better clinical outcomes and increased patient satisfaction (van Empel et al., 2010). There is a need for a strategy to effectively increase the quality of care, particularly the patient-centeredness of care (Dancet et al., 2011).
Study design, size, duration: From August 2016 until mid-February 2017 a cross-sectional study was conducted. A consecutive sample was taken of Dutch adult women planning to visit the same Belgian University fertility center (an appointment was scheduled, but the department was not yet visited). This method guaranteed good representativeness of the entire population. Around 508 women received an email with a link to an online questionnaire. In the end 192 women filled in the questionnaire (response rate of 37.8%).
Participants/materials, setting, methods: A four-part questionnaire was constructed. It focused on: 1) the motivation to go abroad for fertility care, 2) the experiences with Dutch fertility care (based on the Patient-Centredness Questionnaire-Infertility [PCQ-I]), 3) Quality of life [QoL] during treatment (based on the FertiQol-questionnaire) and 4) background of the participants. SPSS 23 was used for statistical analysis (descriptive analysis and Pearson

correlations). The Netherlands was divided into 3 regions for a more profound analysis of the results.

Main results and the role of chance: The PCQ-I was filled in by those who had already been treated in the Netherlands (n = 159). The average total score was 1.90 (range 0-3) which means that patient-centeredness was experienced better than mediocre. The results showed that Dutch fertility care can be improved at the level of the organization (continuity and transition (1.59)) and at the individual level (patient involvement (1.71), respect for patient's values (1.59)). Because the PCQ-I does not focus on the individual expectations of the patient, the questionnaire was expanded. The FertiQol was only completed by non-pregnant women (n = 162). The final score was 63.80 (range 0-100). This means that the QoL in individuals with fertility problems was better than mediocre. The possibility to undergo new and/or experimental investigations (86.0%), the higher level of knowledge and expertise (83.8%) and the higher success rates (82.1%) were the main reasons for choosing Belgian fertility care (n = 179). A significant link was found between the reasons for visiting a Belgian fertility clinic and three Dutch regions. 59.3% of the participants from the second border region (having the widest choice of IVF centers in the neighborhood) indicated that they were not satisfied with Dutch fertility care.

Limitations, reasons for caution: Women were asked to complete the questionnaire alone. Future studies should focus on both partners. In this study, 39.4% of women had already wanted children for more than four years. This duration could have evoked negative feelings which could have negatively influenced how experienced care was scored.

Wider implications of the findings: The significant relationship between the PCQ-I and the FertiQol ($p<0.01$) shows the importance of coping with negative emotions caused by subfertility. Dutch fertility care should focus on the emotional reasons of why patients visit a Belgian hospital. This can lead to a higher quality of care in the Netherlands.

Trial registration number: NA

O-101 A systematic review and meta-synthesis of mobile device fertility applications: More than a glitch in the matrix

S. Costa[1], A. Yazdani[1]

[1]Eve Health, Fertility, Spring Hill, Australia

Study question: The aim of this meta-synthesis was to determine the utility and validity of current mobile device fertility applications and the medical advice given in these applications.

Summary answer: Despite a significant increase in the number of fertility applications, apps have limited validity, make unrealistic claims of efficacy, and have no established review cycle

What is known already: Fertility and cycle tracking applications are consistently among the most popular applications on both Android and iOS platforms. Up to 70% of women initiating fertility treatment track their cycles. There is limited published information on how applications are featured or promoted in either store. Furthermore, little systematic assessment has been performed on the validity of the advice offered despite frequent claims of efficacy. Despite data supporting the belief of health professionals that patient apps promote autonomy and and understanding of health, primary healthcare providers have limited familiarity with these applications, and the features frequently used by patients.

Study design, size, duration: The research protocol followed the published methodology for Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols (PRISMA-P). The research protocol was developed through a staged, iterative process prospectively registered through (PROSPERO ID: 124109). The literature search was conducted of online databases, with a predefined search strategy. All applications up to and including January 8th 2019 were included. Additional applications were identified through snowballing and manual searches of published reviews.

Participants/materials, setting, methods: iTunes and Google Play were systematically searched for iOs and Android applications, respectively. The analysis included paid and free applications, unrestricted by age but limited to English. Each application was reviewed and scored independently by each researcher based on a predetermined matrix. Descriptors were sorted and categorized in EndnoteX7 (Thomson Reuters). Data analysis and synthesis was performed by computer-assisted qualitative data analysis (NVIVO12, QSR International) and analytic induction in a staged independent framework approach.

Main results and the role of chance: 399 applications were identified in the initial search strategy. 381 applications were included after review of the descriptors. 9 non-English applications and 41 duplicates were removed from the final analysis. 332 applications were included in the systematic review. Between January 2015 and January 2019 there has been a 47% increase in the number of mobile fertility applications (from 225-332). Commonly included features are: conception and contraception tracking, health education, flow and ovulation symptom tracking, cycle length information and prediction. Less then 10% of applications cited published literature or professional guidelines. A significant number of applications made unrealistic and unsubstantiated claims with respect to efficacy.

Limitations, reasons for caution: Application sources are unreliable, incomplete and subject to commercial imperatives. There is limited transparency in app development, functionality, ownership, and store ranking. This study did not assess user experience and reproductive outcomes.

Wider implications of the findings: End users, patients and healthcare professionals, are at risk of accepting the advice and information provided by these applications unchallenged..

Trial registration number: Not required however PROSPERO ID: 124109

O-102 Does information changes patient's preference for double embryo transfer between year 2015 and 2018?

S.N.A. Syed Tahir[1], S.K. Lee[2], P. Nadkarni[3], Y.H. Lim[3], M.K. Loke[4], W.A.M. Qiao[5]

[1]KL Fertility & Gynaecology Centre, Nursing, Kuala Lumpur, Malaysia
[2]Universiti Tunku Abdul Rahman, Faculty of Medicine and Health Sciences, Selangor, Malaysia
[3]KL Fertility & Gynaecology Centre, Clinical, Kuala Lumpur, Malaysia
[4]KL Fertility & Gynaecology Centre, Administration, Kuala Lumpur, Malaysia
[5]University of Manchester., Faculty of Medicine, Manchester City, United Kingdom

Study question: Does information on multiple pregnancy risks changes patient's decision on the number of embryos to transfer in year 2015 and 2018?

Summary answer: Information seems to influence patient's preference for number of embryos to transfer in in-vitro fertilisation (IVF) in 2018 compared to 2015

What is known already: Increased multiple birth following an IVF has been a rising concern. When transferring more than one embryo in IVF patients are at risk for maternal complications, fetal mortality and morbidity. These complications leads to higher costs due to perinatal and neonatal expenditures, not including lifelong disabilities and increased needs for social and medical support. However, in Asia, where patients pay out of pocket to do IVF, they are more likely to ask for multiple embryos to be implanted to save their cost and getting pregnant at their first attempt.

Study design, size, duration: A cross sectional study, where 151 patients seeking fertility treatment in KL Fertility Centre were randomly chosen to answer a self-administered questionnaire during a 3-month survey in 2015 and 168 patients in 2018.

Participants/materials, setting, methods: Patients were recruited for a self-administered questionnaire which consists of the same 15 questions. They were asked to fill out the questionnaire before counselling and again after the counselling on multiple pregnancy risks. They were also asked about personal preference in number of embryos to be transferred. Other questions included were their sociodemographic data, pregnancy history, awareness on the risk of multiple pregnancy and knowledge on the risk of more than single embryo transfer (SET).

Main results and the role of chance: This cross-sectional study has gathered information that there was no significant difference in patient's awareness on the risk of multiple pregnancy in year 2015 and 2018. In both years, patients were aware that multiple pregnancy carries a high risk to both mothers and their babies. There was also no significant difference in patient's knowledge on multiple pregnancy risks and the ideal outcome of IVF in both years. Patients agree that single baby is the best outcome. However, patient's personal preference to have SET after counselling being given was significantly higher in 2018 compared to 2015 ($p<0.05$). In 2015, after being counselled, 85.7% still opted for double embryo transfer (DET) but in 2018, only 59.2% wished for DET.

Limitations, reasons for caution: Patients with various backgrounds, language barrier and culture may affect results. However, all patients are able to give full cooperation on completing the survey.
Wider implications of the findings: This study suggests that continuous education and counselling would be able to encourage more patients to choose SET. Clinicians, nurse counsellors and embryologists will advocate patient but until legislation implemented, patients will still decide what they believe is the best for them based on their culture, family background and finance.
Trial registration number: not applicable

INVITED SESSION
SESSION 29: THE PRESENCE OF MOSAICISM. WHAT DO WE DO?
Tuesday 25 June 2019 Mozar 08:30 - 09:30

O-103 Mosaicism in the embryo

C. Rubio LLuesa[1]
[1] *iGenomics SL, PGS Research - Parque Tecnologico, Paterna Valencia, Spain*

Abstract text
Mitotic errors during embryo development can result in chromosomally distinct cell populations. Mosaicism can occur as early as the 2-cell stage, although detection at the blastocyst stage is more common because more trophectoderm (TE) cells can be simultaneously analysed. The introduction of next generation sequencing (NGS) allows the identification of different levels of mosaicism in TE biopsies, but proper validation is required to define detection levels. The concordance between the TE biopsy the inner cell mass (ICM) and the whole embryo can be related to factors such as mosaicism type and degree, biopsy location, the number of cells biopsied, and cell loading. Also, different levels of mosaicism have been described according to the infertility aetiology, the insemination technique, stimulation, culture conditions and embryo quality. In summary from different studies published so far, blastocysts diagnosed as mosaics in TE biopsies were confirmed in 50%–90% of the secondary analysis performed in ICM biopsy, additional TE biopsies, or whole-blastocyst analysis.

Different levels of mosaicism have been reported in preimplantation human embryos, but the incidence in early miscarriages can help to understand the real incidence at blastocyst stage and their capability to implant. Classic cytogenetic studies of miscarriage POCs have reported only a 5%–6% incidence of mosaicism. Most of the mosaic aneuploidies found in established pregnancies are confined to placenta. In the same trend, using both hysteroembryoscopy and molecular analysis using aCGH or NGS, our group has described an incidence of 2% fetoplacental discrepancy in 46 early miscarriages. In ongoing pregnancies, most mosaic aneuploidies are also confined to the placenta and may be associated with a poor perinatal outcome. In rare cases, the placental karyotype is normal and foetal cells show an abnormal karyotype. The frequency of mosaicism in live births is undetermined, because chromosomal analysis in live births, children, and adults are mostly performed only when there is a clinical indication or a strong suspicion for a chromosomal disorder. In fact, the clinical manifestations are represented by a spectrum of phenotypes, and their relationship with different syndromes has been widely described.

Therefore, mosaic embryos can be considered to represent a distinct category in terms of viability, lying in between euploid and fully abnormal embryos. Several groups have described the possibility of healthy livebirths with the transfer of mosaic embryos, mostly when no euploid embryo after the TE biopsy. Mosaic embryos are characterized by decreased implantation and pregnancy potential, as well as increased risk of miscarriage rate and adverse perinatal outcomes. Whether to or not to transfer a mosaic embryo depends on key factors such as the methodology used, the degree of mosaicism, the chromosomes affected, the cohort of sibling embryos, and finally, the medical history and expectation of the patient. If a patient proceeds with transfer of an embryo diagnosed as mosaic, counselling about the benefits, risks, and limitations should be properly explained. In case of an ongoing pregnancy after the transfer of a mosaic blastocyst, amniocentesis should be highly recommended due to the a priori increased risk of foetal aneuploidy.

O-105 Piwi/piRNA dysregulation and human male infertility

L.T. Gou[1], **J.Y. Kang**[1], **P. Dai**[1], **X. Wang**[2], **M.F. Liu**[1]
[1] *Shanghai Institute of Biochemistry and Cell Biology- Chinese Academy of Sciences, State Key Laboratory of Molecular Biology, Shanghai, China*
[2] *Shanghia Institute of Biochemistry and Cell Biology-Chinese Academy of Sciences, State Key Laboratory of Molecular Biology, Shanghai, China*

Abstract text
PIWI proteins, as well as their interacting piRNAs (PIWI-interacting RNAs), are specifically expressed in animal germlines and play essential roles in germ cell development and gametogenesis in animals. Human PIWI proteins are specifically present in testes; however, the function of PIWI or/and piRNAs in human spermatogenesis and male infertility has remained largely unexplored. Our recent studies identified the ubiquitination-deficient mutations, i.e. D-box mutation, in human *Piwi* (*Hiwi*) from azoospermia patients and further revealed that such mutations cause male infertility by impairing Histone-to-Protamine exchange during spermiogenesis. This, for the first time, demonstrate that *Piwi* mutations play a causative role in human male infertility. Of note, we revealed that *Piwi* D-box mutations act to impair sperm formation in a piRNA-independent manner. To pursue whether the piRNA-dependent role of PIWI is also of functional importance in human male fertility, we further screened for potential mutations in the PAZ and MID domains of *Hiwi* in human male infertility. PAZ and MID domains are responsible for piRNA loading in PIWI proteins. Interestingly, from a cohort of patients with idiopathic oligo/astheno/azoospermia and fertile controls, we identified a specific mutation in the PAZ domain of HIWI protein in 5 patients, but none in controls. Importantly, by modeling the mutation in mouse *Piwi* (*Miwi*) in mice, we demonstrate that this genetic defect is directly responsible for male infertility. This supports a functional importance of piRNA-dependent role of PIWI in human male fertility. Together, our findings identify *Piwi* as a new factor in human male infertility and indicate that it functions in multiple ways in regulating male germ cell development.

O-106 Understanding the immune cells of the endometrium and decidua using single cell methods

A. Sharkey[1], **A. Moffett**[2]
[1] *University of Cambridge, pathlogy, Cambridge, United Kingdom*
[2] *University of Cambridge, Pathology, Cambridge, United Kingdom*

Abstract text
Understanding the immune cells of the endometrium and decidua using single cell methods
During early pregnancy the endometrium transforms into the decidua. Extravillous trophoblast cells (EVT) from the fetus invade into this tissue and remodel maternal spiral arteries to increase blood flow to the placenta and support fetal growth. The correct degree of invasion is required; excessive invasion must be avoided, while reduced invasion is associated with major disorders of pregnancy including pre-eclampsia, and fetal growth restriction (FGR).

This process brings together cells from two genetically different individuals and recent work strongly suggests that recognition of trophoblast by maternal immune cells plays a role in determining the depth of placentation. Because

mother and father generally differ in their HLA class I and class II types, there is the potential for allo recognition of EVT. Immune cells in the decidua that can mediate allo-recognition include T cells and Natural Killer (NK) cells, but they do so by quite different mechanisms. EVT has a unique HLA profile: they do not express HLA-A or HLA-B, the dominant T cell molecules, but do express HLA-E, HLA-G (which are essentially monomorphic) and the polymorphic HLA-C molecules. T-cells that are able to recognise EVT directly are thus likely to do so using HLA-C restricted T cell receptors (TCRs).

In contrast, uterine NK cells (uNK) which comprise ~70% of decidual leucocytes, recognise HLA-C via activating and inhibitory receptors of the KIR gene family. Of all human gene families, HLA and KIR exhibit extreme polymorphism, so each pregnancy is characterized by different combinations of maternal KIR and fetal HLA-C genes, resulting in variable uNK inhibition or activation. Our genetic studies have established that that certain maternal KIR/fetal HLA-C combinations increase the risk of disorders of placentation such as pre-eclampsia and FGR. KIR/HLA-C combinations that result in excessive uNK inhibition are associated with low birth weight and increased risk of pre-eclampsia, while activating KIR/HLA-C combinations may result in large babies. However the biological mechanisms underlying these genetic results are unclear.

To better understand how interactions between maternal immune cells and trophoblast in the decidua might regulate EVT invasion, we have collaborated in the development of a single cell atlas of the maternal–fetal interface. Single-cell transcriptome profiling of decidual and trophoblast cells has revealed new types of decidual stromal and perivascular cells and allowed the identification of novel subsets of maternal immune cells. This has also permitted the creation of a database of potential ligand-receptor interactions between decidual cells and EVT (www.CellPhoneDB.org/). This analysis shows multiple mechanisms exist within the decidua to prevent harmful innate or adaptive immune responses. The RNA studies have been combined with high resolution phenotypic and functional analysis of uNK cells using a 43 marker mass cytometry (CyTOF) panel which has revealed in unprecedented detail the heterogeneity of the uNK and decidual T cell compartments. We have also developed an organoid culture system for human trophoblast cells, and these cells can be stimulated to differentiate into invasive EVT in vitro.

Together we hope that these tools will permit investigation of the cellular and molecular interactions between the cells of the decidua and EVT that are important for successful placentation. In particular, the trophoblast organoid model will allow us to determine how uNK responses triggered by different KIR/HLA-C combinations regulate trophoblast differentiation and function, to understand how interactions between immune cells and EVT result in different pregnancy outcomes.

O-107 Advanced tissue engineering to promote female fertility

O-108 3D testicular cultures: Novel tools for the study of human spermatogenesis

J.B. Stukenborg[1]

[1]*Karolinska Institutet, Dept. of Women's and Children's Health- NORDFERTIL Research Lab Stockholm, Stockholm, Sweden*

Abstract text

Title: 3D testicular cultures: Novel tools for the study of human spermatogenesis

Fertility in males relies on the spermatogenic process leading to the production of fertile sperm. It comprises the proliferation of

spermatogonial stem cells (SSCs), meiotic division, and the differentiation and finally the maturation of haploid spermatids. The fact that spermatogenesis is a continuous process which relies on stem cells offers men the opportunity to produce sperm until late in life. However, the production of sperm highly depends on the presence and functionality of SSCs.

Attempts to translate the complex process of spermatogenesis including all maturation steps from SSCs to functional sperm *in vitro* resulted in different strategies, including numerous culture conditions, which have been employed to explore the spermatogenic progress in detail (Alves-Lopes and Stukenborg, 2017). Despite this, understanding of this highly complex process, which is mainly influenced by endocrine and paracrine actions of somatic cells (e.g. Sertoli and Leydig cells), is still inadequate (Stukenborg, et al., 2018). The lack of detailed understanding of mammalian and especially human gametogenesis also results in a paucity of treatment options for patients, who cannot produce sperm and are at the risk of becoming infertile, due to their medical treatment or disease itself. This highlights the need for novel strategies to both understand the process of human spermatogenesis and develop *ex vivo* approaches to differentiate mature gametes from immature germ cells or even pluripotent stem cells.

In recent decades, a broad range of *in vitro* strategies have been applied to study the testicular microenvironment. However, a robust culture condition, suitable to investigate the formation of the human gonad and specifically the formation of the SSC niche has not been reported so far. In addition to first reports on successful differentiation of immature germ cells into functional sperm using explant tissue cultures, the generation of tissue-specific organ-like structures called organoids has created a new possibility, allowing researchers to study paracrine effect in more controlled manner (Alves-Lopes and Stukenborg, 2017). Organoids are small cell aggregates similar to organs found *in vivo*, but generated from single cell suspension containing stem cells. These organ-like structures are also defined by their functionality, which makes them a valuable research model and most likely a useful clinical tool in future. Today only few scientific publications are available focusing on the generation of testicular organoids (Alves-Lopes, et al., 2017, Baert, et al., 2017, Pendergraft, et al., 2017). However, together with other three-dimensional approaches, these novel cell-culture methodologies might provide new tools for more defined research approaches regarding gametogenesis and its failures.

Abstract text

Premature ovarian failure (POI) and infertility are frequent side effects of anticancer therapy, due to the extreme sensitivity of the ovarian follicle reserve to the effects of radiotherapy and chemotherapy. Oocyte and embryo cryopreservation can help some women achieve pregnancy after cancer-induced infertility, but the development of effective methods to protect ovarian function from chemotherapy would have significant advantages.

Cancer patients are commonly treated with combination of multiple drugs, making difficult to determine the mechanism of action of the individual substance on fertility.

Extensive studies have reported the effects of the most commonly used chemiotherapic drugs, such as Doxorubicin, Cisplatin and Cyclophosphamide, on the ovary. These drugs are known to induce follicle depletion, inflammation, stroma and vasculature damage. These adverse effects lead to depletion of the ovarian reserve, therefore to premature ovarian insufficiency, by death and/or accelerated activation of primordial follicles and increased atresia of growing follicles. Kinases have been identified as being central to the action of Cisplatin, Doxorubicin and Cyclophosphamide, and TAp63 as the guardian of primordial/primary oocyte genome integrity through its regulation of DNA damage and apoptosis.

In the last 20 years, attention has focused on the investigation of adjuvant therapies to protect ovarian function against chemotherapy. Mainly in animal models, several potential protective agents have been tested for their action on inhibiting oocyte death, on reducing follicle activation and atresia or reducing oxidative stress.

Understanding the mechanisms underlying the action of chemiotherapic compounds is essential for the development of efficient and targeted pharmacological therapies that could protect and prolong female fertility and ovarian functions.

SESSION 34: NEW INSIGHTS GAINED THROUGH TIME-LAPSE IMAGING

Tuesday 25 June 2019 | Mozart | 10:00 - 11:30

O-113 Halo characteristics during fertilisation are predictive of human pre-implantation embryo development and pregnancy outcome

K. Ezoe[1], **H. Tasaki**[1], **T. Miki**[1], **C. Hickman**[2], **T. Okimura**[3], **K. Uchiyama**[3], **A. Yabuuchi**[1], **T. Kobayashi**[4], **K. Kato**[4]

[4]Kato Ladies Clinic, Department of Gynecology, Tokyo, Japan

Study question:
Is the spatiotemporal halo phenomenon in the cytoplasm of oocytes during the in vitro fertilisation process predictive of embryo viability?

Summary answer:
The presence and time interval (TI) of halo events during fertilisation correlate with cleavage pattern, blastocyst formation, and ongoing pregnancy after single blastocyst transfer.

What is known already:
Embryologists traditionally assess zygotes between fertilisation and the first cell division to grade pronucleates. Using static observations, Stalf et al. (2002) first described the halo effect, a clear half-moon-like zone of the cytoplasm, and its association with improved fertilisation, embryo fragmentation, and clinical pregnancy compared to zygotes not displaying this phenomenon, suggesting halo presence as a potential biomarker for embryo viability. With the flexibility from time-lapse technology, Cottichio et al. (2018) further characterised morphokinetics of halo appearance and disappearance. The association between these stages, in addition to halo centralisation and redistribution, with embryo viability and implantation potential are currently undetermined.

Study design, size, duration:
Time-lapse images from 1,009 zygotes were retrospectively analysed from 560 patients who underwent in vitro fertilisation with minimal stimulation and single vitrified-warmed blastocyst transfer (SVBT) from April 2017 to March 2018. Halo presence, stages, and characteristics were observed in the time between second polar body extrusion and first cell division and compared relative to morphokinetic timing to the blastocyst stage and embryo quality, blastocyst expansion rate, and clinical and ongoing pregnancy rate.

Participants/materials, setting, methods:
Following intracytoplasmic sperm injection, time-lapse images from fertilized oocytes were annotated for halo presence and characteristics including timing of halo appearance (tHa), end of organelle centreing (tHc), initiation of organelle redistribution (tHr), and halo disappearance (tHd). Halo data were compared with morphokinetic data (from first PN appearance to expanded blastocyst), embryo stage of development reached (2-cells to blastocyst), cleavage embryo quality (cleavage symmetry and fragmentation), blastocyst quality (Gardner), and clinical outcome after SVBT.

Main results and the role of chance:
Halo was observed in 88% of fertilised oocytes. Zygotes without halo exhibited significantly higher rates of direct cleavage, reverse cleavage, and asymmetrical division compared with embryos derived from halo-present zygotes. Multivariate logistic regression analysis demonstrated significantly higher developmental rates to the expanded blastocyst stage in embryos with a halo compared to those without, regardless of its distribution (adjusted odds ratio (AOR): 0.435, 95% confidential interval (CI): 0.352–0.717, $P = 0.0004$). Halo presence did not correlate with embryonic morphological grade on days 2 and 5, or the ongoing pregnancy rate (AOR: 0.863, 95% CI: 0.358–2.080, $P = 0.7$). TI from tHa-c, tHc-r, and tHr-d were 4.7 ± 0.1, 7.4 ± 0.1, and 2.3 ± 0.1 h, respectively. TI prolongation from tHc-r ($P = 0.04$) and from tHr-d ($P < 0.0001$) significantly correlated with increased asymmetrical division at the first cell division ($P = 0.006$) and decreased developmental rates to the blastocyst expansion stage ($P = 0.002$). Halo event TIs did not correlate with embryonic morphological grade on days 2 and 5, or the developmental speed to the blastocyst stage. However, extended tHc-r was associated with a decreased ongoing pregnancy rate (AOR: 0.871, 95% CI: 0.788–0.959, $P = 0.006$).

Limitations, reasons for caution:
Although this is the largest and most detailed study of its kind, the uneven distribution between halo-present and halo-absent embryos indicates that there is still insufficient number of embryos in the halo-absent transferred group. Moreover, the data were collected from a single clinic.

Wider implications of the findings:
This is the first report demonstrating a correlation of the spatiotemporal halo phenomenon with blastocyst formation and pregnancy outcome using a time-lapse system. The association between halo characteristics and embryo viability suggests potential applications for diagnosing embryo viability, as a useful tool to aid embryo selection for transfer.

[6]Merck KGaA, Global Medical Affairs Fertility, Darmstadt, Germany

Study question:
Are implantation rates for Day 3/5 embryo transfers selected using early embryo viability assessment (Eeva) plus morphology grading (MG) different than transfers selected using MG?

Summary answer:
Implantation rate did not differ between Eeva+MG and MG alone, possibly due to the high rate of non-compliance in the Eeva+MG group.

What is known already:
Eeva is a time-lapse embryo-monitoring system with integrated software that automatically analyses embryo images to define the precise timing of cell divisions and make a recommendation on the likelihood an embryo will develop to the blastocyst stage. Eeva predicts blastocyst formation at the cleavage stage with a specificity of 85%. However, results from several trials of Eeva to date demonstrate substantial heterogeneity (e.g., different embryo rankings, different primary endpoints, lack of generalizability across different centres), meaning the true benefit of Eeva as an adjunct to morphological assessment for embryo prediction has not been determined.

Study design, size, duration:
In this Phase IV, prospective, 2:1 randomized, exploratory clinical trial at 20 sites in eight countries (Canada, Germany, Italy, France, Norway, Sweden, Spain and UK), 970 participants were randomly assigned to Eeva+MG or only MG. 899 completed the trial: 593 (66%) in the Eeva+MG group and 306 (34%) in the MG group. The choice of embryo for transfer was determined by the embryologist. All analyses are descriptive.

Participants/materials, setting, methods:
Women diagnosed with infertility who failed ≤3 previous IVF/ICSI cycles were included. Participant recruitment continued for 9 months, and participants were followed up to Days 12–18 to verify implantation and up to gestational Weeks 5–8 to verify clinical pregnancy. The study duration was 19 months. The original primary endpoint (positive implantation with fetal heartbeat) was amended (implantation with intrauterine gestational sac) after database lock, owing to errors when recording the original endpoint.

Main results and the role of chance:
The implantation rate with intrauterine gestational sac at Week 8 was 30.1% (95% CI 27.2–33.0) in the Eeva+MG group and 35.3% (95% CI 31.1–39.5) in the MG group. Post-hoc supportive analyses were carried out to identify the patients who met the criteria for Eeva compliance (embryo selection for transfer was based on the Eeva score and the Eeva evaluation was applied as per instructions for use). This analysis showed that only 57.7% of patients in the trial met both compliance criteria, implying that almost a half of patients in the Eeva+MG group were assessed on MG alone or had incorrect application of Eeva. Additional post-hoc supportive subgroup analyses of the original endpoint in the Eeva-compliant subgroup showed the implantation rate with fetal heartbeat after Day 3 embryo transfer was 25.7% in the Eeva+MG group (n=163) and 32.7% in the MG group (n=117). For Day 5/6 transfer, the implantation rate was 45.5% in the Eeva+MG group (n=87) and 38.3% in the MG group (n=99). The implantation rate of the Eeva-compliant subgroup was equal or higher than that of the MG group at five of 12 sites (Day 3 transfer) and seven of 14 sites (Day 5/6 transfer).

Limitations, reasons for caution:

The low compliance was based on reliance on MG scores over Eeva scores and the suboptimal use of Eeva, potentially due to insufficient training of embryologists, meaning the true value of Eeva may not have been fully leveraged by these results.

Wider implications of the findings:

The results of this trial are in line with the inconclusive results reported for other trials of Eeva. Our findings also highlight the potential limitations in the conduct of trials of devices to improve embryo assessment and also in the training of embryologists in the use of the Eeva system.

[3]Hôpital Cochin - Port Royal, Service d'Histologie-Embryologie-Biologie de la Reproduction, Paris 14, France

[4]Institut Curie, PSL Research University- CNRS UMR3215- INSERM U934, Paris, France

Study question:

To analyze quantitative parameters of compaction during human embryo development by time-lapse imaging and their impact on blastocyst implantation.

Summary answer:

Dynamics and geometrical parameters were defined in order to describe human embryo compaction and no relation was observed with implantation success.

What is known already:

The shaping of the human embryo results from the action of morphogenetic forces generated by its own blastomeres. Previous studies on mouse embryos mapped the forces shaping the embryo during compaction using non-invasive biophysical methods [Maitre et al., 2015]. Mouse embryos compact at the 8-cell stage by increasing the tension at their surface (γcm) and by reducing the tension at cell-cell contacts (γcc). This changes the ratio of tensions ($\alpha = \gamma cc/2\gamma cm$) and leads to the increase of the contact angle (θ), making the embryo more compact. Very little is known about the forces shaping human embryo during compaction.

Study design, size, duration:

A total of 224 blastocysts obtained from diploid zygotes after IVF or ICSI at Day 5 or Day 6 between February 2016 and April 2017 were included in this retrospective study performed in the Reproduction Biology laboratory in Bichat Hospital (AP-HP, Paris, France). They were cultivated and imaged by time-lapse microscopy (EmbryoScope, Vitrolife). Among them, 117 blastocysts were transferred fresh (n=7) or after freezing-thawing cycles (n=110), corresponding to 75 oocytes retrievals (in 70 couples).

Participants/materials, setting, methods:

Videos were retrospectively analyzed to determine the timing of cell divisions (7-8, 8-9, 15-16 and 16-17cells) and compaction (disappearance of cell limits) and to measure the contact angles at their stages. They were measured using the angle tool from Fiji software through the equatorial plane of two contacting cells. Embryos were classified according to their compaction stage and the relation to implantation success was evaluated. Only embryos reaching the blastocyst stage (Gardner's classification) were considered.

Main results and the role of chance:

During compaction, the contact angle (θ) grew from (103° ± 9°) to (151° ± 9°) (mean ± SEM, n=224), all stages considered. The majority of embryos (64%, n=144) increases their θ angles between the initial 16-cell stage (15 to 16 cells) and the final 16-cell stage (16 to 17 cells). A minority of embryos compacted during the 8-cell stage (36%, n=80). We find no difference in the compaction stage (repartition of compaction stage : 7-8 cells stage 9%. *vs*. 5%, 8-9 cells stage 22% *vs*. 22% and 16 cells stage 69% *vs*. 73%, n=117, P=0.67), in the maximal θ angle (150° ± 8° *vs*. 151° ± 11°, n=117, Student's *t* test P > 0.05) or in the compaction rate between embryos that implant and those which do not (α=0.328 ± 0.095 *vs*. 0.294 ± 0.071, n=117, Student's *t* test P=0.42).

Limitations, reasons for caution:

Further investigations are required to determine whether some differences in culture conditions or fertilization method (IVF or ICSI) could impact the parameters of embryo compaction and to evaluate their interest as a predictor of human embryo development.

Wider implications of the findings:

This study defines objective and physically relevant parameters for the quantitative analysis of compaction of human embryos reaching the blastocyst stage. We find that compaction takes place at the 16-cell stage in the majority of embryos but can also occur at other cleavage stages, without impact on implantation success.

O-116 Non-invasive embryo selection: Live birth can be predicted by means of the kinetic analysis of female and male pronuclei formations

J. Otsuki[1,2], T. Iwasaki[2], N. Enatsu[2], Y. Katada[2], K. Furuhashi[2], M. Shiotani[2]

[1]Okayama University, ART Center, Okayama, Japan

[2]Hanabusa Women's Clinic, Reproductive Medicine, Kobe- Hyogo, Japan

Study question:

Is there a method of non-invasive embryo evaluation which may exceed the success rates of PGT-A using trophectoderm cells?

Summary answer:

Yes. We have established a non-invasive evaluation of euploid embryos, focusing on kinetic analyses, from the second polar body extrusion to the pronuclear membrane breakdown.

What is known already:

It is generally known that even if embryos are implanted by means of ART procedures, nearly 30 % of them miscarry. Most miscarried embryos are chromosomally abnormal. To select embryos most likely to be normal and result in a successful transfer, the kinetic analysis of embryos using time-lapse observation systems has been employed in many ART laboratories worldwide. Although at present the precise chromosomal abnormalities, such as mosaic or subchromosomal imbalances, cannot be detected without performing pre-implantation genetic testing for aneuploidy (PGT-A), the live-birth rate of embryos transferred after PGT-A is around 50%.

Study design, size, duration:

A retrospective study of 213 frozen-thawed single blastocyst transfers(ICSI:112, IVF:101) between June 2013 and December 2016 was performed. Normal live birth was considered a successful conclusion to this study.

Participants/materials, setting, methods:

Time-lapse recordings were performed and the areas of male and female pronuclei were retrospectively analyzed by measuring their vertical and horizontal diameters. These measurements were taken 4 and 8 hours before the pronuclear membrane breakdown (PNMBD), and immediately before the PNMBD. The difference in microns squared of the 2PNs in embryos resulting in live-births was compared with that of embryos from failed pregnancies.

Main results and the role of chance:

The cut-off values for the differences in area between male and female pronuclei immediately before PNMBD, among embryos resulting in live birth, were 39.3 (AUC: 0.631, CI: 0.518-0.745) for IVF, and 40.0 (AUC: 0.670, CI: 0.568-0.771) for ICSI. (Definition A: the difference in area between the male and female pronuclei immediately before PNMBD should be below the cut-off value). Of the 15 embryos which had female pronuclei larger than male pronuclei 8 hours before PNMBD, none achieved live birth. (Definition B: The size of male pronuclei 8 hours before PNMBD should be larger than female pronuclei). The difference in the sizes of pronuclei in patients with successful births gradually decreased (IVF: $p<0.001$, ICSI: $p=0.012$), while the difference in the size of pronuclei in patients who did not achieve live birth did not decrease.

(Definition C: The difference in size between the male and female pronuclei 8 hours before PNMBD should be larger than the size of immediately prior to PNMBD). When normal embryos were defined as A∪C∩B, the birth rates for IVF and ICSI were 68.1% (47/69) and 50.0% (32/64) respectively. For the remaining embryos, defined as abnormal, birth rates were 9.3% (3/32) for IVF and 4.2% (2/48) for ICSI.

Limitations, reasons for caution:

Birth could have occurred following natural conception, which sometimes occurs during frozen-thawed embryo transfer cycles with hormone therapy. As the detection rate for male and female pronulcei with our current time-lapse system was approximately 50%, this method of evaluation requires further improvement prior to implementation.

Wider implications of the findings:

In this study, we established a method of non-invasive embryo evaluation which may exceed the success rates of PGT-A using trophectoderm cells. Evaluating and transferring embryos at an early stage could simplify laboratory procedures and avoid monozygotic twinning caused by prolonging the use of culture medium to the blastocyst stage.

Not applicable

O-117 Impact of reverse cleavage on in vitro development and reproductive outcomes of human embryos

J.M. Capdevila[1], S. Novo[1], J. Massó[1], M. Solans[1], B. Freijomil[1], C. Castelló[1], M. López-Teijón[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question:

What are the effects of reverse cleavage (RC) on embryo development and clinical outcomes on in vitro fertilization (IVF) treatments?

Summary answer:

RC has drastic effects on embryo development. However, embryos with RC achieving a good quality blastocyst stage have equal reproductive outcomes as embryos without RC.

What is known already:

Reverse cleavage has gone unnoticed until the implementation of time-lapse technology on IVF labs. The influence of RC is poorly documented, and its effects are unclear. Most of the studies describe a multinucleation increase on embryos with RC. However, there are some discrepancies about the RC effects on the embryo development and clinical outcomes. Several publications have proved no detrimental effects on in vitro development of embryos with RC, but a clear decrease in implantation and pregnancy rates. Conversely, other authors published a lower blastocyst rate but an equivalent euploid rates on embryos with RC.

Study design, size, duration:

This is a retrospective study including 23,340 embryos from 6,340 cycles performed between 2014 and 2018. The sample was split in two groups: RC negative group (RC-) with 23,007 embryos without reverse cleavage in D+2 or D+3 and, RC positive group (RC+) represented for 303 embryos showing reverse cleavage in D+2 and/or D+3.

Participants/materials, setting, methods:

All the cycles were inseminated through intracytoplasmic sperm injection technique and the embryos were cultured in time-lapse incubators until blastocyst stage using one step culture media. Good quality blastocyst, multinucleation, clinical pregnancy and live birth rates were compared between embryos with and without RC. In vitro fertilization cycles inseminated conventionally and/or cultured inside incubators without time-lapse technology were excluded from this study. A Chi-square test has been used to compare the groups.

Main results and the role of chance:

At least one RC event was showed by 1.3% of the embryos on day 2 or 3 of culture (n =303). This RC rate fit with previously published values for others laboratories which ranges between 0.4% and 7%.

The in vitro development rate of embryos RC+ up to day 5/6 (19.1%) was significantly lower than the embryos RC- (54.2%) ($p<0.05$). Also, the presence of some multinucleated cell was more frequent in embryos RC+ (71.5%) than embryos RC- (33.5%) ($p<0.05$). However, embryos RC+ achieving a good quality blastocyst stage showed the same clinical results as blastocysts RC-. In this sense, clinical pregnancy and live birth rates were equivalent between blastocyst RC+ (54.2%; 37.5%) and blastocysts RC- (55,9%; 36,5%). By these findings, the power of the blastocysts culture is enhanced and shows us how embryos can successfully overcome abnormal encounter cleavage patterns, such as reverse cleavage.

Limitations, reasons for caution:

RC happens with a relative low frequency on embryo development. There is a huge difference on the sample number between the compared groups.

Wider implications of the findings:

With the obtained results, we consider that RC could be a part of some cellular error-detection mechanism. Embryos that are able to overcome this checkpoint, repairing or discarding the involved cells to reach a good quality blastocyst, would have the same reproductive potential as blastocyst without RC.

Trial registration number:

Doesn't apply

O-118 Time-lapse imaging acquired nucleation status of 2-cell pre-implantation embryos is predictive of implantation and live births following IVF

S. Sayed[1], M. Myhre Reigstad[2], B. Molt Petersen[3], A. Schwennicke[1], J. Wegner Hausken[1], R. Storeng[2]

[1]Klinikk Hausken, IVF and Gynecology, Haugesund, Norway

[2]Norwegian National Advisory Unit on Women's Health, Oslo University Hospital, Oslo, Norway

[3]BMP Analytics, Consultancy, Viby J, Denmark

Study question:

May nucleation error phenotypes during the first embryo cleavage as observed by time-lapse imaging be used to predict implantation and live birth following IVF treatment?

Summary answer:

Nucleation errors at the 2-cell embryo stage may be used in selecting embryos for transfer and be predictive of implantation and live birth.

What is known already:

Reliable selection of embryos based on morphology and morphokinetic patterns has been promoted in clinical practice with the establishment of Time-lapse imaging (TLI). One visible nucleus in blastomeres has been indicative of the implantation potential of embryos. Nucleation errors such as binucleation (presence of two nuclei per blastomere), micronucleation (one or two larger nuclei surrounding several smaller nuclei) and multinucleation (more than two similar sized nuclei per blastomere) have been indicative of lower implantation rates and higher miscarriage rates. Self-repair of multinucleated embryos however during early cleavage divisions has been shown to occur, resulting in euploid blastocysts and live births.

Study design, size, duration:

Retrospectively collected TLI data derived from transferred embryos cultured in the EmbryoScope ™ incubator between June 2011 and August 2018 in a private IVF clinical setting was included. Only Known Implantation Data (KID) for implantation and live births were used. Nucleation errors such as micronucleation, binucleation, multinucleation and other minor error groups, were annotated in the time-lapse images which were taken every 10 or 20 minutes for a minimum of 44 hours post insemination.

Participants/materials, setting, methods:

Nucleation error phenotypes (NEP) data was collected from TLI for 2959 transferred embryos. A total of 2082 treatment cycles with exact traceability of transferred embryos were included in the analysis. The association between NEPs and both known implantation and live birth was assessed. The analysis controlled for potential confounding factors by adjusting for maternal age (above and below 36 years) and infertility diagnosis. Fisher's exact test was used to analyse categorical variables.

Main results and the role of chance:

The analyses showed statistically significant lower implantation and live birth rates for embryos with all types of nucleation errors at the 2-cell stage (22.9% of the transferred embryos), compared to embryos not presenting nucleation errors; 14.2% vs. 23,9% for implantation and 11.8% vs. 21.0% for live birth respectively, $P<0.001$. No differences in NEP occurrence were observed when the results were stratified according to type of NEPs and infertility diagnoses.

The occurrence of NEP was significantly ($P<0.02$) higher for women > 36 years old. The woman's age by itself had a significant effect on implantation and live birth rates; 32.9% vs. 10.5% and 29.6% vs. 8.5% respectively for women less than and more than 36 years' old; $P<0.001$. The decline in implantation and live birth by NEP occurrence was 40.7% and 43.8% respectively and was unaffected by age.

Retrospective TLI data analysis of almost 3000 transferred embryos offers a strong indication towards predictive role of NEPs in embryo selection. Given the large data set and high statistical significances in the study, the role of chance in this case may be limited. Hence, confounding factors that can arise due to transfer selection and exclusively analysing embryos with known implantation may be more important.

Limitations, reasons for caution:

Rates are given per KID /embryo, which cannot be compared directly with per treatment rates. Only transferred embryos were analysed retrospectively, so the effect of TLI on other NEP embryos and hence their ability to self-repair is not investigated.

Wider implications of the findings:

Our study provides insight regarding the role of nucleation errors on live births. None of the investigated NEPs completely invalidate the possibility of live birth, but rather lowers the probability of this occurrence. Therefore, the significance of incorporating nuclear status annotations in embryo selection, alongside morphology and morphokinetics, is imperative.

O-119 Differentiation of embryonic stem cells into germ line cells using decellularized seminiferous tubules bathed in a conditioned medium

P. Xie[1], A. Trout[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question:

We test the suitability of a biochemical and biomechanical microenvironment to allow differentiation of mouse embryonic stem cells into male germ line cells.

Summary answer:

A bioreactor concept approach supported by a biological scaffold allows de novo generation of meiotic male germ cells from murine embryonic stem cells.

What is known already:

In the past decade, tissue engineering has been a rapidly developing field of study that aims at artificially regenerating functional tissues. Extracellular matrix (ECM)-derived scaffold produced by decellularization of different types of connective tissues can provide a microarchitecture suitable for tissue regeneration for prosthetics and transplantation by allowing stem cells to regenerate functional tissue in vitro. In vitro testicular tissue culture can be used to study the process of spermatogenesis. The differentiation process, however, has several limitations due to the complex architectural organization of the seminiferous epithelium and requires a suitable three-dimensional scaffold to progress.

Study design, size, duration:

Eighty embryonic bodies (EBs) constituted mainly by PGCLCs were generated for utilization in the bioreactors, in contact with decellularized seminiferous tubule matrices (DSTMs) and bathed in media conditioned by interstitial cells isolated from adult mouse testes. Ninety 3-mm sections of DSTM, longitudinally sliced open and flattened, were derived from 3 adult B6D2F1 mice; interstitial cells were isolated from the respective contralateral testes. Germ cell stage–specific markers were assessed every 3 days after complete recellularization.

Participants/materials, setting, methods:

Interstitial cells were isolated through differential plating and layered on the interphase of twelve bioreactors. Seminiferous tubules, isolated from the contralateral testicles of these mice following decellularization by exposure to 1% sodium dodecyl sulfate for 24 hours, were placed below the interphase in direct contact with differentiated cells from digested EBs. DAPI and H&E staining were used to confirm complete decellularization. Cell characteristics were analyzed by germ cell stage–specific markers on an H&E-stained background.

Main results and the role of chance:

After culturing mESCs in Activin A, bFGF, and KSR for three days, persistent expression of OCT4 (>90%) and decreased positivity of Nanog (45%) indicated successful progression to EpiLCs. PGCLCs rich in embryonic bodies expressed positive surface SSEA-1 after six days of culture in hanging droplets containing BMP4, BMP8b, SCF, LIF, and EGF. After incubation in the bioreactor, the earliest attachment of PGCLCs onto DSTM occurred on day 3, and complete recellularization occurred approximately at day 10, as observed by optic microscopy. Following complete recellularization, about half of all isolated cells, which were obtained from the enzymatic digestion of recellularized tubules from the bioreactor, displayed decreased expression of OCT4, while about 5% displayed nuclear DAZL positivity at day 10. At around day 16, cytoplasmic VASA staining in 5% of the cells suggested meiotic/post-meiotic germ line differentiation. In 1% of the cells, a perinuclear DAZL confirmed spermatocyte differentiation. The timeline of our bioreactor system was comparable with in vivo spermatogenesis in the mouse, occurring in the course of 21 days.

Limitations, reasons for caution:

Although this culture method is capable of providing a suitable microenvironment to initiate spermatogenesis in vitro, complete in vitro spermato-/spermiogenesis remains challenging. Further refinements of the bioreactor are required to allow complete differentiation into the later post-meiotic stages.

Wider implications of the findings:

The ability of a 3D biocompatible scaffold to induce maturational meiosis will provide insights to overcome human spermatogenic arrest. Neogametogenesis from genotyped stem cells carried out in a scale-down microfluidic device may help to treat men afflicted by Sertoli cell-only syndrome.

O-120 Human embryonic stem cells derived trophoblastic spheroids (BAP-EB) as human embryo surrogate for identification of attachment-related endometrial surface molecules

Y.L. Lee[1], S.W. Fong[1], C.L. Lee[1], C. Yue[1], K.C. Lee[1], A.C.H. Chen[1], K.F. Lee[1], W.S.B. Yeung[2], E.H.Y. Ng[1]

[1]The University of Hong Kong, Obstetrics and Gynaecology, Hong Kong, Hong Kong [2]The University of Hong Kong Shenzhen Hospital, Shenzhen Key Laboratory of Fertility Regulation, Shenzhen, China

Study question:

Does BAP-EB induce expression of attachment-related molecules in endometrial epithelial cells?

Summary answer:

BAP-EB produced soluble factor(s) that induced expression of surface proteins on endometrial cells involving in BAP-EB-endometrial cells attachment.

What is known already:

Implantation failure can be caused by impaired endometrial receptivity. However, mechanistic study of the implantation process in humans is limited by lack of an appropriate implantation model. Trophoblastic spheroids (BAP-EB)

derived from human embryonic stem cells by bone morphogenic protein 4, A83-01 and PD173074 treatment possess human blastocoel-like structure and attach specifically onto receptive endometrial epithelial cell lines. The use of BAP-EB as human embryo surrogate for mechanistic study of early implantation is explored in the current report.

Study design, size, duration:

Human embryonic stem cells (H9) were induced to differentiate into BAP-EB for 48h and 72h. Endometrial epithelial cells (EEC) were isolated from endometrial biopsies obtained from infertile women on day 2 (hCG+2, n=20) or day 7 (hCG+7, n=13) post-hCG induction of ovulation. The BAP-EB spent media were collected before (0h) and after BAP differentiation for 48h and 72h.

Participants/materials, setting, methods:

The attachment rates of H9-BAP-EB onto the cultured EEC were compared after 3 hours of coculture. The spent media of BAP-EB-48h (attachment incompetent) or BAP-EB-72h (attachment competent) were used to treat the receptive endometrial Ishikawa cells for 3 hours, and the differentially expressed cell surface proteins were identified by mass spectrometry. The functional roles of the target surface proteins were studied by antibody blocking during the attachment assays.

Main results and the role of chance:

The attachment rates of BAP-EB derived from H9 onto EEC isolated from receptive (hCG+7 day) phase were significantly higher than those of pre-receptive (hCG+2 day) phase (hCG+7: 26.7±14.7% vs hCG+2: 2.3±3.0%, $p<0.001$) endometria. After incubation with the spent media of attachment competent (72h) or incompetent (0h, 48h) BAP-EB for 3 hours, cell surface proteins of treated endometrial Ishikawa cells were biotinylated and identified by liquid chromatography-mass spectrometry. In total, eight cell surface proteins were induced by the spent medium of attachment competent BAP-EB-72h when compared to that of the incompetent BAP-EBs. Five of them namely Catenin alpha-1, Catenin delta-1, Plexin-B2, Extended synaptotagmin-2 and CD98hc were selected for further study. Their expressions were significantly higher in the receptive endometrial cell lines (RL95, Ishikawa) when compared to the non-receptive ones (HEC-1B, AN3CA). The BAP-EB attachment rates were significantly reduced after treating Ishikawa cells with antibodies against CD98hc (42%) and Catenin delta-1 (36%) when compared to normal IgG control (62%, $p<0.01$, chi-square test).

Limitations, reasons for caution:

The soluble factor(s) that secreted from BPA-EB have not been identified. BAP-EB and the endometrial cell lines used may not fully represent the in vivo developed human blastocysts, and the primary endometrial cells, respectively.

Wider implications of the findings:

The number of human embryos donated for research use is limited. The results obtained in this study demonstrated the usefulness of BAP-EB as human embryo surrogate for studying human implantation, and the role of human embryos in inducing attachment related endometrial epithelial cell surface molecules.

nil

O-121 Improving three-dimensional in vitro culture methods of human endometrial stem cells: bioengineering tissue-specific hydrogels

S. López Martínez[1], H. Campo[1], L. De Miguel-Gómez[1], A. Faus[1], H. Ferrero[1], I. Cervelló[1]

[1]IVI Foundation, Research, Valencia, Spain

Study question:

Can tissue-specific extracellular matrix (ECM) hydrogels derived from decellularized (DC) porcine endometrium improve three-dimensional (3D) culture of human endometrial stem cells (ICE6-7, Cervelló et al.,2011)?

Summary answer:

ECM hydrogels from DC porcine endometrium are biocompatible and improve ICE6-7 proliferation compared to standard 3D culture, showing much potential for future regenerative medicine purposes.

What is known already:

The use of hydrogels made of tissue-specific ECM from DC organs represents a revolution in regenerative medicine due to its therapeutic potential. This is attributable to the presence of bioactive components that mimic the natural tissue-specific environment, together with low immunogenicity. Recently, our group has established a method to decellularize whole pig uteri (Campo et al., 2017). Here we furthered this line of investigation using the DC organ to create endometrial ECM hydrogels. These were used in novel *in vitro* approaches and will be tested in the near future *in vivo* as a novel solution for untreatable endometrial pathologies.

Study design, size, duration:

Pig uteri (n=4) were collected for whole organ decellularization, endometrium isolation and hydrogel creation. Physicochemical features were determined and compared with hydrogels from a non-DC endometrium and DC myometrium. Biocompatibility of DC endometrial hydrogels (at 3, 6 and 8 mg ECM/ml) were studied using stem cell lines from epithelial (ICE6) and stromal (ICE7) origins (n=3) during 24 and 72hrs in different conditions. Standard matrix for 3D culture, collagen and Matrigel, were used as controls.

Participants/materials, setting, methods:

To create hydrogels, uteri were decellularized by perfusion and endometrium was isolated by microdissection. Subsequently, DC endometrial tissue was milled, lyophilized and enzymatically digested. The characterization was carried out by turbidimetry, scanning electron microscopy (SEM), quantification of ECM proteins and proteomic analysis. ICE6 and ICE7 cell lines were cultured on top of (2.5D) or embedded in (3D) hydrogels and cell proliferation was measured by MTS Assay. Two-way Anova was used for statistical analysis.

Main results and the role of chance:

While decellularization removes much of the protein fraction (81%), a significant amount of elastin (18%) and glycosaminoglycans (18%) was retained. Moreover, a significant enrichment of collagen (50%) was observed. SEM showed that endometrial ECM hydrogels are porous scaffolds with a homogenous, randomly interlocking fibrillar structure. No significant differences in fiber thickness (0.10 µm) and ultrastructure were found between non-DC endometrial, DC myometrial hydrogels and different concentrations. Turbidimetry showed that stable endometrial ECM hydrogels quickly formed after incubation at standard culture conditions (12.97±1.46 min at 37°C), independently of the concentration. After 72hrs, cell proliferation of both cell lines was improved in 3D culture system with endometrial ECM hydrogel (all concentrations) compared to collagen and Matrigel controls. A fold change of up to 2.13 and 2.11 (6 mg/ml $p<0.0001$) compared to collagen, for ICE7 and ICE6 respectively was measured. In 2.5D culture, collagen and Matrigel poorly retained the cells compared to the endometrial hydrogels. Here, a fold change of up to 1.84 and 1.83 (8mg/ml, $p<0.0001$) for ICE7 and ICE6 respectively was observed. These data showed that porcine endometrial ECM hydrogels are biocompatible and improve *in vitro* proliferation of human endometrial stem cells.

Limitations, reasons for caution:

This study was only performed with endometrial stem cell lines, *In vivo* studies will be required to confirm the regenerative potential of endometrial ECM hydrogels under pathological conditions.

Wider implications of the findings:

These findings support the hypothesis that porcine endometrial ECM hydrogels are biomimetic to the native endometrium and stem cell niche. This study represents a first step to the use of this biomaterial to improve 3D *in vitro* culture, opening a window towards *in vivo* studies and treatment of endometrial pathologies.

O-122 Single cell sequencing reveals gene expression signatures and key transcriptional regulators during human folliculogenesis.

Y. Zhang [1], Z. Yan [1], Q. Qin [1], J. Yan [1], L. Yan [1], J. Qiao [2]

[1]Peking university third hospital, medical center for human reproduction, beijing, China

[2]peking university third hospital, medical center for human reporduction, beijing, China

Study question:

Can single-cell resolution RNA-seq analysis on a cohort of women showing the dynamic transcriptional regulation and interactions of human germlines and surrounding somatic cells during folliculogenesis?

Summary answer:

This approach is effective to clarify the transcriptome datasets of oocytes and granulosa cells and to reveal signature genes and candidate markers for ovarian reserve.

What is known already:

Folliculogenesis is a complex and highly regulated process that involves bidirectional interactions of the oocytes and surrounding granulosa cells. Follicle growth and oocyte maturation are associated with dynamic transcriptional regulation in both oocyte and GC compartments of the follicle. The selection of primordial follicles in the ovarian reserve, established early in life, provides all growing follicles and ovulated oocytes. The transition from the primordial to the growing follicle through the antral follicle, which culminates in dominance was achieved in waves by one or more follicles.

Study design, size, duration:

To explore the mechanism of transcriptional regulation of human follicle development and oocyte-granulosa interactions, the whole transcriptome datasets of human oocytes and granulosa cells at each stage of folliculogenesis were obtained.

Participants/materials, setting, methods:

We collected adult ovarian tissues, digested them by mechanical and enzymatic digestion, isolated and obtained follicles and oocyte-granulosa cell complex in five developmental stage (primordial follicle, primary follicle, secondary follicle, antral follicle and preovulatory follicle). Furthermore, follicles or oocyte-granulosa cell complexes were digested to obtain oocytes and granulosa cells. The single cell cDNA libraries of oocytes and granulosa cells were obtained by single cell transcriptome amplification, and transcriptome sequencing was performed.

Main results and the role of chance:

According to the characteristics of transcriptomic profiles, oocytes and granulosa cells can be divided into five groups, which are coincident with the follicular development stage (primordial follicle, primary follicle, secondary follicle, antral follicle and preovulatory follicle). The stage-specific expressed genes of oocytes and granulosa cells at different stages are identified, as well as secretory protein coding genes that are candidate biomarkers for ovarian reserve. During the activation of primordial follicles, Insulin, GnRH, Neurotrophin and mTOR pathways may play a co-regulatory role in oocytes and granulosa cells, while JAK-STAT pathway may play a regulatory role in granulosa cells. The analysis of the interaction between oocytes and granulosa cells during follicular development indicated that NOTCH and TGF-β signaling pathways exhibited stage-specific interaction during follicular development.

Limitations, reasons for caution:

Despite rigorous experimental approach and robust analyses, our findings are not sufficient to confirm the functional characteristics of the identified transcripts. Our methods relied on the mechanical or enzymatic dissociation of follicular compartments, thus the information on temporal and spatial regulation of gene expression in GCs was not reflected.

Wider implications of the findings:

This provides key insights into the crucial features of the transcriptional regulation in the stepwise folliculogenesis and offers important clues for improving follicle recruitment *in-vivo* and restoring fully competent oocytes *in-vitro*.

Trial registration number:

not applicable

O-123 Human Adipose Tissue-Derived Stem Cells improve ovarian function in a mouse model of chemotherapy-induced partial Premature Ovarian Failure

G. Salvatore[1], A. Camaioni[1], M. De Felici[1], S. Dolci[1], F.G. Klinger[1]

[1]University of Rome Tor Vergata, Dep. of Biomedicine and Prevention, Rome, Italy

Study question:

Are human Adipose Tissue-Derived Stem Cells (hADSCs) able to counteract the impairment of ovarian function induced by chemotherapy?

Summary answer:

hADSC transplantation alleviates the damage induced in the ovary by busulfan (BU) and cyclophosphamide (CY) reducing follicle depletion and improving the oocyte quality.

What is known already:

Mesenchymal Stromal Cells (MSCs) hold great promise in the field of regenerative medicine because of their ability to home to the injury site, where they repair tissues mainly secreting various growth factors, cytokines and chemokines that decrease local inflammation. Several studies have recently shown that the *in situ* or systemic injection of MSCs of various animal species and from different anatomical sources are able to restore impaired ovarian functions in animal models of Premature Ovarian Failure (POF), but no information exists whether hADSCs, which are the least invasive MSCs to harvest, possess such capability.

Study design, size, duration:

Thirty-seven 11 weeks old female CD1 mice with regular oestrous cycle were randomly assigned to four groups: vehicle treated control group (CTR), chemotherapy group (CH), *in situ* (IS) and intravenous (IV) hADSC transplanted groups. Chemotherapy and transplanted groups received a single injection of BU+CY to induce POF. A week later (day0) IS and IV received cell transplant. At day28 mice were sacrificed to collect ovaries, or superovulated and mated to recover 2-cell embryos.

Participants/materials, setting, methods:

12mg/kg BU and 120mg/kg CY were intraperitoneally administered. hADSCs were isolated from female patients and injected into one of the two ovaries for IS group (75.000 cells) or through the tail vein for IV group ($1x10^6$cells). Body weight was recorded at day0 and day28. Ovaries were weighted at day28 and sectioned for follicle counting (H&E staining). After superovulation and harem mating, 2-cell embryos were isolated and developed *in vitro* up to blastocysts.

Main results and the role of chance:

At day28, IS and IV females showed a significant body weight increase compared to day0 (IS: 36.1±2.0g vs 31.0±1.7g, $p<0.001$; IV: 32.8±1.9g vs 29.3±3.1g, $p<0.01$; n=3), while such increment did not occur in CH or CTR groups. Moreover, ovarian weight, normalized for the animal weight, was significantly higher in the same groups compared to CH group (IS: 0.97±0.07mg/g and IV: 1.02±0.03mg/g vs CH: 0.64±0.12mg/g, $p<0.05$ and $p<0.01$, n=2). Interestingly, for IS group, ovarian weight significantly increased also when compared to the untreated controlateral ovary (0.97±0.07mg/g vs 0.65±0.05mg/g, $p<0.05$, n=2). Follicle number in CH ovaries was significantly lower than in CTR (CH: 572.2±138.1 vs CTR: 2688.0±65.9, $p<0.01$, n=2), while such depletion was reduced in IV (CH: 572.2±138.1 vs IV: 1399.0±145.8, $p<0.05$, n=2). If such difference occurs also in IS ovaries is under investigation. Despite the reduced number of follicles, superovulated CH females did not show reduced fertilization rate or number of 2-cell embryos compared to the other groups. However, the percentage of 2-cell embryos able to develop into blastocyst was significantly higher in IV compared to CH (65.8±6.0% vs 36.8±3.3%, n=2, $p<0.05$), but still slightly lower than CTR group (CTR: 90.9±1.7%, p=0.051, n=2).

Limitations, reasons for caution:

Results were obtained from low number of animals. The chemotherapy protocol used, although caused a marked depletion of follicles, did not result in loss of fertility. Different chemotherapy and mating protocols must be chosen to reproduce POF. The transfer of the results obtained in mice to human requires caution.

Wider implications of the findings:

The results suggest that hADSCs transplantation might be useful to alleviate follicle depletion and improve the quality of oocytes in chemotherapy treatments of human patients. In this regard, hADSCs would provide a new, abundant, easy to harvest and minimally invasive alternative source of MSCs for clinical treatment of chemotherapy-induced POF.

O-124 Autologous bone marrow derived CD34+ stem cell therapy for refractory Asherman syndrome (AS) and endometrial atrophy (EA): 5 year follow up study

N. Singh, M.B.B.S.- M.D.[1], S. Kumar[1], B. Shekhar[1], S. Mohanty[2], T. Seth[3]

[1]All India Institute Of Medical Sciences AIIMS, Department of Obstetrics & Gynaecology, New Delhi, India

[2]All India Institute Of Medical Sciences AIIMS, Department of Stem Cells Facility, New Delhi, India
[3]All India Institute Of Medical Sciences AIIMS, Department of Haematology, New Delhi, India

Study question:
Can bone marrow derived stem cells (BMSCs) regenerate functional endometrium in cases of endometrial atrophy (EA), or Asherman Syndrome (AS) and improve fertility outcome?

Summary answer:
Autologous bone marrow derived stem cell treatment is promising novel approach for refractory cases of Asherman syndrome (AS) and endometrial atrophy (EA) and improves fertility.

What is known already:
Endometrium has high capacity for self renewal- 400-500 cycles in reproductive life, regulated by Hormones. Endometrium derived stem cells (EDRSCs) present in niche basal layer are responsible for regeneration of endometrium after complete shedding. It is the absence of functional endometrium, which leads to endometrial atrophy (EA) or intrauterine adhesion (AS) and infertility. BMSCs are CD34+ adult stem cells with characteristics of self-renewal, multi potential differentiation, and auto transplantation without immune rejection. Since there is no effective treatment available for refractory AS and EA, based on these observations, the role of BMSCs for endometrial regeneration was explored

Study design, size, duration:
Prospective, single arm longitudinal study, 25 patients (12 with AS and 13 with EA)

5 year follow up study. Patients underwent stem cell implantation between September 2013 and January 2014 and each patient was followed up at 3 months, 6 months, 9 months and 5 year interval.

approved by the Institutional Ethics Committee and National Human Ethics Committee for Stem Cell therapy & Research. Untreated patients were internal controls

Participants/materials, setting, methods:
25 women (24 - 37 years) with AS and/or EA with infertility (16 primary and 9 secondary)

19 =scanty menses, 6 = amenorrhea. all cases had failed to respond to standard treatment (Hysteroscopic adhesiolysis and extended estrogen treatment).

Tertiary care University hospital

Bone marrow aspirated from iliac crest of cases,Stem cells harvested, CD 34+ cell count done

2-3 ml injected sub-endometrial zone at 2-3 sites once under trans-vaginal ultrasound (TVS)guidance by vaginal route using oocyte aspiration needle

Main results and the role of chance:
Statistical analysis using STATA version 9.0. Changes in ET values due to treatment at 3, 6, 9 months and 5 years were compared using paired *t*-test. For all the statistical tests $P < 0.05$ was considered for statistical significance. Menstrual flow and endometrial thickness were assessed at 3, 6, 9 months and 5 years. Mean ET (mm) prior to treatment was 3.3 + 1.0 which increased to 5.1+ 1.9 (P = 0.001), 5.6 + 1.5 (P = 0.001) and 6.1 + 1.7 (P = 0.001) at 3, 6 and 9 months respectively. 6 out of 7 cases presenting with secondary amenorrhea resumed menses 6 months after treatment. At the 5-year visit, only 15 patients (7 with AS and 8 with EA) showed up. EA subgroup showed improvement in Endometrial thickness in 6 of 8 cases. All 15 cases showed improvement in the endometrial cavity on 4D USG and hysteroscopy. Fertility outcomes (n=15) 2 conceived spontaneously 3 years after treatment, 1 conceived 4 years post treatment by in-vitro fertilization (IVF) with successful pregnancy outcomes (20%). 1 had an ectopic pregnancy following IVF which required salpingectomy. There were no pregnancies among untreated controls.

Limitations, reasons for caution: Small sample size (but largest amongst published literature till date) and high loss to follow up (due to a long follow up period).

No reason for caution. No adverse effects of therapy noted in any of the patients.

Wider implications of the findings:
Stem cell treatment may give new hope for infertile women with refractory Asherman syndrome and endometrial atrophy who may otherwise require surrogacy, which is facing scrutiny world over. However more robust multi centric studies are needed to validate the results.

Trial registration number: Trial was registered with CTRI - CTRI/2013/08/003896

[9]Tor Vergata University Hospital, Medical Engineering Service, Rome, Italy
[10]Tor Vergata University Hospital, Surgical Sciences Department for Integrated Activities- Section of Gynecology, Rome, Italy

Study question:
To classify RPL patients in different risk class by AI *algorithm*, through a diagnostic work-up to validate it for the appropriate prognosis and therapeutic approach.

Summary answer:
AI approach provides a *Support Decision System*tool to stratify RPL patients and address them in an objective way to the proper clinical management.

What is known already:
RPL is a very debated and controversial field for researchers and clinicians. RPL definition, etiological factors to investigate, therapies to apply are not shared by the several research groups in this field: this leads to the inability of reaching an evidence-based medicine level, through systematic reviews or metanalysis. In this line, *biomedical engineering* and AI could lead the clinicians to reach an objectiveness in RPL access to care. Furthermore, although there are several known causes for RPL, 40-50% of the cases remains unexplained, and the clinical approach to this subgroup of patients is debated.

Study design, size, duration:
Retrospective study on data collected from the "Tor Vergata University Hospital" Gynecologic Section, and analyzed by Biomedical Engineering Team of the same hospital. 677 patients were enrolled: 579 cases (RPL) and 98 controls, according to the ESHRE guidelines (2017) RPL definition. Patients were divided into 4 risk class, according to the numbers of miscarriages (I class: 0 miscarriage; II class: 1 miscarriage; III class: 2-3 miscarriages; IV class $\geq$ 4 miscarriages).

Participants/materials, setting, methods:

A *bootstrap* procedure was performed to balance the dataset risk class size: to deal with the problem of low size of control study population (since it does not undergo the specific RPL diagnostic work-up), we introduce the *bootstrap method* to balance the numbers of each class patients. This procedure was essential to apply the AI method, called *Support Vector Machine*(SVM).

Main results and the role of chance:

The *training set* is made of 42 *features*(diagnostic assays) and their corresponding *labels*(risk class), which in combination generate a model, by an *algorithm*, to use in the *testing set*. In the *testing set* each patient's *features* are introduced in input to obtain the predicted *label* in output, by using the model created. In the *testing set* each patient's result is represented as a percentage of belonging to the different risk classes and the higher percentage is assumed as the *predicted class*. By comparing the *predicted class* versus the *real class* of all patients, we have obtained a correct classification in 81,5% of cases. By applying the same method, introducing the only *features* recommended by ESHRE guidelines 2017, we obtain a correct classification in 56,5%. The method used in this study is in line with the scientific trend drawing RPL as a multifactorial disease, which could be represented by a *threshold model*. This model could help to find the correlation between different factors that cannot cause itself the disease, but that taken together lead to a *classification score* for the appropriate clinical management. The diagnostic standardization could be reinforced by the application of AI to this clinical model.

Limitations, reasons for caution:

SVM method applied prospectively in a larger population could lead to a higher percentage of correct classification. On the other, to obtain this, the diagnostic work-up applied in this study, should be extended to both sporadic and recurrent pregnancy loss couples, weighed down with the national health system finance.

Wider implications of the findings:

The AI application through a validated diagnostic-therapeutic algorithm could guarantee: an objective clinical management of RPL patients; a more appropriate communication closer to real prognosis to patients, in terms of successful subsequent pregnancy; an ultra-stratification of RPL patients in risk subclasses, generated from different combinations of etiological features groups.

Trial registration number:

Not applicable.

O-126 GM-CSF TREATMENT IN RECURRENT IMPLANTATION FAILURE WOMEN AFTER PGS: A RANDOMIZED CONTROLLED TRIAL

F. Scarpellini[1], M. Sbracia[2]

[1]*CERM, Hungaria, ROMA, Italy*
[2]*CERM, IVF Dept., Rome, Italy*

Study question:

Is GM-CSF (sargramostim) a possible treatment for recurrent implantation failure in women undergoing IVF?

Summary answer:

The clinical use of G-CSF in women experienced implantation failure may be useful

What is known already:

The GM-CSF is a cytokine promoting leukocyte growth as well as trophoblast development. We described that this cytokine may be used in the treatment of recurrent abortion.

Study design, size, duration:

The study is a randomized controlled trial conducted on 73 women with recurrent implantation failure after IVF cycles. Patients were randomly divided in two groups: one (36 women) treated with subcutaneous GM-CSF 1.5mg/kg/daily (60-100) from the day of embryo transfer to the day of b-hcg day : the control group (37 women) was treated with subcutaneous saline solution infusion in the same way of the study group.

Participants/materials, setting, methods:

The study was conducted to the CERM, Rome, Italy,, on 73 women with recurrent implantation failure after IVF cycles. Inclusion criteria were: at least 9 good embryos previously transferred, women less than 38 years old, absence of systemic diseases. These women underwent IVF cycle and PGT-A on blastocysts obtained. Single healthy blastocyst transfer was performed in the next cycle. Primary outcome was the pregnancy rate.

Main results and the role of chance:

Epidemiological data of the two groups did not show statistically significant differences. Pregnancy rate in the group treated with GM-CSF was 75.0% (27/36) whereas in the control group was 43.2% (16/37), P= 0.0087. No side effects were observed.

Limitations, reasons for caution:

The number of patients weras low and more patients are needed for definitive conclusions.

Wider implications of the findings:

These results when confirmed can offer to clinicians a valid treatment to improve IVF outcome.

Trial registration number:

NCT01718210

O-127 Does uterine natural killer (uNK) cells density predict euploid miscarriage in women with a history of recurrent miscarriage?

X. Chen[1], Y. Liu[1], W.C. Cheung[1], J.P.W. Chung[1], T. Zhang[1], Y. Zhao[1], C.C. Wang[1], T.C. Li[1]

[1]*The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong*

Study question:

Does uterine natural killer (uNK) cells density in the peri-implantation endometrium predict a subsequent miscarriage with euploid product of conception in women with a history of recurrent miscarriage (RM)?

Summary answer:

Uterine NK cells density is of prognostic value for a subsequent euploid miscarriage in women with a history of RM.

What is known already:

Previous studies have shown an increase percentage of uNK cells in the peri-implantation endometrium of non-conception cycles in women with RM. However, the predictive value of uNK cells density in the maintenance of pregnancy is controversial.

Study design, size, duration:

It is a prospective cohort study. A total of 134 women with a history of RM participated in the study from January 2015 to August 2018, of whom 75 women became pregnant following biopsy. Forty-five women had an ongoing pregnancy and the other 30 women miscarried in the subsequent pregnancy and karyotyping analysis for the product of conception was performed.

Participants/materials, setting, methods:

All the endometrial biopsies were obtained precisely 7 days after luteinizing hormone surge in non-conception natural cycles. Endometrial sections were immunostained for CD56 to identify uNK cells and cell counting was performed based on a standardized protocol. Results were expressed as percentage of CD56+ uNK cells/ total stromal cells.

Main results and the role of chance:

The median uNK cells density in women who miscarried (n=30, median 2.80%, range 1.17-8.77%) was significantly higher than those who had ongoing pregnancy (n=45, mean 1.97%, range 0.16-6.97%). The median uNK cells density in women with euploid miscarriage (n=19, median 3.57%, range 1.25-8.77%) was significantly higher than those with aneuploid miscarriage (n=11, median 2.31%, range 1.17-7.52%). In addition, the median uNK cells density in women with euploid miscarriage was significantly higher than those with ongoing pregnancy. However, there was no significant difference in uNK cells density between aneuploid miscarriage group and ongoing pregnancy group.

Limitations, reasons for caution:

The association between uNK cells density and the definitive outcome of live birth in the subsequent pregnancy has yet to be confirmed.

Wider implications of the findings:

Embryonic factor should be taken into account when investigating the association between endometrial factor and implantation failure or miscarriage in the future studies.

Trial registration number:
None.

O-128 In patients with repeated implantation failures, endometrial receptivity window turns on gradually under HRT compared to natural cycle: highlights by genomic testing

F. Entezami[1,2], D. Haouzi[2,3], C. Innocenti[3], A. Ferrieres-Hoa[2,3], C. Baron[2], C. Vincens[3], S. Bringer-Deutsch[3], E. Vintejoux[3], A. Torre[4], S. Hamamah[2,3]

[3]Hopital Arnaud de Villeneuve, Art-PGD, Montpellier, France
[4]University of Nottingham, Ob-Gyn, Nottingham, United Kingdom

Study question:
To identify the receptivity window in patients with repeated implantation failure (RIF) prepared for frozen embryo transfer under hormone replacement therapy (HRT) treatment or natural cycle.
Summary answer:
The acquisition of the endometrial receptivity phenotype is more progressive under HRT compared to natural cycle. Personalized embryo transfer improves pregnancy outcome for RIF patients.
What is known already:
Many approaches for human endometrial receptivity testing including microarray have been previously reported. Accordingly, identification of a delay of the receptivity window has been reported in repeated implantation failure patients under hormone replacement therapy. How far a delay of the receptivity window can be observed in RIF patients under natural cycle remains debated.
Study design, size, duration:
Endometrial biopsies were performed during the implantation window 7-9 days after the LH surge in natural cycle or 5-9 days after progesterone administration under HRT respectively. According to genomic testing result, the transfer strategy was: blastocysts transferred at the specific day where endometrium is identified as 'receptive' and D2/D3 cleavage stage embryos transferred 72/48 hours before the specific cycle day where endometrium is identified as 'receptive'.
Participants/materials, setting, methods:
141 RIF patients with several unsuccessful fresh and/or frozen embryo transfers were included. The number of previous failed attempts and non-implanted embryos were 4.5±2.1 and 6.6±4 respectively. Genomic testing of endometrial biopsies was performed under natural cycle or HRT. RNAs from biopsies were extracted and mRNA expression levels of specific genes predictive of endometrial receptivity were established using RT-qPCR. Clinical pregnancy was defined by visualization of a gestational sac with a positive fetal heartbeat.
Main results and the role of chance:
Analyses of endometrial receptivity status in 141 RIF patients (age 37.9± 3.8 years) revealed a strong inter-patient variability in the occurrence of the receptivity window with mostly a delay between 1 to 3 days. More precisely, biopsies were evaluated under natural cycle (n=29), natural cycle with recombinant human chorionic gonadotropin (hCG, Ovitrelle) (n=7) HRT (n=68) and HRT with GnRH analogue (Decapeptyl) (n=37). In patients evaluated under plain natural cycle, the majority were receptive at LH+8 (52%). The remaining 48% displayed receptivity equally at LH+6/+7 (24%) and LH+9 (24%). Under natural cycle with recombinant hCG, 72 % of RIF patients were receptive at hCG+9 while 14% were at hCG+6/+7 and 14 % at hCG+8. In patients under HRT, 38% and 41% were receptive at Pg+7 and Pg+8, respectively, whereas the remaining 21% were receptive before (Pg+5/+6 for 18%) or after (Pg+9 for 3%). Under HRT with GnRH analogue, the majority of RIF patients were receptive at Pg+8 (67%). Others were receptive at Pg+5/+6 (22%), Pg+7 (5%) and Pg+9 (8%). After personalized embryo transfer using the genomic testing strategy, the clinical pregnancy and live birth rates were 36.2 % and 28.4% respectively.
Limitations, reasons for caution:
The benefit of this innovative strategy should be analysed with respect to the genetic status of the transferred embryos after PGT for aneuploidy.
Wider implications of the findings:
The majority of RIF patients displayed a delay in occurrence of their receptivity window revealing a potential cause for the previous implantation failures. Personalized embryo transfer according to the specific cycle day where endometrium is 'receptive' improves clinical pregnancy and LBR in RIF patients under both HRT and natural cycle.

O-129 The impact of previous live births on peripheral and uterine natural killer cells in patients with primary and secondary recurrent miscarriage

K. Vomstein[1,2], B. Toth[1], V. Daniel[3], T. Strowitzki[2], R.J. Kuon[2]

[1]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine, Innsbruck, Austria
[2]Ruprecht-Karls University, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany
[3]Ruprecht-Karls University, Institute of Immunology- Transplantation-Immunology, Heidelberg, Germany

Study question:
To evaluate alterations in peripheral and uterine natural killer cells (pNK and uNK) in patients with primary and secondary recurrent miscarriage (pRM and sRM).
Summary answer:
The immune profile of pRM and sRM patients shows distinct differences in pNK as well as uNK cell numbers.
What is known already:
PNK and uNK cells are key players in the establishment and maintenance of pregnancy and are disturbed in patients with RM. Different immunologic risk factors have been proposed for patients with pRM (no previous live birth) and sRM (≥ 1 previous live birth). However, so far, study populations were small and results controversial. Therefore, we aimed to analyse pNK and uNK cells in a large, well defined study population.
Study design, size, duration:
Within the outpatients clinic of the University Hospital Heidelberg n=575 couples with ≥3 consecutive RM were included in this single-center prospective study between March 2012 and October 2018. Analyses were performed in the mid-luteal phase at least 3 months after the last pregnancy.
Participants/materials, setting, methods:
Subgroups consisted of n=245 pRM and n=101 sRM patients. After screening for established risk factors, n=156 idiopathic RM (iRM) were identified, including n=102 primary iRM (piRM) and n=54 secondary iRM (siRM) patients. Differences between CD45+CD3-CD56+CD16+ NK cells (analysed by FACS /µl and percentages of total lymphocytes) and CD 56+ uNK cells (analysed by immunohistochemistry; absolute numbers per mm^2) were defined as primary outcome measures.
Main results and the role of chance:
Patients with pRM and piRM showed significant higher absolute numbers and percentages of pNK cells compared to sRM and siRM patients (pRM/piRM vs sRM/siRM, mean±SD /µl: 239.1±118.7/244.9±112.9 vs 205.1±107.9/206.0±105.6, p=0.004/ p=0.009; mean±SD %: 12.4±5.5/ 12.8±5.4 vs 11.1±4.6/11.1±4.3, p=0.001; p=0.002). Only patients with siRM showed significantly higher uNK levels compared to patients with piRM (mean±SD /mm^2 288.4±239.3 vs 218.2±184.5, p=0.044). Our large cohort revealed a positive correlation between CD56+ uNK cells and CD45+CD3-CD56+CD16+ pNK cells in piRM patients (/µl: r=0.393, n=102, p<0.001; percentages: r=0.331, n=102, p<0.001). Number of miscarriages and luteal phase progesterone levels did not differ between the subgroups of RM patients. Patients with siRM had a significant higher BMI than patients with piRM. Mean age, gravidity and parity of patients were significantly higher in sRM and siRM versus pRM and piRM patients respectively.
Limitations, reasons for caution:
Differences in pNK and uNK cell numbers were analysed in patients, not in controls. However, most recently we showed differences in pNK and uNK cells between RM patients and controls. This study was therefore designed to show the specific differences of pRM and sRM patients.

Wider implications of the findings:

Differences in pNK and uNK cells in RM patients depending on previous live births might indicate distinct pathways in NK cell recruitment and potentially different underlying immune disorders between pRM and sRM.

O-130 Treatment strategies to increase the live birth rate in patients with KIR-HLA-C mismatch: a retrospective cohort study

D. Alecsandru[1], A. Guerrero[2], P. Aparicio[1], M. Romero[1], A. Barrio[3], A. Pellicer[4], J.A. Garcia Velasco[3]

[1]IVI RMA-Madrid- Spain, Department of Reproductive Immunology, Madrid, Spain
[2]Universidad de Valencia, Universidad de Valencia, Valencia, Spain
[3]IVI RMA-Madrid- Spain, Department of Reproductive Endocrinology and Infertility, Madrid, Spain
[4]IVIRMA Rome, Department of Reproductive Endocrinology and Infertility, Rome, Italy

Study question:

Does the selection of HLA-C1C1 oocyte donor or the administration of granulocyte colony-stimulating factor (G-CSF) improve the live birth rate/cycle in couples with KIR-HLA-C mismatch?

Summary answer:

The selection of HLA-C1C1 oocyte donors improves live birth rate (LBR) compared to random HLA-C donors or to G-CSF administration in couples with KIR-HLA-C mismatch.

What is known already:

Increased risk of recurrent miscarriage (RM), preeclampsia, and fetal growth restriction has described in KIR AA mothers when the fetus has more HLA-C2 genes than the mother, and this HLA-C2 are paternally or egg donor inherited. In ART oocyte donor cycles, oocyte HLA-C behaves as the paternal HLA-C and KIR-HLA-C combination is not currently taken into consideration on donors' selection. KIRAA women have lower live birth rates (LBR) after double embryo transfer (DET) in egg-donation ART cycles especially when the embryo carries HLA-C2. G-CSF administration seems to improve the LBR in patients with recurrent miscarriages lacking activating KIR.

Study design, size, duration:

Between January 2017 and December 2018, we performed a retrospective study that included 72 women whose RM/RIF were of unknown etiology and 261 embryo transfers (ET). All couples had KIR-HLA-C mismatch: maternal KIR AA and paternal HLA-C2. All the patients underwent egg donation. Forty-five couples (group 1) had 135 ETs (70% SET and 30% DET) and 27 couples (group 2) had 126 ETs (83% SET and 27% DET).

Participants/materials, setting, methods:

All the patients were selected from IVI RMA Clinics. Group 1 had 90 ETs with random HLA-C egg donor and 45 SET with HLA-C1C1 egg donor. Group 2 had 99 ETs with random HLA-C egg donor and 27 SET with HLA-C1C2/C2C2 egg donors and G-CSF administration. We performed genetic typing for maternal KIR and paternal and oocyte donors HLA-C. Pregnancy, miscarriage and LBR/transfer have studied by groups and cycles. Fisher test has used.

Main results and the role of chance:

The median age of our patients was 40 years, and 25 years for oocyte donors. In our cohort, all women had KIR AA and their partners HLA-C2.

A higher LBR/cycle was observed in group 1 when their HLA-C1C1 egg donor cycle (48.89%) was compared to the previous random HLA-C egg donor cycles (5.77%) (OR 42.82).

A higher LBR/cycle was observed in the group 2 when compared the cycles using G-CSF administration (14.81%) and their previous random HLA-C egg donor cycles (6.38%) (OR 6.86).

Higher LBR/cycle was observed in HLA-C1C1 egg donor cycles - group 1 (48.89%) when compared to HLA-C1C2/C2C2 egg donors and G-CSF administration cycles -group 2 (14.29%) (OR 6.82, $p<0.002$).

A higher pregnancy rate was observed in group 1 when compared their HLA-C1C1 egg donor cycles (80%) to HLA-C1C2/C2C2 egg donors and G-CSF administration cycles -group 2 (24.44%) (OR 3.8, $p<0.01$).

We did not observe any differences on miscarriage rates between both groups (C1C1 egg donor 13.33% and G-CSF 17.86%).

Limitations, reasons for caution:

Our sample was small and this is the first report to observe differences in LBR by oocyte donor/embryo HLA-C or C-GSF administration in KIR AA mothers with embryos HLA-C2 and egg donation. However, apart from statistical significance, the association strength was noticeably high, which confers our findings more confidence.

Wider implications of the findings:

We speculate that completing a normal pregnancy is posible only for those KIR AA mothers who carry a baby with a least one non-self HLA-C1. Therefore, selecting HLA-C1C1 amongst oocyte donors for KIR-HLA-C mismatch couples could improve the LBR compared to random HLA-C egg donors or the G-CSF administration.

Tuesday 25 June 2019 Haydn 4 10:00 - 11:30

O-131 Fertility in female cancer survivors: a systematic review and meta-analysis

A. Busnelli [1], A. Vitagliano [2], L. Mensi [3], F. Filippi [3], E. Somigliana [3]

[1]University of Milan, Clinical sciences and community health, Milano, Italy
[2]University of Padua- Padua- Italy, Obstetrics and Gynaecology Unit- Department of Women and Children's Health-, Padua, Italy
[3]Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Obstet Gynecol, Milan, Italy

Study question:

What are the chances of female survivors of different types of cancer to fulfil their reproductive desire?

Summary answer:

Bone, breast, brain and kidney cancer survivors have reduced chances of childbirth. Women with thyroid cancer, melanoma and Non Hodgkin lymphoma can be reassured.

What is known already:

Several epidemiological studies investigated the effects of cancer therapies on fertility considering the chances of pregnancy and childbirth as primary outcomes. However, conflicting data have been reported for the different cancer sites and a global interpretation of the results is not possible due to the different weight of the individual studies. In the absence of a data synthesis, at present, it is therefore not possible to provide an accurate counselling to patients on the fertility damage of oncological treatments and to share decisions regarding fertility preservation options.

Study design, size, duration:

The present systematic review and meta-analysis was restricted to published research articles that investigated the chances of pregnancy or live birth in women after treatment of different types of cancer (i.e. leukaemia, breast cancer, Hodgkin lymphoma, Non Hodgkin lymphoma, brain cancer, soft tissue cancer, liver cancer, digestive tract cancer, kidney cancer, thyroid cancer). We systematically searched Pubmed, MEDLINE, Embase and Scopus, from database inception to January 15, 2019. The study is registered with PROSPERO (CRD42019119786).

Participants/materials, setting, methods:

The literature overview was reported according to the PRISMA guidelines. Published cohort, case-control and cross-sectional studies were eligible for inclusion. All pertinent articles were retrieved, and the relative reference lists were reviewed. Studies were excluded if: (i) crude or adjusted effect estimates with corresponding 95%CIs or results allowing their calculation were not reported, (ii) control population was not clearly defined. The quality of case-control and cohort studies was evaluated by means of the Newcastle-Ottawa scale.

Main results and the role of chance:

Our searches identified 41 non-duplicate records, of which 18 relevant studies were included in the qualitative and quantitative analysis. Childbirth chances resulted significantly reduced in women with a history of bone cancer (HR 0.86, 95%CI[0.77-0.97]; I^2=0%; p=0.02; RaR 0.76, 95%CI[0.61-0.95]; I^2=69%; p=0.01), breast cancer (HR 0.74, 95%CI[0.61-0.91]; RaR 0.51, 95%CI[0.47-0.57]; I^2=0%; p<0.00001), brain cancer (HR 0.61, 95%CI[0.53-0.70]; I^2=14%; p<0.00001; RaR 0.44, 95%CI[0.33-0.60]; I^2=95%; p<0.00001; OR 0.49, 95%[0.40-0.60; RR 0.62; 95%CI [0.42-0.91]; p=0.02) and kidney cancer (RaR 0.69, 95%CI[0.61-0.78]; p<0.00001; RR 0.66; 95%CI [0.43-0.98]; p=0.04). Data pooling showed conflicting results in soft tissue cancer, Hodgkin lymphoma, and leukaemia patients. Reproductive chances in women survived from Non Hodgkin lymphoma, melanoma and thyroid cancer resulted unaffected.

Limitations, reasons for caution:

Most of the studies did not report detailed information on the characteristics of the oncologic treatments. Possible lurking variables should also be considered. In fact, physical and psychological sequelae of such aggressive therapies may affect the relationship life confounding the association between cancer or cancer treatment and fertility.

Wider implications of the findings:

WomNNen are currently informed providing data on the chemotherapy effects on poorly reliable fertility markers and on the reproductive chances cumulatively calculated for many cancer sites. Estimates by type of cancer are therefore of utmost importance to counsel patients and to assess the risk-benefit ratio before starting fertility preservation programs.

O-132 In Vitro Maturation Rates in Young Pre-Menarche Patients

N. Schachter - Safrai[1], G. Karavani[1], A. Revel[1], D. Bauman[1], T. Imbar[1]

[1]Hadassah Medical Center- Jerusalem, Obstetrics and Gynecology, Jerusalem, Israel

Study question:

To evaluate oocyte retrieval rates and in vitro maturation (IVM) efficacy following ovarian tissue cryopreservation (OTC) in young pre-menarche girls facing chemo-radiotherapy.

Summary answer:

IVM performed following OTC in pre-menarche girls and specifically in very young girls (under 5 years) yields substantially decreased maturation rates compared with post-menarche patients.

What is known already:

As childhood cancer survival rates improve, ovarian cortex harvesting and cryopreservation became an ancillary standard procedure of fertility preservation prior to gonadotoxic treatment. Immature oocyte can be found during ovarian tissue handling and the ability to mature them in vitro and cryopreserve them as mature oocytes, provides additional option of fertility preservation. Recent studies showing outcomes of IVM in children demonstrated retrieval and maturation of oocytes even in the pre- pubertal age. However, these studies investigated only a small group of pre-pubertal patients and included mixed population of both chemotherapy naive and exposed patients.

Study design, size, duration:

This is a retrospective cohort study which included a total of 84 chemotherapy naïve patients aged 0-18 years referred for fertility preservation between 2004 and 2017. Of them, 33 were pre-menarche and 51 were post-menarche.

Participants/materials, setting, methods:

A comparison was made between the pre- menarche and post-menarche patients with regard to OTC and IVM outcomes. Additionally, a correlation between age and OTC and IVM outcomes was performed in the pre- menarche group. This group was later divided into two age groups: 0-4 years and 5-10 years. A further analysis was aimed to evaluate the differences between the very young patients and the older pre-menarche patients regarding IVM outcomes.

Main results and the role of chance:

Number of oocytes retrieved did not significantly differ between the post-menarche and pre-menarche groups (10.8±8.5 and 8.1±6.8, respectively). However, the overall in vitro maturation rate was significantly higher in the post-menarche group (28.2% vs. 15.5%, respectively; p<0.001, OR=0.47). A separate analysis for patients up to 4 years of age demonstrated significantly less oocyte yield compared with the older (5-10 years) pre-menarche girls (4.7±5.2 vs.10.3±7.0 oocytes, respectively; p=0.02) and much lower IVM rates (4.9% and 18.2% respectively, p=0.02). Correlation of age with number of retrieved and matured oocytes showed a positive significant correlation (r=0.45 and r=0.64, respectively; p<0.05 for both).

Limitations, reasons for caution:

This is a retrospective study with a limited sample size, as such, it is more prone to selection bias. No routine assessment of the ovarian reserve before or after OTC was performed. Finally, the clinical utility of the IVM procedure in the pre- menarche group is yet unknown.

Wider implications of the findings:

Our cohort of chemotherapy naïve pre-menarche patients undergoing IVM is the largest published so far. As previously described on smaller groups of pre-menarche patients, we demonstrated that IVM is feasible in these patients although in a significantly lower yield of retrieved oocytes and in vitro maturation rate of these oocytes.

Trial registration number:

O-133 Short exposure to low-dose rapamycin reduces the negative impact of PTEN inhibition on DNA damage response but maintains follicle growth activation in bovine cortical strips

M. Maidarti[1,2,3], Y.L. Clarkson[2], M. McLaughlin[2], R.A. Anderson[1], E.E. Telfer[2]

[1]MRC Centre for Reproductive Health- Queen's Medical Research Institute, University of Edinburgh, Edinburgh, United Kingdom

[2]Institute of Cell Biology and Genes and Development Group- CDBS- Hugh Robson Building, University of Edinburgh, Edinburgh, United Kingdom

[3]Reproductive Endocrinology Infertility Division- Obstetric and Gynecology Department- Faculty of Medicine, University of Indonesia, Jakarta, Indonesia

Study question:

Does pharmacological inhibition of mTOR (mammalian target of rapamycin) by rapamycin, modify the defective DNA damage response following PTEN inhibition whilst promoting follicle growth activation?

Summary answer:

Ovarian strips exposed to bpv(HOpic) and rapamycin show increased follicle activation and significantly reduced negative effects on DNA damage response observed with bpv(Hopic) alone.

What is known already:

Modulation of phosphoinositide 3-kinase (PI3K)/Akt/mTOR signalling pathway determines the balance between activation and inhibition of primordial follicle growth. Inhibition of phosphatase and tensin homolog (PTEN) is known to activate primordial follicles but may compromise further developmental potential, with oocytes showing increased DNA damage and reduced DNA repair functions. A recent study showed that modulation of the activation rate by inhibiting mTOR1 may improve the quality of *in vitro* activated follicles. We hypothesised that combined inhibition of PTEN and mTOR to modulate *in vitro* activation of follicles may improve DNA damage response of follicles *in vitro*.

Study design, size, duration:

Bovine ovarian fragments (4x2x1mm) were cultured for 24 hours in medium containing either: 1) PTEN inhibitor, 1μM bpv(HOpic), 2) 1μM bpv(HOpic)+0.1nM rapamycin or 3) vehicle control (0.001% DMSO), then incubated for a further 5 days in control medium. Cultured fragments were fixed and analysed by immunohistochemistry and immunofluorescence to determine follicle activation and expression of markers reflecting DNA damage and repair mechanisms. 116 ovarian cortical strips and 12,242 follicles from four independent experiments were analysed.

Participants/materials, setting, methods:

Cortical fragments of bovine ovaries were prepared for culture. After a total of 6 days in culture, fragments were fixed and analysed histologically. Immunostaining for: 1) nuclear exclusion of Forkhead Box O3 (FOXO3) as a marker of follicle activation 2) γH2AX as a marker of DNA damage; 3) DNA repair factors: meiotic recombination 11 (MRE11), Ataxia telangiectasia

mutated (ATM), Breast cancer susceptibility gene 1 (BRCA1), Breast cancer susceptibility gene 2 (BRCA2) and Rad51.

Main results and the role of chance:

Tissue exposed to 1μM bpv(HOpic) or 1μM bpv(HOpic)+0.1nM rapamycin contained a higher proportion of growing follicles (81.9% and 70.2%) compared to control (57%) ($p \leq 0.001$). In the bpv(HOpic) only group, increased growth was associated with increased nuclear exclusion of FOXO3 and increased γH2AX expression in oocytes of non-growing and primary follicles (80.0% and 64.5%) compared to control (20% and 17.0%)($p<0.05$). γH2AX expression in oocytes was reduced with the addition of rapamycin (23.0% and 29.5%) ($p \leq 0.001$). The mean percentage of granulosa cells per follicle expressing γH2AX was higher in bpv(HOpic) treated growing follicles (16.0±1.1%) compared to control (0.48±0.19%)($p=0.03$) and was significantly reduced with the addition of rapamycin (1.4±1.3%)($p=0.01$). MRE11, ATM and Rad51 expression was lower in oocytes of primary follicles in bpv(HOpic) (69.5%, 30.1% and 31.3% respectively) compared to control (88.0%,$p \leq 0.001$; 65.0%,$p=0.014$; and 74.0%,$p \leq 0.001$) but increased in rapamycin+bpv(HOpic) (85.7%,$p=0.033$; 65.3%,$p \leq 0.001$; 49.3%,$p=0.007$). Neither bpv(HOpic) (13.5%;63.0%) or bpv(HOpic)+rapamycin (8.0%;56%) affected BRCA1 and BRCA2 expression in oocytes of primary follicles compared to control (5.7%, 44.0%)($p>0.05$). Expression of MRE11, BRCA1, BRCA2 and Rad51 in granulosa cells of growing follicles showed no significant differences between any treatments ($p>0.05$). ATM expression decreased in granulosa cells exposed to bpv(HOpic) (72.1±4.6%) compared to control (91.8±2.6%) and rapamycin+bpv(HOpic) group (90.4±2.4)($p<0.05$).

Limitations, reasons for caution:

This study is limited to primordial follicle activation and implications for later stages of follicle development have not been assessed. While the bovine ovary is a good large mammalian mono-ovulatory model for the human, it may not recapitulate all aspects.

Wider implications of the findings:

A more controlled increase in follicle activation may preserve bidirectional signalling between oocyte and granulosa cells. This model may be useful to provide additional insights into DNA damage response prior to their use in human ovaries, which may subsequently lead to improvements in systems that support *in vitro* follicle growth.

Trial registration number:

Not applicable.

O-134 In vivo imaging of human primordial follicles and growing follicles by new optical coherence tomography (OCT)

R. Zhang[1], T.S.M. Law[2], J.P.W. Chung[2], T.C. Li[2], C.C. Wang[2]

[1]*Chinese University of Hong Kong, Obstetrics and Gynecology, Hong Kong, Hong Kong*

[2]*Prince of Wales Hospital, Obstetrics and Gynecology, Hong Kong, Hong Kong*

Study question:

Can primordial follicles and growing follicles be identified and measured by OCT in vivo?

Summary answer:

Human primordial follicles and growing follicles can be identified and measured by the new OCT imaging system in cooperate with endoscopy in vivo.

What is known already:

Optical Coherence Tomography (OCT) is a non-invasive imaging technique with resolution 100 times higher than ultrasound. OCT can detect tissue structure down to micrometer scale and the depth of detection is up to 3mm. OCT technology has been widely used mainly in/through surface organs, such as ophthalmology and dermatology. Recently a report used OCT to assess localization of primordial follicles in ovarian tissue using non-fixed ex vivo human ovary sections that had been cryopreserved for fertility preservation due to premature ovarian insufficiency for treatment of hematological disease or cancer. In vivo OCT imaging of ovary has never been reported.

Study design, size, duration:

New OCT imaging system (OCTISTM) with newly designed catheter-based rotational and pullback optical probes and improved OCT technologies were used in animal experiment in vitro and also in in human study incorporate with laparoscopy in vivo.Prospective observation study of animal experiments in vitro and human studies in vivo. 5 animals and 10 human subjects between Oct 2018 and Oct 2019 will be recruited for the study.

Participants/materials, setting, methods:

To test the detection and accuracy of OCTISTM, pig ovaries were excised and examined by OCTISTM. 3D reconstruction was employed to examine the spatial distribution of follicles in ovary. To evaluate the accessibility and sensitivity of OCTISTM, human ovaries undergoing laparoscopic ovarian surgery (such as ovarian drilling, cystectomy, oophorectomy) were examined by OCT before the surgery. The corresponding tissue sections were prepared for histological examination and comparison.

Main results and the role of chance:

Follicles at different size were clearly identified and accurately measured by the OCTISTM in pig ovaries in vitro. Size and distribution of follicles in the ovary can be reconstructed in 3D imaging. In human subjects, primordial follicles and growing follicles can be observed in vivo through laparoscopic surgery and after laparoscopic ovarian drilling. The OCTISTM probe can be immobilized inside the ovary to obtain full images closer to the ovarian cortex and closer to the primordial follicle in vivo. Distribution of the primitive follicles can be imaged easily in the cortex of the ovary. However, the OCTISTM probe is not easily fixed on the surface of ovary in vivo, so quality of the OCT image is not as good as reported in vitro.

Limitations, reasons for caution:

OCT penetration is still limited. OCTISTM imaging depth is up to 3mm, so it is suitable for superficial imaging of organs. As human ovarian capsule and cortex are thick, we can only detect follicles close to ovary surface, but cannot detect the follicles in the deeper part of the cortex.

Wider implications of the findings:

We can assess the location of primordial follicles by minimally/non-invasive, real-time, high-resolution, cross-sectional, and potentially microscopic structural OCTISTM imaging in vivo through laparoscopic surgery. Our experiment indicated that OCT may help select the most reproductive ovarian tissue for in-vitro activation (IVA) and ovarian tissue transplantation, thus potentially better pregnancy outcome.

Trial registration number:

CREC 2016.160-T

O-135 Outcomes from heterotopic and orthotopic grafting of human cryopreserved ovarian tissue.

D. Gook[1], L. Hale[2], A. Polyokov[2], K. Stern[1]

[1]*The Women's Hospital, Reproductive Services /Melbourne IVF, Parkville- Victoria, Australia*

[2]*Melbourne IVF, Melbourne IVF, East Melbourne, Australia*

Study question:

Is the outcome from ovarian tissue grafted at a heterotopic site similar to that grafted at an orthotopic site?

Summary answer:

Similar outcomes in terms of number of oocytes recovered, number mature, proportion of fertilized oocytes which cleave (day 2), was observed with both graft sites.

What is known already:

Over 120 live births have been reported from cryopreservation of ovarian tissue and subsequent grafting. In the majority of these, tissue was grafted into the remaining ovary (orthotopic site). Although heterotopic grafting to a non ovarian, non pelvic site (e.g. abdominal) has also resulted in births, it has been suggested that compromised outcomes may be expected from a non-pelvic site.

Study design, size, duration:

The aim of the study was to assess the outcome from cryopreserved ovarian tissue grafted to heterotopic (abdominal) or orthotopic (pelvic) sites. Ovarian tissue was slow frozen using the cryoprotectants propanediol and sucrose (n=17 women) or using DMSO and sucrose (n=1 women). Tissue was thawed appropriately and prepared on 6.0 vicryl sutures for grafting. Tissue was placed laparoscopically into an abdominal pocket and a pelvic side wall pocket close to the ovary.

Participants/materials, setting, methods:

Following resumption of cycling, gonadotrophin stimulation commenced with FSH, LH and antagonist and a trigger was given when one follicle was >13 mm in diameter. Abdominal follicles (heterotopic) were aspirated under abdominal

ultrasound guidance; ovarian and pelvic follicles were aspirated transvaginally. Due to an inability to distinguish under ultrasound between pelvic and ovarian follicles, both were classified as orthotopic.

Main results and the role of chance:

Age at time of grafting was generally 6 years older than at time of cryopreservation. Resumption of cycling occurred on average 3.5 months post grafting regardless of graft site. Mean follicle diameter was 14 mm for both sites. Aspiration failed to retrieve an oocyte in 29.8% (31/104) of heterotopic and 33.3% (48/144) of orthotopic follicles. A similar proportion of retrieved oocytes were mature in both sites [66.7% (44/66) heterotopic, 63.5% (54/85) orthotopic]. The proportion of embryos which developed on day 2 from those fertilized was also similar in both groups [88.9% (32/36) heterotopic, 86.5% (32/36) orthotopic]. This is the first reported in house comparison of outcomes from ovarian tissue grafted to heterotopic (abdominal) and orthotopic (pelvic) sites.

Limitations, reasons for caution:

Study reports outcomes from a small number of women following grafting. Follicle density and amount of tissue grafted varies between patients. Outcomes from orthotopic grafting may be biased by the inclusion of non-ovarian grafts ie pelvic side wall.

Wider implications of the findings:

Preliminary data suggests that the outcomes assessed are similar from the heterotopic and orthotopic graft sites and that an abdominal site is a suitable site for ovarian grafting.

not applicable

O-136 Improving Autologous Ovarian Transplantation Outcomes with Robotic Surgery and the Utility of a Neovascularizing Human Extracellular Matrix (ECM) Scaffold

K.H. Oktay[1,2], G. Bedoschi[3], T. Kawahara[1,4], L. Marin[1,5], Y. Sugisihita[1,4], E. Taylan[1], L. Ursillo[2]

[2]*NYU Winthrop Hospital, Department of Obstetrics and Gynecology, Mineola, U.S.A.*

[3]*Universidade de São Paulo, Faculdade de Medicina de Ribeirao Preto, Ribeirão Preto, Brazil*

[4]*St. Marianna University School of Medicine, Department of Obstetrics and Gynecology, Kawasaki, Japan*

[5]*University of Padua School of Medicine, Department of Woman's and Child's Health, Padua, Italy*

Study question:

Can Autologous Cryopreserved Ovarian Tissue Transplantation (ACOTT) outcomes be improved with the utility of robotic surgery and neovascularizing ECM scaffold combined with peri-operative pharmacological support?

Summary answer:

The robotic ACOTT technique with the use of ECM scaffold and peri-operative pharmacological support leads to higher rates of ovarian function restoration then previously reported.

What is known already:

First successful case of ACOTT was reported in 2000. The procedure has resulted in over hundred livebirths since then. However, a major rate-limiting factor for this procedure is the initial ischemia following grafting, resulting in significant primordial follicle loss. As a result, according to a recent meta-analysis, only about one out of three women has had a child after ACOTT and the average longevity of the grafts is approximately 3 years. We developed a robot-assisted technique combined with the use of a neovascularizing ECM and peri-operative pharmacological support to improve ACOTT outcomes.

Study design, size, duration:

Six women underwent laparoscopic ovarian cortical tissue cryopreservation before or shortly after initiating gonadotoxic treatments in a prospective study. These women then underwent robot-assisted laparoscopic ACOTT 7-12 years following ovarian tissue cryopreservation.

Participants/materials, setting, methods:

Inclusion criteria were: cryopreservation with slow freezing, ovarian failure caused by gonadotoxic treatments (chemo and/or radiation therapy), peri-operative pharmacological support (transdermal estrogen 4 weeks prior and post-op and baby aspirin 10 days prior), robot assisted ACOTT by single surgeon, utility of ECM scaffold (Alloderm, regenerated human cadaver skin with neovascularizing effects), and a minimum of 1 year follow up. Receiving gonadotoxic treatment before tissue harvesting was not an exclusion criterion.

Main results and the role of chance:

The amount of transplanted tissue was based on the pre-transplant follicle density assessment and varied from 50-70 % of cortex from one ovary. Patients were perioperatively treated with transdermal estrogen and low dose aspirin to enhance recipient site vascularization. Tissues were sutured on the ECM prior to grafting onto the bivalved remaining ovary in 4 cases, onto mesosalpinx in one and retroperitoneally in lower abdomen in the other. Ovarian function returned 13.9±2.7 weeks (range 11-16.2) after transplantation with a mean duration of function 34.2±17.7 months (14-67) at the time of this report. Endocrine function and follicle development rates were 100%. Oocytes were retrieved from all patients. One patient dropped out after cryopreserving one oocyte. In remaining 4 patients, multiple embryos were generated (8.2± 3.4 per case, range 3-12). Two of those women had two livebirths each, while remaining two had two (+1 pending PGT-A result) and six euploid embryos cryopreserved for future embryo transfer. In the case of heterotopic ovarian transplantation, embryo quality was consistently poor, not resulting in blastocyst formation.

Limitations, reasons for caution:

Although our findings suggest that robotic assisted orthotopic ACOTT technique with the use of ECM scaffold and perioperative pharmacological support leads to high fertility and endocrine function restoration rates than previously reported, larger studies are needed to strengthen this conclusion.

Wider implications of the findings:

Robot-assisted orthotopic ACOTT results in 100% success based on endocrine function, follicle development, livebirths and/or euploid embryo development even when ovarian tissue was cryopreserved after chemotherapy exposure. On the other hand, egg quality seems to be impaired with heterotopic ACOTT which has also been an observation with previous techniques.

SESSION 39: CLINICAL RESEARCH IN ENDOMETRIOSIS AND ENDOMETRIUM: FROM DIAGNOSIS TO TREATMENT AND PREVENTION

Tuesday 25 June 2019 Strauss 1+2 10:00 - 11:30

O-137 Bidimensional rectal-water contrast-transvaginal ultrasonography (2D-RWC-TVS) versus 3D-RWC-TVS in the diagnosis of rectosigmoid endometriosis: a pilot prospective comparative study

F. Barra[1], C. Scala[1], V.G. Vellone[2], S. Ferrero[1]

[1]*IRCCS Ospedale Policlinico San Martino- University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy*

[2]*IRCCS Ospedale Policlinico San Martino- University of Genoa, Department of Surgical and Diagnostic Sciences, Genoa, Italy*

Study question:

This study aims to compare the performance of bidimensional rectal-water contrast-transvaginal ultrasonography (2D-RWC-TVS) with 3D-RWC-TVS for diagnosing the presence of rectosigmoid endometriosis.

Summary answer:

Despite of being both feasible and well tolerated, 3D acquisitions do not seem to improve the performance of RWC-TVS for the diagnosis of rectosigmoid endometriosis.

What is known already:

An accurate diagnosis of the presence, location and extent of the rectosigmoid endometriosis is of paramount importance for the clinicians in order to inform the patients on the potential surgical or medical treatments. It is well established that TVS is the first-line investigation in patients with suspicion of

deep infiltrating endometriosis and improvement in the performance of TVS in diagnosing rectosigmoid endometriosis may be obtained by RWC-TVS.

Study design, size, duration:

This pilot prospective comparative study was performed between January 2018 and December 2018, including 36 women of reproductive age who were referred to our institution because pain symptoms and intestinal complaints suggestive of rectosigmoid endometriosis. Exclusion criteria for the study were previous surgical or radiological diagnosis of rectosigmoid endometriosis.

Participants/materials, setting, methods:

2D-RWC-TVS was performed at the time of the first consultation at our institution. A flexible catheter was introduced into the rectal lumen in order to injected up to 300 mL of sterile saline solution. Patients underwent a second evaluation by 3D-TVS in the same consultation by a physician blinded to the findings of the first exam. The results of the two exams were compared with surgical findings and histology.

Main results and the role of chance:

The mean (± SD) age of the study population was 33.6±5.2 years. At the time of the study, 20 women (55.5%) were under hormonal therapies. 21 patients (61.1%) had rectosigmoid endometriosis at surgery. The McNemar's test demonstrated that 3D-RWC-TVS and 2D-RWC-TVS had similar performance in the diagnosis of rectosigmoid endometriosis (p=0.50). The sensitivity, specificity, positive predictive value, negative predictive value, positive likelihood ratio and negative likelihood ratio of 2D-RWC-TVS and 3D-RWC-TVS were respectively 90.1% (95% CI, 70.8%-98.9%), 78.6% (49.2%-95.3%), 87.0% (70.8%-94.8%), 84.6% (58.8%-95.5%), 4.2 (1.5-11.7), 0.1 (0.0-0.4) and 86.4% (65.1%-97.1%), 85.7% (57.2%-98.2%), 90.5% (72.3%-97.1%), 80.0% (57.8%-92.1%), 6.1 (1.7-22.1), 0.2 (0.1-0.5). Overall, there was no significant difference in the accuracy of 2D-RWC-TVS and 3D-RWC-TVS in estimating the volume of the largest intestinal nodule (P=0.524) and in estimating the distance between the lower endometriotic bowel nodule and the anus (P=0.860).

Limitations, reasons for caution:

The limitations of this study are the small sample size and that the surgeons were aware of the findings of 2D and RWC-TVS.

Wider implications of the findings:

Despite of being both feasible and well tolerated, 3D acquisitions do not seem to improve the performance of RWC-TVS for diagnosing rectosigmoid endometriosis.

O-138 The IDEAL study: MRI for suspected deep endometriosis assessment prior to laparoscopy is equally reliable as radiological imaging as a complement to transvaginal ultrasonography

D. Bielen[1], L. De Wever[1], D. Vanbeckevoort[1], D. Van Schoubrouck[2], C. Tomassetti[2]

[1]University Hospitals Leuven, Radiology, Leuven, Belgium
[2]University Hospitals Leuven, Gynaecology, Leuven, Belgium

Study question:

Can a 'one-stop' abdominal MRI (magnetic resonance imaging) replace ionizing radiological imaging (urography plus barium-enema) in the preoperative work-up of suspected deep endometriosis (DE)?

Summary answer:

'One-stop' MRI plus transvaginal ultrasound (TV-US) predicts intra-operative findings equally well as compared to standard radiological imaging plus TV-US.

What is known already:

When planning surgery for suspected DE, guidelines emphasize the importance of assessing the extent of involvement of ureter, bladder and bowel. Whereas several techniques are available (e.g. double-contrast barium-enema (DCBE), TV-US, trans-rectal ultrasonography, MRI, intra-venous pyelography (IVU), there is no current guidance on which type of technique is more adequate. In our institution, standard work-up has since long included the combination of TV-US, IVU and DCBE. Although the radiological techniques clearly have the disadvantage of ionizing radiation exposure, so far it is not well established whether they can be replaced reliably by an MRI for (pre-)operative patient-counselling and planning.

Study design, size, duration:

Single-centre prospective study, between 20/2/2014 and 23/11/2015, including 120 women who underwent TV-US, IVU, DCBE and MRI. The sample size was based on the presumed accuracy for DCBE (75%) and MRI (85%). Both standard (TV-US with IVU/DCBE) and MRI-based imaging (TV-US with MRI) were compared with the laparoscopic findings and the extent of the surgery (multidisciplinary or not). Radiologists performing the DCBE, IVU and MRI were blinded; MRI-results were unblinded at the end of surgery.

Participants/materials, setting, methods:

120 women with suspected DE in a tertiary referral centre, with an presumed indication for excisional surgery, received standardized hormonal treatment (nomegestrol acetate) for at least 4 weeks prior to their work-up which was planned in a 2-week timeframe. Work-up included TV-US, DCBE, IVU and contrast-enhanced abdominal MRI.

All MRI scans were performed on a 1.5 Tesla scanner with vaginal and rectal opacification to obtain adequate distention and delineation of the vaginal and rectal wall.

Main results and the role of chance:

Imaging and surgical data of 74/120 women were available for analysis. Both the standard work-up as the MRI-based work-up predicted correctly whether surgery eventually was mono- or multidisciplinary in 90.5% of the women (67/74).

In both approaches, the severity of the rectal involvement was underestimated in 2.7% (2/74), whereas it was overestimated in 6.8% (5/74) of the patients; in 2 different patients with obvious DIE lesions findings were false negative due to a perceptual error on DCBE, and incomplete bowel filling on MRI. Both lesions were located at a distance > 15 cm from the internal anal orifice.

The overall assessment of the involvement of the bowel wall, gynaecological structures, bladder and ureters was correct in 50/74 patients (67,6%) for the standard preoperative imaging, as compared to in 64/74 patients (86,5%) for the MRI-based work-up (absolute difference between of 18,9% (3,2% to 33,7% CI 95%) (p-value 0,02)).

In one patient, a deep lesion on the diaphragm was only detected by MRI-based work-up and confirmed laparoscopically. Four lesions were not detected on any preoperative work-up, but only during surgery: involvement of the ischioanal fossa (n=1), small intestine (n=2), and abdominal wall (n=1).

Limitations, reasons for caution:

Due to symptom improvements, or failure to comply with the study prerequisites, 46/120 patients didn't undergo all exams and/or surgery.

Significant delay between preoperative work-up and time of surgery (mean 327 days) may have an negative effect, but this is applicable to all techniques.

Wider implications of the findings:

MRI shows the direct DIE signs and its consequences on the surrounding tissues, especially the involvement of the organs that tend to escape routine evaluation, e.g. the small bowel, diaphragm or abdominal wall, without any ionizing radiation. Better bowel filling and MR hydrogram without contrast may further improve the technique.

Trial registration number:

The study was registered on ClinicalTrials.gov, a service of the U.S. National Institutes of Health, with identifier NCT01939535 'Preoperative staging of endometriosis with MRI (IDEAL)'.

O-139 Association between disease extent and pain symptoms in patients with deep infiltrating endometriosis (DIE)

E. Montanari[1,2], B. Dauser[3], J. Keckstein[4,5], E. Kirchner[1], Z. Nemeth[1], G. Hudelist[1,5]

[1]Hospital St. John of God- Vienna, Department of Gynecology, Vienna, Austria
[2]Medical University of Vienna, Department of Obstetrics and Gynecology, Vienna, Austria
[3]Hospital St. John of God- Vienna, Department of General Surgery, Vienna, Austria
[4]Gynecological Clinic Drs Keckstein, Gynecological Clinic Drs Keckstein, Villach, Austria
[5]Stiftung Endometrioseforschung SEF, Stiftung Endometrioseforschung SEF, Westerstede, Germany

Study question:

The aim of this study was to assess associations between preoperative symptoms in patients with deep infiltrating endometriosis (DIE) and the intraoperatively determined disease extent described by the ENZIAN score.

Summary answer:

Disease localization and extent as described by the ENZIAN score correlated with presence and severity of different preoperative symptoms.

What is known already:

The revised American Society for Reproductive Medicine (rASRM) score is the currently most widely used classification system for endometriotic lesions. However, deep infiltrating endometriosis (DIE) is not fully taken into account and disease extent shows only a poor correlation with pain and sterility.

In order to describe DIE more accurately, the ENZIAN classification was developed in addition to the rASRM score and was revised in 2010 and 2011. Up to now, there were only very limited data available on the association between anatomical extent of DIE as described by the ENZIAN score and symptoms such as dysmenorrhea, dyspareunia, dysuria or dyschezia.

Study design, size, duration:

This study was a retrospective data analysis of prospectively collected data of 245 women who underwent surgery for deep infiltrating endometriosis between 2014 and 2018 at a tertiary referral center for endometriosis.

Participants/materials, setting, methods:

Data of women who underwent surgery for deep infiltrating endometriosis between 2014 and 2018 at a tertiary referral center for endometriosis were analysed. Possible associations between presence and severity of different preoperative symptoms such as dysmenorrhea, dyspareunia, dysuria and dyschezia and the intraoperatively determined disease extent as described by the ENZIAN score were assessed.

Main results and the role of chance:

Data of 245 women were analysed. Statistically significant associations between involvement of ENZIAN compartment B (uterosacral ligaments, parametrium) and presence of dyspareunia (p=0.002), ENZIAN compartment C (rectum, sigmoid colon) and dyschezia (p <0.001) and ENZIAN compartment FB (urinary bladder) and dysuria (p <0.001, Fisher's exact test) were found. Statistically significant correlations were also detected between symptom severity of dyschezia and lesion size in ENZIAN compartment C (Spearman's correlation coefficient: 0.334, p <0.001) as well as dyspareunia and lesion size in ENZIAN compartment B (correlation coefficient: 0.127, p=0.046). Severity of dysmenorrhea correlated with lesion size in ENZIAN compartment A (Spearman's correlation coefficient: 0.244, p <0.001) and with presence of adenomyosis (ENZIAN compartment FA, p=0.005, Mann-Whitney-U-test). Additionally, the number of affected compartments (A, B, C and FA) significantly correlated with the severity of dysmenorrhea (Spearman's correlation coefficient: 0.256, p <0.001) and dyschezia (correlation coefficient: 0.161, p=0.012).

Limitations, reasons for caution:

Symptom presence and severity may not only depend on involvement of a single anatomical site but rather represent a cumulative effect of single DIE lesions. Resulting symptom severity may therefore be greater or lesser than expected. However, the number of affected ENZIAN compartments correlated with severity of dysmenorrhea and dyschezia.

Wider implications of the findings:

In contrast to previous studies evaluating disease extent based on the rASRM score, disease localization and extent described by the ENZIAN score correlated with presence and severity of different preoperative symptoms, which underlines the importance of DIE extent evaluation using the ENZIAN score in addition to the rASRM score.

O-140 The effect of post-operative medical interventions on endometrioma recurrence: A systematic review and meta-analysis

N. Abdullah[1], M. Hamdan[2], S.Z. Omar[2], N.A. Kasim[3]

[1]University Malaya Medical Centre- Hospital Putrajaya, Department of Obstetrics and Gynaecology, Kuala Lumpur, Malaysia

[2]University Malaya Medical Centre, Department of Obstetrics and Gynaecology, Kuala Lumpur, Malaysia

[3]Hospital Putrajaya, Department of Obstetrics and Gynaecology, Putrajaya, Malaysia

Study question:

Does post-operative medical intervention prevent the risk of recurrent endometrioma? What is the medical intervention of choice in preventing recurrence?

Summary answer:

In women who had surgery for endometrioma, post-operative medical intervention reduces the endometrioma recurrence compared to no intervention. All medical interventions are found equally effective.

What is known already:

Surgery for endometrioma is often difficult as they are more adherent. The primary surgery is important to remove as much disease as possible to prevent recurrence as repeated surgeries are more difficult and cause more damage to the normal ovarian tissues. Post-operative medical intervention is given to delay or prevent endometrioma recurrence although the effectiveness of these interventions is not clear. Several systematic review and meta-analysis have described the effects of oral contraceptive (OC), gonadotrophin releasing hormone (GnRH) analogue and levonogestrel intrauterine system (LNG-IUS) in reducing endometrioma recurrence. However, these reviews are dated and none have combined all the interventions.

Study design, size, duration:

We searched Pubmed, MEDLINE and Cochrane Library for relevant studies published online up to December 2018 in English language using predefined keywords. Published randomised controlled trials (RCT) and non-RCTs were included. We included all medical interventions using OC, GnRH-analogue, all kind of oral progestogens and LNG-IUS. The disease recurrence was separated where possible into disease recurrent (reoccurrence of endometriotic cyst) and pain symptoms at any time post operatively.

Participants/materials, setting, methods:

From the initial search we found 426 studies, out of which 405 were excluded after reviewing the abstracts. Further, after retrieving the full-text 2 review authors agreed to include 9 RCTs (N=1245 patients) and 12 Non-RCTs (N = 2381 patients). We calculated Mantel-Haenszel odds ratio (OR) and presented 95% confidence interval for all outcomes. Statistical heterogeneity was measured by I^2 with random effect model was used in substantial heterogeneity (I^2 more than 50%).

Main results and the role of chance:

Compared to placebo, medical interventions reduced the overall risk of recurrence (OR 0.26, 95% CI 0.15-0.45, P=<0.00001, 16 studies, 2721 patients, I^2=81%) with GnRH analogue (OR 0.66, 95% CI 0.45-0.96, P=0.59, 6 studies, 716 patients, I^2=0%); OC (OR 0.19, 95% CI 0.09-0.40, P=0.002, 6 studies, 1097 patients, I^2=73%), Dienogest (OR 0.08, 95% CI 0.02-0.30, P=0.002, 5 studies, 1027 patients, I^2=77%) and LNG IUS (OR 0.35, 95% CI 0.10-1.81, P=0.19, 2 studies, 135 patients, I^2=43%).

Head to head comparison between each medical interventions showed that GnRH has no advantage against OC (OR 0.98, 95% CI 0.33-2.92, P=0.23, 2 studies, 179 patients, I^2 32%) and Dienogest (OR 1.86, 95% CI 0.71-4.83, P=0.58, 3 studies, 212 patients, I^2=0%). GnRH analogue also shows no significant reduction in post-operative endometriosis related pain when compared to placebo (OR 0.73, 95% CI 0.41-1.33, P=0.69).

Pooling the result comparing the effectiveness of LNG IUS against OC showed that LNG IUS was not superior to OC in preventing recurrent endometrioma (OR 1.52 95% CI 0.15-14.86, P=0.02, 2 studies, 191 patients). However, the result has significant heterogeneity I^2=83%.

Limitations, reasons for caution:

We included cohort studies in this meta-analysis, as there is no enough data from RCTs. Therefore, it is difficult to control for confounding and selection bias which may attribute to tight confidence interval around spurious result. This meta-analysis also exhibits high heterogeneity, hence the result should be interpreted with cautions.

Wider implications of the findings:

The result of this meta-analysis suggests that it is reasonable to prevent endometrioma recurrence with medical interventions rather than by conservative management. However, we cannot conclude which agent has higher superiority. Therefore, more large scale RCTs are needed to compare the effectiveness of various post-operative medical interventions.

O-141 Linzagolix for treating endometriosis-associated pain: efficacy and safety results from a randomized, placebo-controlled, multinational, phase 2b dose-ranging trial

E. Bestel[1], A. Humberstone[1], V. Lecomte[1], R. Dubouloz[1], P. Terrill[2], J. Donnez[3], H. Taylor[4], R. Taylor[5], E. Loumaye[6]

[1] *ObsEva S.A., Research and Development, Geneva, Switzerland*
[2] *Cytel, Strategic Consulting, London, United Kingdom*
[3] *Catholic University of Leuven, Infertility Research, Brussels, Belgium*
[4] *Yale, School of Medicine, New Haven, U.S.A.*
[5] *University of Utah Health, Obstetrics & Gynecology Research Network, Salt Lake City, U.S.A.*
[6] *ObsEva S.A., Head Office, Geneva, Switzerland*

Study question:
What are the effects of once daily oral doses of 50, 75, 100 and 200 mg taken for 24 weeks in women with endometriosis-associated pain (EAP)?
Summary answer:
Linzagolix significantly reduced EAP compared to placebo with once daily oral doses of 75 mg to 200 mg. All doses were well tolerated.
What is known already:
Suppression of estradiol (E2) using GnRH analogues has been shown to be an effective treatment for EAP. However, suppression of E2 leads to menopausal symptoms including vasomotor symptoms and bone mineral density (BMD) loss. It has been postulated that partial suppression of E2 could provide reduction in endometriosis pain symptoms without significant long-term BMD loss. Linzagolix is a new, non-peptide, GnRH receptor antagonist being developed to treat EAP. It has previously been shown to suppress E2 and decrease EAP in Japanese patients.
Study design, size, duration:
Study treatments were taken once daily for 24 weeks. The primary endpoint was the proportion of subjects with 30% or more reduction in pelvic pain over 28 days, assessed on a Verbal Rating Scale using an electronic diary. Secondary endpoints included dysmenorrhea, non-menstrual pelvic pain (NMPP), dyspareunia, dyschezia, serum E2, difficulty of doing daily activities, Patient Global Impression of Change/Severity (PGIC/S), Endometriosis Health Profile-30 (EHP-30), amenorrhea, BMD with Dual-energy X-ray Absorptiometry (DXA) and adverse events.
Participants/materials, setting, methods:
327 women aged 18 to 45 years with moderate-to-severe EAP were recruited in USA and Europe in 2016 to 2018. Participants had to have surgically confirmed endometriosis. Women with a history of osteoporosis or other metabolic bone disease were excluded. BMD of the femoral neck, total hip and lumbar spine was assessed by DXA at baseline and after 12 and 24 weeks of treatment. Reading of DXA scans and monitoring of scan quality was centralized.
Main results and the role of chance:
Compared to placebo, doses ≥ 75 mg resulted in a significant increase in the proportion of responders at 12 weeks (34.5%, 49.5% (P=.155), and 61.5% (P=.003), 56.4% (P=.039) and 56.3% (P=.034) for placebo, 50, 75, 100 and 200 mg, respectively). A similar pattern was seen for dysmenorrhea and NMPP. The effects were maintained or increased at 24 weeks. Median E2 levels were 35 to 47 and 12.5 to 13 pg/mL with 75 mg and 200 mg, respectively. Side effects, such as hot flashes, were consistent with E2 levels.

Doses ≥ 75 mg also consistently and significantly (P<.05) improved dyschezia and patient well-being as assessed by EHP-30, PGIC, PGIS and difficulty of doing daily activities. Dyspareunia was also improved, reaching statistical significance at 200 mg (P=.02). The incidence of amenorrhea increased with increasing dose up to about 75% of women at 12 weeks for 200 mg.

Mean percent (95% CI *P* value) BMD changes for lumbar spine from baseline to week 24 in the 50, 75, 100 and 200 mg dose groups were 0.137% (-0.83, +1.11 *P*=.777), -0.798% (-1.57, -0.03 *P*=.042), -1.365% (-2.14, -0.59, *P*<.001), -2.602% (-3.56, -1.65, *P*<.001), respectively. BMD of femoral neck and total hip showed a similar pattern.
Limitations, reasons for caution:
This was a dose-ranging study with about 55 patients per treatment group treated for 6 months. The findings of this study need to be confirmed in larger confirmatory trials.
Wider implications of the findings:
Phase 3 confirmatory trials will include a 75 mg (partial E2 suppression) daily dose without need for concomitant estrogen/progestin add-back therapy (ABT), and a 200 mg (full E2 suppression) daily dose in combination with low dose ABT (1 mg E2 / 0.5 mg norethisterone acetate) to mitigate BMD loss.

[7] *Rijnstate Hospital, Department of Obstetrics and Gynaecology, Arnhem, The Netherlands*
[8] *Franciscus Hospital, Department of Obstetrics and Gynaecology, Rotterdam, The Netherlands*
[9] *Amsterdam UMC- location University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands*
[10] *Zaans Medical Centre, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands*

Study question:
What are the long term costs and effects of oil- versus water-based contrast in infertile women undergoing hysterosalpingography (HSG)?
Summary answer:
Over a 3-5 year follow-up period, HSG with oil-based contrast results in higher live birth rates than HSG with water-based contrast for a comparable cost.
What is known already:
We recently showed in a randomized clinical trial (RCT) that HSG with oil-based contrast (Lipiodol®, Guerbet, France) results in higher 6-month ongoing pregnancy and live birth rates compared to water-based contrast (Telebrix®) (Dreyer et al., 2017). Within a time horizon of 6 months, the use of oil-based contrast costed US$8,198 for an additional ongoing pregnancy as compared to water-based contrast. A follow-up study of this RCT showed shorter time to pregnancy after tubal flushing during HSG with the use of oil-based contrast compared to water-based contrast. However, the long-term costs and effects of oil-based contrast have not been studied.
Study design, size, duration:
We performed an economic evaluation of the long-term follow-up of the H2Oil trial. The H2Oil trial was a multi-center RCT in the Netherlands in which 1,119 women were included and randomized to hysterosalpingography with oil-based contrast (n= 557) or water-based contrast (n= 562). Here, we present the long-term cost-effectiveness of the use of oil- versus water-based contrast in infertile women undergoing HSG.
Participants/materials, setting, methods:
The economic evaluation took a health care system perspective, and compared costs related to all treatment in the 3-5 years since randomization. The effectiveness outcome was ongoing pregnancy leading to live birth up to 5years. We calculated incremental cost-effectiveness ratios (ICERs) (differences

in costs versus differences in ongoing pregnancy rates) between the two groups. Bootstrapping was used to estimate the level of uncertainty around the ICERs. Data were analyzed using the intention to treat principle.

Main results and the role of chance:

Between February 2012 and October 2014, we randomized 1,119 women to receive an HSG with oil-based (n=557) or water-based (n=562) contrast medium. Of the women in the oil-based contrast group, 40% had no other treatment, 35% had intrauterine insemination (IUI), and 25% had in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) in the 5 years following HSG. Comparatively, of the women in the water-based contrast group, 35% had no other treatment, 34% had IUI, and 31% had IVF/ICSI in the 5 years following HSG (p=0.11).

In the oil-based contrast group, 445 women (80%) had an ongoing pregnancy leading to live birth within the 5 years of follow-up compared with 420 women (75%) in the water-based contrast group (HRR 1.27; 95% CI 1.10-1.46).

The mean costs per couple were €5,341 for oil-based contrast and €5,441 for water-based contrast. After 5 years of follow-up, HSG using an oil-based contrast resulted in comparable costs (-€100; 95% CI -€652 - +€402, p=0.642) for a 5% higher cumulative ongoing pregnancy rate compared with HSG using water-based contrast, making it the dominant strategy.

Limitations, reasons for caution:

This study was limited to women at low risk for tubal pathology, <39 years of age and without known endocrinological diseases. The findings should therefore not be generalized to other groups of infertile women.

Wider implications of the findings:

Tubal flushing with oil-based contrast resulted in higher cumulative live-birth rates. The higher price of oil-based contrast was compensated by lower IVF-uptake. Since HSG with oil-based contrast gives better ongoing pregnancy rates and shorter time to pregnancy for similar costs, we recommend it as preferred strategy for tubal testing.

Abstract text

ABSTRACT TITLE

International Committee for Monitoring Assisted Reproductive Technologies (ICMART) Preliminary World Report on ART, 2015

STUDY QUESTION

In 2015 what was global utilization, effectiveness and safety of ART?

SUMMARY ANSWER

Globally, ART utilization and data collection continue to increase but with wide variations in utilization, effectiveness and safety.

WHAT IS KNOWN ALREADY

ICMART began ART global data collection in 1991. Utilization, effectiveness and safety have continuously improved with more cycles, higher pregnancy rates and lower multiple birth rates, the latter as a result of transfer of fewer embryos. Frozen embryo transfer (FET) and donor egg cycles continue to increase. However, wide variations in practice and outcomes exist globally. Approximately 8 million ART babies have been born. ICMART has helped develop registries internationally, notably with the African Network and Registry for Assisted Reproductive Technology (ANARA). A new electronic data collection platform is being developed; nevertheless, data collection and quality remain challenging.

STUDY DESIGN, SIZE, DURATION

Countries and regions annually collect ART data, some prospectively and others retrospectively. ICMART retrospectively requested these data from all known global sources for 2015 and reviewed them for missing or incorrect data. The dataset was corrected and then analyzed utilizing standardized definitions from The ICMART/WHO Revised Glossary on ART Terminology, 2009 which was current at the time but is now replaced by The International Glossary on Infertility and Fertility Care, 2017, and previously developed methods. Preliminary results are presented.

PARTICIPANTS/MATERIALS, SETTING, METHODS

The European IVF Monitoring Consortium (EIM), Latin American Network of Assisted Reproduction (REDLARA), Australian/ New Zealand Registry and ANARA submitted regional data, and other countries contributed national data, through standardized formats to ICMART. A few individual clinics with no registry access also contributed. Data were reviewed, corrected, validated to the extent possible, analyzed and summarized by ICMART using descriptive statistics.

MAIN RESULTS AND THE ROLE OF CHANCE

Data collection and analysis are ongoing, so presented results are preliminary. The number of ART cycles continues to increase, but utilization is still highly variable among countries and regions. Regional and country differences persist in the age of the population treated, number of embryos transferred, rate of multiple births, use of ICSI, cryopreservation cycles and other factors.

The role of chance is minimal. Actual global ART results are limited to reporting countries and clinics representing approximately 2/3 of global cycles. However, this is a very large sample size from which imputation of total global results is performed.

LIMITATIONS, REASONS FOR CAUTION

Some countries have limited data and many countries have limited data validation. ICMART can perform only minimal verification of submitted data. Widespread adherence to consensus definitions provided in the Glossary takes time and requires translation into multiple languages.

WIDER IMPLICATIONS OF THE FINDINGS

ICMART World Reports standardize data, track trends, enable comparisons, stimulate questions and improve ART quality. Better understanding of ART increases societal acceptance and support for equitable access and ART research.

O-145 Access to ART: Concepts, indicators, impact

S.J. Dyer[1], G. Chambers[2], F. Zegers-Hochschild[3], G.D. Adamson[4]

[4]*Stanford University, School of Medicine, Palo Alto, U.S.A.*

Abstract text

This presentation has three objectives: to address the importance of ART utilization, present new terminology pertaining to it, and explore relevant correlations between drivers of ART utilisation and access to quality care.

The global drive towards reaching health-related Sustainable Development Goals (SDG) requires the identification of key indicators and subsequent monitoring of change over time. In addition, the recognized need to reduce

inequality requires data and analyses that identify inequities in access to care and possible drivers.

According to the World Health Organization, the right to access health care comprises four domains: availability, accessibility, acceptability, and quality. Utilization of health services lies downstream from these domains and is an indicator of realized access. The association between all these indicators applied to ART may provide insight into barriers and facilitators of access to fertility care.

There is as yet no universally accepted key indicator for access to infertility care. ART utilization can be considered a proxy indicator for realized access to ART as well as infertility care *per se*. ICMART proposes that ART utilization be adopted for this purpose. This in turn requires more accurate reporting systems pertaining to ART utilization. ICMART proposes new terminology and an approach to deal with missing data.

Using ICMART data and global indicators of health and welfare, correlations will be shown between ART utilization and facilitators or barriers, as well as ART practices and outcomes. These possible associations further emphasise the importance of ART utilization in the global context of the right to infertility health care; and ICMARTs role in reporting ART data at a global level.

SESSION 41: LUTEAL PHASE SUPPORT – HAVE WE GOT IT RIGHT?

Tuesday 25 June 2019 Haydn 2 11:45 - 12:45

O-146 The artificial endometrial preparation for embryo transfer: The litmus test for a sex steroid regimen?

E. Labarta Demur[1]

[1] *IVI RMA Valencia, Human Reproduction, Valencia, Spain*

Abstract text

The artificial endometrial preparation for embryo transfer: The litmus test for a sex steroid regimen?

The administration of exogenous progesterone (P) is needed for the luteal phase support in artificial endometrial preparation cycles with hormone replacement therapy (HRT) for embryo transfer. By promoting endometrial maturation, is essential for the embryo implantation process. The transformation of the endometrium from a proliferative to a receptive state depends on an adequate exposure to P, which prepares the uterus for implantation and the maintenance of pregnancy.

Progesterone has also non-hormonal actions such as allowing immune tolerance during pregnancy, especially affecting the synthesis of cytokines and the function of Natural Killers cells. Low exposure to P at the time of implantation or during early pregnancy may result in an implantation failure or spontaneous miscarriage.

Surprisingly, there is no individualization in the best route, dose or time of exogenous P administration, as published studies do not demonstrate that there is a clearly superior protocol. There are different administration routes of P such as vaginal, subcutaneous, intramuscular, oral or rectal. Until now, the vaginal route has been the most used in Europe. It has been shown that although serum P levels appear to be lower after vaginal than intramuscular administration, vaginal route results in an adequate secretory transformation and good pregnancy rates. This discrepancy suggests that the bioactivity of vaginal P in the uterus is higher, due to the effect of the first step of the uterus. For this reason, no measurement of serum P levels have been conducted to analyse if the absorption was adequate.

The best context to analyse the net impact of exogenous P is the artificial cycle, in which there is no endogenous production, in comparison with the stimulated or natural cycle. In this scenario, recent studies have suggested that serum P levels have a correlation with the success rate in artificial cycles when using the vaginal route. The only published prospective study analysing this topic was carried out in oocyte donation cycles performed in our centre, showing that there is a serum P threshold (9.2 ng/ml) below which ongoing pregnancy rates significantly decrease (32.7% vs 52,8%, p=0.016). These results have been confirmed and validated in a large prospective study of almost 1200 unselected patients undergoing an embryo transfer in an artificial cycle, regardless the origin of the oocytes and after adjusting for any confounding factors (submitted to this ESHRE meeting).

Once demonstrated that these results can be extrapolated to the general infertile population, new research is focused on finding the best way to increase serum P levels and improve the live birth rate. Moreover, data about the reproducibility of this situation in a subsequent cycle when using the same doses of P or even the ability to predict at the beginning of the luteal phase that serum P levels will be low in the mid luteal phase will be also presented.

This unexpected finding has opened a line of research on the role of serum P on endometrial receptivity and the possibility of reversing the cases with low serum P levels, which could imply a change in our daily clinical practice and management of the luteal phase.

O-150 Regulating human germline gene editing: should we be concerned about human dignity?

S. Segers[1], **H. Mertes**[1]

[1] *Bioethics Institute Ghent Ghent University, Department of Philosophy and Moral Sciences Ghent University, Ghent, Belgium*

Study question:

Is the violation of human dignity a convincing argument against human germline gene editing?

Summary answer:

Dignity concerns cannot underpin the current ban on heritable genome editing, but they can inform the implementation of side constraints.

What is known already:

Fast developments in the field of genome editing put pressure on legislators and ethicists to investigate whether – and if so: how – this research can be translated into clinical practice in an acceptable way. In 2018, the first genome-edited human babies were reportedly born, despite widespread moral concerns about the safety risks of these techniques. Official international documents (like the so-called Oviedo Convention) mainly oppose germline gene editing on the basis of concerns about human dignity. It is, however, unclear whether dignity concerns can serve as a basis to hold on to a ban on human germline gene editing.

Study design, size, duration:

A literature study of the scientific literature was performed to inventory the state-of-the-art of gene editing techniques. Next, official international and legal documents were analysed and claims about how germline gene editing

assumedly breaches human dignity were inventoried. This was evaluated against the backdrop of ethical analyses of the concept 'dignity' and contextualized by referring to recent reports by international committees that call for an update of current regulations in the light of recent developments.

Participants/materials, setting, methods:

Literature study, conceptual analysis, normative analysis.

Main results and the role of chance:

Human germline gene editing is opposed by both the Council of Europe and UNESCO. Their plea for banning heritable gene editing is based on the argument that this would breach human dignity. However, it is highly dubious whether germline gene editing leads to infractions against human dignity, especially when germline interventions are aimed at avoiding diseases. It is argued in this study that the concept of 'human dignity' can also be invoked to plead *for* germline gene editing, at least for non-trivial interventions. This is not to deny that a focus on dignity may signal risks of breaching people's rights, but it is argued that if 'dignity' is left unspecified and if it is invoked in a way like it is now by current European and international documents, it has to be concluded that the argument is self-defeating. This is problematic in the light of fast technical developments in gene editing and challenges the legislative and ethical aim of responsible innovation. We show that this underpins recent calls – like those by The European Society of Human Genetics (ESHG) and the European Society of Human Reproduction and Embryology (ESHRE) – to rekindle the debate about the regulation of gene editing.

Limitations, reasons for caution:

The feasibility of germline gene editing is hypothetical. Except for the reported birth of the genome-edited babies in China (November, 2018), the use of these techniques has been limited to research contexts. In addition, 'human dignity' is an ambiguous concept, and there is no general consensus on its meaning.

Wider implications of the findings:

The argumentative link between germline gene editing and human dignity is weak which might undermine current international regulations. This underpins recent calls for a public debate about genome editing and how it should be regulated.

Trial registration number:

Not applicable

O-151 Between innovation and precaution: the role of offspring safety considerations in strategies of introducing new reproductive techniques

V. Jans[1], W. Dondorp[1], G. De Wert[1]

[1]*Maastricht University, Health- Ethics and Society, Maastricht, The Netherlands*

Study question:

How did offspring safety considerations play a role in strategies of introducing new reproductive techniques and what can we learn from this?

Summary answer:

Responsible strategies of introducing new ARTs require explicit accountability with regard to dealing with offspring safety risks.

What is known already:

As several commentators have pointed out, many assisted reproductive technologies (ARTs) have been introduced without systematic research on possible offspring safety risks. However, the lack of safety studies does not mean that safety considerations were absent from earlier debates about innovation in this field. Explicitly or implicitly, professionals and policy-makers have translated their views about the relative importance of these considerations into concrete policy choices.

Study design, size, duration:

In this study, we describe how offspring safety considerations have played a role in selected case-studies of the introduction of potentially risky new ARTs: Intracytoplasmic Sperm Injection (ICSI), Pre-implantation Genetic Diagnosis (PGD) and Mitochondrial Replacement Therapy (MRT). As a framework for analyzing these cases we use Per Sandin's account of the four dimensions of dealing with risks (threat, uncertainty, action, command) that are central to debates about the possible role of the so-called 'precautionary principle'.

Participants/materials, setting, methods:

This combined empirical/ normative ethics study has three parts. 1) Literature study (ethics of technological innovation, precautionary principle, history of case studies: debates about introducing ICSI, PGD, and MRT). 2) Interviews with key figures: professionals who were actively involved in one of those case studies. 3) Ethical analysis of the findings with an eye to defining 'lessons for the future'. Our aim here is to contribute to guidance for the responsible introduction of new ARTs.

Main results and the role of chance:

In our case studies, we found that possible offspring safety effects were clearly part of the debate about whether and how to introduce the relevant technology ('threat-dimension'). However, especially the lack of evidence about the chances of those effects materializing ('uncertainty-dimension') led to divergent answers as to what (if any) measures aimed at reducing possible risks were desirable ('action-dimension') and whether or not those measures should somehow be imposed ('command-dimension'). On one end of the spectrum, a tendency in the field has always been to deal with such uncertainty in the light of the so-called 'innovation principle', stating that the benefits of innovation should only be weighed against *known* harms. On the other end, we found some examples of relatively strong precautionary measures such as the legally imposed moratorium on ICSI using surgically obtained sperm that was in place in the Netherlands around the turn of the century. Positions in between focus on trying at least to reduce the level of uncertainty through preclinical and/or follow-up studies. We conclude that if both 'anything goes' and forgoing important benefits are problematic, transparency and explicit accountability are essential elements of a responsible approach to dealing with offspring health risks of new ARTs.

Limitations, reasons for caution:

Our reconstruction of the three case studies is partly based on interviews, which may introduce bias. Moreover, as in all contributions to normative ethics, our conclusions are based on arguments that we have tried to make as strong as possible, but about which reasonable people may still disagree.

Wider implications of the findings:

With new promising and potentially risky new ARTs on the horizon (e.g. reproductive use of stem cell derived gametes, gene-editing in a reproductive context) our analysis and conclusions can enrich the necessary debate about how to responsibly introduce those technologies.

Trial registration number:

not applicable

O-152 Guarding the bounds of a morally sensitive practice. The role and verdicts of the Dutch National Indications Committee for preimplantation genetic diagnosis (PGT-M/SR).

W.J. Dondorp[1], C. De Die-Smulders[2], G. De Wert[1]

[1]*University of Maastricht, Dept of Health- Ethics- & Society HES Fac of Health-Medicine- & Life SciencesFHML, Maastricht, The Netherlands*

[2]*Maastricht University Medical Centre MUMC+, Clinical genetics, Maastricht, The Netherlands*

Study question:

How did the Dutch National Indications Committee (LIC) fulfill its task of assessing new indications for preimplantation genetic diagnosis (PGT-M/SR)?

Summary answer:

Instead of prescribing the boundaries of PGT-M/SR, the LIC's verdicts ultimately refer to the consultation room as the place to decide about treatment requests

What is known already:

Many European countries have legislation limiting the scope of acceptable PGT-M/SR indications to conditions entailing a 'high risk of serious genetic disorder'. Of the countries upholding this standard, most leave its application to individual centres and practitioners. Some countries (Germany and Norway) require that each PGT-M/SR case must have the prior approval of a multidisciplinary ethics committee. An in between position is taken in two other countries (the Netherlands and the U.K.), who have a national committee or authority determining on a more general level which 'new' conditions are sufficiently 'high risk' and 'serious' to be acceptable as PGT-M/SR indications.

Study design, size, duration:

Since 2009, the Netherlands has a National Indications Committee (LIC) for PGT-M/SR, tasked with ensuring that PGT is only done for couples at a 'high risk' of a child with a 'serious hereditary disorder'. The LIC's green light is

needed for any new conditions, i. e. conditions for which PGT-M/SR has not as yet been done in the Netherlands. We have analysed all LIC-verdicts In order to assess how this system has functioned in practice.

Participants/materials, setting, methods:

The LIC has issued >100 verdicts. Its remit requires it to use a decisional framework defined in the Statutory Regulation of 2009, referring to relevant co-determinants of risk/seriousness. In addition to medical criteria, the framework also acknowledges 'psychosocial or moral factors' that however are only allowed to weigh in for conditions considered acceptable on medical grounds. This is comparable to the framework used by the Human Fertilisation & Embryology Authority (HFEA) in the UK.

Main results and the role of chance:

The LIC has been given a difficult task: to guard responsible indications-setting on the basis of criteria that can only partly be operationalized in general terms. Taking a different approach than the HFEA (which assesses new indications on the basis of a 'worst case analysis'), the LIC presents its verdicts as general assessments that allow for divergence in concrete cases. None of the verdicts we found was a flat 'yes' or 'no'; all were a qualified 'yes, provided that. . ..', or no, unless. . .'. Interestingly, the scope for making exceptions was not only linked to medical criteria (e.g. allowing the centre to take account of the specific phenotype of affected family-members), but also to the subjective perspective of the applicants. For instance, with regard to a condition where the LIC considered the impact to be psychosocial rather than strictly medical, the verdict was still 'no unless', allowing the centre to consider 'highly special circumstances and motives of the applicants'. By taking this line, the LIC seems to deviate from the policing task envisaged for her by Dutch politics. However, we argue that precisely by taking a more advisory role she has contributed to the responsible development of PGT practice in the Netherlands.

Limitations, reasons for caution:

This study concerns the regulation of PGT-M/SR practice in one specific European country.

Wider implications of the findings:

As the issues at stake (e.g. how to deal with the applicants' subjective perspective of risk/seriousness in debates about indications setting) are of a general nature, our observations about the role and verdicts of the Dutch National Indications Committee may be relevant for policy discussions in other countries as well.

not-applicable

O-153 International consensus: Ovarian tissue cryopreservation in young Turner syndrome patients

M.J. Schleedoorn[1], B.H. Mulder[1], D.D.M. Braat[1], C.C.M. Beerendonk[1], R. Peek[1], W.L.D.M. Nelen[1], E. Van Leeuwen[2], J.A.E.M. Van Alfen - van der Velden[3], K. Fleischer[4]

[1]Radboud university medical centre, Obstetrics and Gynaecology, Nijmegen, The Netherlands

[2]Radboud university medical centre, Medical Ethics, Nijmegen, The Netherlands

[3]Radboud university medical centre Amalia Children's Hospital, Paediatric Endocrinology, Nijmegen, The Netherlands

[4]Radboud University Medical Center, Department of Obstetrics and Gynaecology, Nijmegen, The Netherlands

Study question:

What is the standpoint of an international expert panel on ovarian tissue cryopreservation (OTC) in young females with Turner syndrome (TS)?

Summary answer:

The majority of the expert panel states that OTC should be offered to young females with TS.

What is known already:

OTC is a valid option to preserve the fertility of young females at risk of iatrogenic premature ovarian insufficiency (POI). Offering OTC to females with a genetic cause of POI seems a logical next step. One of the most common genetic disorders related to POI is TS. Due to an early depletion of the ovarian reserve, most females with TS are confronted with infertility before reaching adulthood. However, before offering OTC as an experimental fertility preservation option to young females with TS, the medical and ethical concerns need to be addressed first.

Study design, size, duration:

A three-stage ethical[Z2] Delphi study was conducted to discuss the pros and cons of OTC in young females with TS in a systematic manner. The aim of this study was to reach group consensus and to form an international standpoint based on selected key statements. The study was conducted between February and December 2018.

Participants/materials, setting, methods:

A mixed panel of 12 gynaecologists, 13 (paediatric) endocrinologists, 10 medical ethicists and 20 patient representatives participated in this international Delphi study. In the first two rounds, all experts were asked to rate and rank 38 statements and 155 supporting arguments regarding OTC in females with TS. Opinions were swayed via repetitive feedback after each round. The selection of key statements was based on strict inclusion criteria.

Main results and the role of chance:

A total number of 46 participants from 16 different countries completed the first Delphi-round (response rate 84%). Based on strict selection criteria, 6 key statements were selected and 13 statements were discarded. The remaining 19 statements and 2 additional statements submitted by participants were re-evaluated in the second round by 41 participants (response rate 76%). The analysis of the second survey resulted in the inclusion of 2 additional key statements. The final selection of key statements was approved by 96% of the participants. After the pros and cons were discussed and the main arguments were selected, the majority of our expert panel (75%) believed that OTC should be offered to young females with TS in a safe and controlled research setting. Arguments that focused on beneficence, autonomy, and justice outweighed statements regarding non-maleficence. The remaining participants (25%) did not object, but chose to remain neutral.

Limitations, reasons for caution:

The anonymous nature of this study might have led to lack of accountability. The selection of experts based on their willingness to participate, and the fact that not all panellists took part in all rounds, might have resulted in selection bias

Wider implications of the findings:

This international standpoint is the first step in the global acceptance of OTC in females with TS. Future collaborative research with focus on efficacy and safety and long-term follow-up are urgently needed. Furthermore, we recommend an international registrar for fertility preservation procedures in females with TS.

Trial registration number:

not applicable

INVITED SESSION

SESSION 44: MHR SYMPOSIUM: DYNAMIC INTERACTION BETWEEN THE MALE GAMETE AND ITS ENVIRONMENT

Tuesday 25 June 2019 Haydn 1 14:00 - 15:00

O-154 Epididymis contribution to male fertility

O-155 A step by step development of a bovine oviduct-on-a-chip model for better biomimicking in vivo early embryo development

B.M. Gadella[1]

[1]Utrecht University - Institute of Biomembranes Facultity of Veterinary Medicine, Dept of Biochemistry and Cell Biology, Utrecht, The Netherlands

Study question:

Can a double perfusion microfluidic oviduct on a chip culture system provide a more in vivo like in vitro fertilization environment and does this improve embryo production?

Summary answer:

Yes as it allows exclusive monomeric fertilization while conventional IVF results also in polyspermic fertilization and parthenotes. Moreover, the (epi)genome is more in vivo like.

What is known already:

ART only focuses on increasing the low efficiency of obtaining and maintaining pregnancy or live birth, whereas the long-term impact on the health of the resulting child has been relatively neglected. Animal models have highlighted

that *in vitro* embryo culture is not exactly mimicking embryo development in the female genital tract and also has effects after embryo transfer on subsequent offspring development and health. *In vivo*, the oviduct hosts the first embryo developmental period coinciding with a complete reprogramming of its (epi)genome in preparation for the reacquisition of (epi)genetic marks.

Study design, size, duration:

A 3D-printed oviduct-on-a-chip model using a stereo-lithographic technique was used in which bovine oviduct epithelial cells were cultured and regained and maintained their ciliated and cuboidal to columnar epithelium for a period of at least 6 weeks, with a mixed population of ciliated and secretory cells comparable to that in the in vivo oviduct epithelium. This was used to condition the apical medium and to study both bovine IVF and embryo production.

Participants/materials, setting, methods:

The oviduct on a chip was made from PDMS material and a polycarbonate porous filter. The culture was followed on an live imaging inverted confocal microscope at zygote stage individual embryos were sequences to monitor their (epi)genome. these were compared with routine IVF zygotes and with zygotes flushed from cow oviducts in vivo also the (de)methylation of DNA was followed at fertilization until the two cells stage.

Main results and the role of chance:

A non-toxic material (PDMS) to create an improved bovine oviduct-on-a-chip. Cultured oviduct epithelial cells were responsive to steroid hormone stimulation, mimicking the luteal- and pre-ovulatory phases. Moreover, the oviduct-on-a-chip supported not only exclusive monomeric fertilization, but also embryo development up to the blastocyst stage. The zygotes resulting from on chip (CH) culture were more similar to their in vivo counterparts (VV) than to conventional in vitro (VT) zygotes, in terms of their global DNA methylation level and transcriptome. Interestingly, VV and CH zygotes exhibited lower global DNA methylation levels than VT zygotes, which is presumably a factor of the up-regulation of genes related to DNA demethylation in 80% of the VV and 50% of the CH zygotes (G2). This reduced level of DNA methylation seems to be essential to the minor embryonic genome activation event, since an up-regulation of genes related to transcription and translation initiation was observed in G2 zygotes. Suggesting that standard IVP conditions delay zygote minor transcriptome activation, but that the delay can be partially ameliorated using our oviduct-on-a-chip platform. Finally, our results highlight the importance of using a more in vivo-like environment to study pathways related to normal fertilization and embryo development in vitro.

Limitations, reasons for caution:

(i) Biofabricated materials may release endocrine disrupting agents. We have used non-toxic materials but other 3D-printed materials used released such components and blocked embryo development after the second cleavage. (ii) Although (epi)genetic changes have been noted at zygotes it is not clear whether is influences later (epi)genetic remodeling.

Wider implications of the findings:

Our approach permits live imaging for tracking cell migration and/or specific molecular pathways. Thus it opens avenues for interrogating pathways associated with tubal derived ovarian cancers and thereby for the identification of biomarkers for the early diagnosis of this lethal disease. This could be extremely valuable for personalized medicine purposes.

O-161 De novo mutations affecting male infertility

J. Veltman[1]

[1]*Newcastle University, Institute of Genetic Medicine, Newcastle upon Tyne, United Kingdom*

Abstract text

During spermatogenesis and oogenesis the 6 billion letters of our diploid genome need to be accurately copied in order for the gametes to successfully pass on our genetic information. By studying the genomes of children and their parents, we now know that each human is born with 50-100 *de novo* mutations. These *de novo* mutations, by affecting important genes during development, can result in severe neurodevelopmental disorders such as intellectual disability or epilepsy. In this research we test the hypothesis that these *de novo* mutations may explain a significant proportion of the most severe forms of male infertility and may point us to many new male infertility genes. I will discuss our first studies in which we studied the DNA of 100 patients with azoospermia and severe oligospermia and compared this DNA to that of their unaffected parents. We identified not only de novo point mutations but also de novo deletions in the genome, determined the parent of origin and are currently replicating this work as well as performing functional studies within the framework of the International Male Infertility Genomics Consortium (www.IMIGC.org). This work is aimed at furthering our understanding of the genetic causes of male infertility with the goal to improve diagnostics, provide more insight into the success of assisted reproductive technologies, as well as the health of future offspring.

O-162 Genes involved in sperm functional impairment

M.K. O'Bryan[1]

[1]*Monash University, School of Biological Sciences, Clayton- Victoria, Australia*

Abstract text

The presence of large numbers of functionally competent spermatozoa is a primary determinant of male fertility in both humans and animals, and for animals wherein polyandrous mating is the norm, a primary determinant of evolution. We are interested in how sperm are built and the relationship between sperm form and function. A greater understanding of these processes will improve our understanding of the normal processes of male fertility, and the aetiology of human male infertility in the large number of patients who present with teratozoospermia and/or asthenozoospermia. To define these processes, we are using both forward genetic (clinical phenotype to underlying gene) and reverse genetic (gene to phenotype) approaches, and in doing so have uncovered many novel regulators of male fertility. Within this presentation I will focus on the validation of causal genes in human male infertility and the definition of their mechanism within normal spermatogenesis.

INVITED SESSION

SESSION 47: PATIENT SESSION - COMMUNICATION DURING THE INFERTILITY JOURNEY

Tuesday 25 June 2019 Haydn 4 14:00 - 15:00

O-163 First visit - problems in communication with fertility specialists

S. Jovanovic[1]

[1]*Association Chance for parenthood, Association Chance for parenthood, Belgrade, Serbia*

Abstract text

The First Visit – Problems in Communication with Fertility Specialists

Research goal:

The first part of the research is aimed at presenting the basic problems in communication between patients and infertility specialists on the first visit – the first consultations at an IVF clinic. Problems in communication between doctors and patients may influence the quality of the treatment, the establishment of a diagnose, the very course of the IVF procedure, an increased fear from the continuation of the treatment, as well as the quality of patients' life. Also, problems in the first communication, in the first consultations, may substantially influence patients' very choice where they will continue the treatment, which means they directly influence the very choice of a clinic and a doctor.

The second part of the research is focused on questioning specialists. This part of the research includes the aspect and perception of communication problems in the first consultations by infertility specialists. The accent is placed on doctors' point of view, the problems that doctors possibly notice, as well as the possibilities of solving the same.

Both the first and the second parts of the research are aimed at improving the quality of the services provided by clinics and doctors towards patients.

Methods: The research was conducted during one month. About 700 patients and more than 50 specialists were questioned. The questionnaire was fully anonymous, displayed online, and the respondents were not time-limited in completing it. The research covers patients and doctors from throughout Europe, and the largest number of the questioned patients and doctors were from Serbia – the country the researcher herself comes from. The research (survey) contained 25 short questions with the offered answers for the patients and 11 questions with the offered answers for the infertility specialists. The survey was only possible to complete once.

Based on the obtained answers, we wanted to demonstrate:

- the current and realistic situation showing the manner of patient-doctor communication in the first consultations;
- patients' assessment and first impression after the first IVF consultations;
- the expectations patients come to an IVF expert with and whether their expectations are met;
- whether patients receive all necessary information about the IVF process and the very course of the procedure;
- what patients expect from the IVF team – which, what and how big patients' expectations are;
- if patients inform themselves on the Internet after the first consultations, and why;
- based on what they chose the doctor and the clinic for the first consultations;
- how long it took them from becoming aware of the need for consultations with an IVF expert to the first consultations;
- whether doctors think patients are sufficiently informed;
- whether, in doctors' opinions, patients ask clear and direct questions regarding their treatment;
- whether, in doctors' opinions, patients come to an infertility specialist late;
- what doctors expect from patients in the first consultations – what their expectations are;
- if doctors consider themselves to be sufficiently supportive already in the first consultations.

The general goal of this research was to assess the quality of the service and care from patients' and doctors' perspectives in the first consultations regarding the IVF treatment, and also to show the realistic condition, for which reason the questionnaires were absolutely anonymous.

General conclusion: The first consultations and communication with an IVF specialist are of vital importance to patients when the continuation of the procedure, the quality of further treatment and life, too, are concerned.

O-164 Dear Doctor - can you hear me? Improving communication between professionals and patients

O-165 When there's a big disappointment, we don't know if that's the end of the story

E. Van der Valk[1]

[1]*Fertility Europe, n/a, Naaldwijk, The Netherlands*

Abstract text

Communications during the infertility journey

When there is a big disappointment, we don't know if that is the end of the story . . .

Ellen van der Valk tells her vulnerable story about deciding to stop further fertility treatments and how her life went after that.

By sharing her experiences and those of other women in this situation, she wants to give professionals in the field of fertility health care insight in:

- the impact of fertility treatments on your patients' daily lives
- the internal struggle between the wish to have a child versus the wish to enjoy life again
- the pressure of the idyllic 'happy familiy' picture on your patients' decisions
- how to help your patients in their decission making process

As an experience expert she feels that fertility doctors should not only talk about the next steps for treatment, but also consider no (further) treatment as an option to be discussed.

INVITED SESSION

SESSION 48: IMPACT OF PELVIC PATHOLOGY ON PREGNANCY OUTCOMES

Tuesday 25 June 2019 Strauss 1+2 14:00 - 15:00

O-166 Endometriosis and obstetric outcomes

O-167 The effect of fibroids on reproductive outcomes

M. Metwally[1]

[1]*Sheffield teaching hospitals, Reproductive medicine, Sheffield, United Kingdom*

Abstract text

Uterine fibroids are the most common benign uterine tumours in women and hence it is not surprising that they are commonly encountered in woman with reproductive problems. It is estimated that uterine fibroids may be found in 5-10% of women presenting with infertility[1]. In addition, fibroids have been associated with other reproductive problems such as miscarriage, preterm labour, foetal malpresentation, increased risk of caesarean section, low birth weight and postpartum haemorrhage.

Since fibroids do not represent a single entity, their effect on reproductive performance is variable according to their number, size and position. The general consensus is that the closer the fibroid is to the endometrium, the more adverse effect it can have on fertility. Submucous fibroids therefore are commonly thought of as having the greatest effect. This is supported by a number of primary and secondary studies showing that women with submucous fibroids have significantly lower fertility rates, clinical pregnancy rates, ongoing pregnancies and higher miscarriage rates[2]. However, despite the

wide practice of hysteroscopic myomectomy, there is a paucity of evidence from well-designed randomised controlled studies investigating the value of surgical removal for the sole purpose of improving fertility and further evidence from well-designed trials is needed, balancing the gains against any potential harm from surgical intervention[3].

At the other end of the spectrum lie subserous fibroids, where the evidence has shown them to have no direct adverse effect on fertility[2]and there is currently no evidence that their removal improves fertility. However, surgery may be considered in large subserous fibroids that distort the pelvic anatomy and may lead to difficult access to the ovaries for oocyte retrieval or cause problems such as pain during pregnancy or interfere with labour and delivery.

The most controversial fibroids however are of the intramural type. An early meta-analysis had initially suggested that they had no effect on fertility while a follow up meta-analysis from the same group suggested that they may indeed have a negative effect[2,4]and this was supported by a later meta-analysis from another group[5]. However, a later study highlighted the heterogeneity and therefore the unreliability of the evidence and hence the urgent need for good quality randomised controlled studies[6]. Until such studies are available, the management of intramural fibroids needs to be considered on a case to case basis.

SESSION 49: INTELLIGENT AUTOMATION IN THE EMBRYOLOGY LABORATORY

Tuesday 25 June 2019 Mozart 15:15 - 16:30

O-168 Automatic morphological grading of human blastocysts with time-lapse imaging and artificial intelligence

M.F. Kragh[1], J. Rimestad[2], J. Berntsen[2], H. Karstoft[3]

[1]*Vitrolife A/S & Aarhus University, Research & development, Aarhus S, Denmark*
[2]*Vitrolife A/S, Research & development, Aarhus S, Denmark*
[3]*Aarhus University, Department of Engineering, Aarhus N, Denmark*

Study question:

Can human blastocyst evaluation be fully automated with time-lapse imaging and artificial intelligence (AI) to provide similar or improved morphological grades compared to experienced embryologists?

Summary answer:

AI performed better than embryologists on inner cell mass (ICM) and trophectoderm (TE) grading and provided better implantation rates for the highest graded embryo groups.

What is known already:

Blastocyst morphology grading is the most commonly used criteria for embryo selection, although subjective and prone to both inter- and intra-observer variances. Different automated approaches have been proposed to predict blastocyst quality from static images, acquired at a fixed time after fertilisation. These approaches are deterministic and thus ensure consistent annotations. However, due to the dynamic nature of embryo development, evaluation at a fixed time may easily be affected by slow blastocyst formation, collapses, and hatching. Today, no automated methods for morphological blastocyst grading have been proposed to address this issue by leveraging the temporal information available with time-lapse.

Study design, size, duration:

7438 human embryos from 4 different fertility clinics were recorded with time-lapse imaging. ICM and TE were graded by experienced embryologists according to the Gardner blastocyst scoring system. For AI development, the dataset was split into training (80%), validation (10%), and testing (10%). Furthermore, a second, independent test set of 55 embryos was graded by multiple experienced embryologists, allowing comparison of the embryologist´s majority votes vs. AI performance.

Participants/materials, setting, methods:

A convolutional neural network (CNN) was trained to jointly predict ICM and TE grades (A,B, or C) from static blastocyst images with 3 focal planes (fixed method). A recurrent neural network (RNN) was then trained on the same task using the CNN outputs from a sequence of time-lapse images ranging from time of blastocyst formation to time of maximum blastocyst size (dynamic method).

Main results and the role of chance:

On static images acquired at 110 hours after fertilisation, the fixed method achieved accuracies of 59.2% and 56.8% on ICM and TE predictions, respectively, when evaluating against single embryologist annotations in the first test set. Using sequences of time-lapse images, on the other hand, the dynamic method achieved higher accuracies of 66.9% and 70.8% on ICM and TE predictions, respectively. Furthermore, only 1.9% and 1.5% of the examples had A-C or C-A disagreements with the embryologists on ICM and TE, respectively. On the second test set with multiple annotators, leave-one-annotator-out cross-validation was applied to allow comparison of embryologist vs. AI performance. Here, AI achieved average ICM and TE accuracies of 72.7% and 75.6%, whereas average embryologist accuracies were 65.1% and 73.8%. When evaluating the AI against outcome data (fetal heartbeat) on the first test set, the AI had an implantation rate of 46.0% for top quality blastocysts (ICM/TE: A/A; n = 100) and 34.4% for good quality blastocysts (ICM/TE: A/B, B/A, B/B; n = 131). For embryologists, the same implantation rates were 44.6% (n = 112) and 30.7% (n = 127).

Limitations, reasons for caution:

Our results suggest the AI to be at least on level with individual embryologist annotations of both ICM and TE. However, more data from multiple annotators are needed to determine superiority.

Wider implications of the findings:

Automated blastocyst grading using AI is consistent, faster, labour saving, and potentially more accurate than the equivalent annotations from human embryologists. The proposed AI applies the widely used Gardner scoring system and can therefore help embryologists in their daily annotations without introducing new parameters or requiring new implantation models.

O-169 Metabolic activity of human preimplantation embryos relates to their morphokinetics, morphological grade, KIDScore and artificial intelligence selection

L. Ferrick[1], Y.S.L. Lee[2], D.K. Gardner[1]

[1]*University of Melbourne, Biosciences, Melbourne, Australia*
[2]*Melbourne IVF, IVF Lab, Melbourne, Australia*

Study question:

Is there a relationship between preimplantation embryo metabolic activity and other biomarkers of embryo viability?

Summary answer:

Embryos consuming higher levels of glucose exhibit faster blastocoel formation, and higher morphological grades, KIDScores, and EmbryoScores generated by artificial intelligence / deep learning (Ivy).

What is known already:

Glucose is the key metabolite utilised by the embryo post-compaction to support blastocyst development and has been reported as a biomarker of day 4 and 5 human embryo viability. Morphology, morphokinetics, KIDScore and more recently EmbryoScore (a measure of the chance an embryo will result

in a fetal heartbeat), have been correlated to transfer outcomes and used as biomarkers of embryo viability to aid embryo selection.

Study design, size, duration:

110 human preimplantation embryos from 21 patients were cultured in a time-lapse incubator system in both freeze all and fresh transfer cycles. A retrospective analysis of morphokinetics, morphology, KIDScore, EmbryoScore and day 5 glucose metabolism was conducted.

Participants/materials, setting, methods:

ICSI was conducted in patients, aged ≤37 years, who previously had no more than two oocyte collections, and no more than four embryo transfers. Embryos were cultured in a time-lapse incubator system, and those reaching the blastocyst stage had their morphokinetics annotated and were each assigned a morphology grade, KIDScore and EmbryoScore. Glucose concentration in spent media samples were analysed using ultramicroflurescence and compared to control media.

Main results and the role of chance:

Analysis of glucose metabolism of embryos that reached blastocyst stage revealed embryos with top morphological scores (AA) consumed significantly more glucose than lower scoring embryos (<AA) (126.0 ± 17.5 pmol/embryo/h vs 69.2 ± 8.6 pmol/embryo/h, $p<0.01$). Assessment of embryo morphokinetics revealed blastocoel formation was delayed in embryos exhibiting significantly lower glucose uptake on day 5 of preimplantation period (53.1 ± 13.9 vs 94.9 ± 9.5 pmol/embryo/h, $p<0.05$). Additionally, embryos assigned a KIDScore higher than the median score exhibited a significantly higher glucose uptake on day 5 of preimplantation development than embryos with a lower KIDScore (104.6 ± 11.0 vs 54.9 ± 8.9 pmol/embryo/, $p<0.001$). Similarly, embryos that were assigned an EmbryoScore above the median score consumed significantly more glucose than embryos that were assigned a lower EmbryoScore (95.0 ± 10.4 vs 64.8 ± 10.9 pmol/embryo/h, $p<0.05$).

Limitations, reasons for caution:

Samples were collected from one clinic.

Wider implications of the findings:

These results demonstrate a direct link between embryo glucose metabolism and specific morphokinetic events. Additionally, these results provide further evidence that glucose is a valid biomarker of embryo viability and, therefore could be used in conjunction with other biomarkers to aid embryo selection methods.

O-170 Clinical validation of an automatic time-lapse algorithm classification system for blastocyst selection

B. Aparicio-Ruiz[1], S. Perez[1], L. Romany[1], T. Viloria[1], L. Alegre[1], J. Remohi[2], M. Meseguer[1]

[1]IVIRMA Global, IVF Laboratory, Valencia, Spain
[2]IVIRMA Global, Gynecologist Department. IVI President, Valencia, Spain

Study question:

Is there a correlation between an automatic time-lapse algorithm classification(Xtend) with blastocyst implantation potential? If so, is standard morphology compatible or combinable with Xtend analysis?

Summary answer:

There is a direct correlation between Xtend-categories with implantation potential of blastocysts. This relationship is even more evident in good-quality embryos according to standard morphology.

What is known already:

Aparicio-Ruiz et al. 2016 validated an automatic algorithm by which embryos were classified based on the values of P2 (t3-t2; second cell cycle) and P3 (t4-t3; synchrony). This algorithm was improved including more parameters (number of cells on day 3, egg age and changes of the texture of the embryo from 42 to 60 hours after ICSI) in order to classify embryos in 5 different categories (1-5).

Study design, size, duration:

Retrospective cohort study (egg donation program) performed in a University-affiliated infertility clinic on 1031 embryos analyzed from April 2016 to October 2018.

Participants/materials, setting, methods:

The study includes 362 patients and 1031 embryos generated by ICSI in the egg donation program and incubated in a GERI Time-Lapse Incubator (Genea, Australia) with especially designed scopes that used dark field microscope and an automatic cell-tracking software (Eeva, Xtend).

Main results and the role of chance:

A total of 1031 embryos were incubated in the Geri-system. Without distinguishing if embryos transferred were fresh or previously thawed, implantation rates of KID blastocysts(n=514) were directly correlated with the Xtend classification(1:53.91%; 2: 52.63%; 3:45.68 %; 4:39.02%; 5:24%). These differences were statistically significant p=0.017.

We assembled different Xtend categories and studied implantation rates in two groups: 1-3(52%) or 4-5(32.90%), showing significant differences between both groups (p= 0.003).

To check if algorithm selection properties were conditioned by morphology of blastocysts, we separated good quality(A/B according to ASEBIR morphology classification) from those with worse quality(no A/B).When Xtend categories were grouped, important differences were observed in percentage of A/B blastocyst between 1-3(83.9%) and 4-5(16.10%) that were less evident for not good quality blastocysts: 1-3(54.1%) and 4-5(45.9%)($p<0.0001$).

Even though no significant differences were observed, the algorithm seemed to define better implantation potential in good quality blastocysts(1:56.7%; 2:55.9%; 3:51.6%; 4:39.35; 5:27.8%) than in those not classified as A/B(1:33.3%; 2:36.4%; 3:23.5%; 4:41.7%; 5:18.2%). We also performed a logistic regression model for implantation, in which BMI, number of MII donated and standard morphology were included. The model assembled Xtend(1-3 vs 4-5) presented an OddsRatio(OR) of 1.917(CI95%1.40-3-77) and blastocyst morphology(A/B vs not A/B) OR of 2.30 (CI95% 1.11-3.30).

Limitations, reasons for caution:

Retrospective nature of this study may be a reason for caution; nevertheless, is the largest sample size reported with this test, based in blastocyst transfer with>90% of single-embryo-transfer, additionally a multivariable-analyisis confirmed the magnitude of the results. The classification system has some errors due to difficulties in cell-tracking generating "none-result".

Wider implications of the findings:

To our knowledge, this is the biggest set of data using Xtend-algorithm. Results obtained validate the utility of this classification and showed higher accuracy in good-morphology blastocysts. It confirms that morphology and time-lapse classifications are independent and combinable showing that not all embryos classified morphologically asA/B correspond with better Xtend-categories.

Trial registration number:

Not applicable

O-171 Embryo development detection by automated software vs. embryologist team.

R. Del Gallego Bonilla[1], L. Alegre[1], L. Bori[2], T. Peura[3], S. Azaña[2], M. Meseguer[1]

[1]IVI Valencia- SL, IVF Laboratory, Valencia, Spain
[2]IVI Valencia- SL, Research, Valencia, Spain
[3]Genea, Research, Sydney, Australia

Study question:

To compare outcomes and accuracy of embryo morphokinetic event annotations performed in a routine clinical practice to those performed by an automated embryo assessment software.

Summary answer:

High detection rate accordance was found between embryologist and embryo assessment software. This novel technology is a useful tool under a qualified embryologist supervision.

What is known already:

Time-lapse technology has helped to elucidate key events of embryo development. The relevance of this methodology has increased in the last years, since it reduces subjectivity and makes possible to perform deeper and more accurate analyses of embryo development. The use of deep learning algorithms to analyse developmental events automatically is a step towards implementation of artificial intelligence into embryo assessment, which is becoming a significant trend in the future.

Study design, size, duration:

This is a retrospective study with data collected between December 2017 and August 2018 in IVI Valencia clinic from embryos analysed manually by

IVI team and automatically by GeriÒ Assess 2.0 automated annotation software for nine embryo development events. Percentage of events detected by either IVI team, the software or both was calculated, as well as the accuracy of event timings between the two.

Participants/materials, setting, methods:

A busy embryologist team at IVIRMA clinics annotated embryos for nine developmental events as per normal clinical practice using GeriÒ Assess 1.3 software. The same videos were then analysed retrospectively with a stand-alone GeriÒ Assess 2.0 software, applying the same pre-determined filtering time-ranges for the events as are incorporated in the full GeriÒ Assess 2.0 system. Finally, the event detection rates, and event timings as mean and standard deviation between the two were compared.

Main results and the role of chance:

From 12,618 possible developmental events, IVI detected 86% (10,857), GeriÒ Assess 2.0 software 81% (10,191), and both concurrently 75% (9,470).The mean and standard deviation of the event timings between manual and automated annotations were as follows (hrs): PN appearance 0.3 (±4.1), PN disappearance 0.6 (±1.1), 2-cell 0.6 (±1.3), 3-cell 0.5 (±2.1), 4-cell 0.7 (±4.1), 5-cell 1.1 (±4.3), 6-cell 0.1 (±4.4), morula 4.1 (±7.4) and early blastocyst 1.1 (±5.4). Time-ranges for filtering of automatic annotations were: PN disappearance 17-30 h, 2-cell 20-40 h, 3-cell 30-48 h, 4-cell 32-54 h, 5-cell 38-68 h, 6-cell 46-78 h, morula 64-100 h and early blastocyst 86-126 h. Thus excluded data points represented 12% of all automatically annotated events.

The lowest accordance rates in detection were found in the more subjective events: PN disappearance, morula or expanded blastocyst stage, and especially after the events were filtered according to time-ranges. Differences in timings varied according to the event, the largest differences detected in the later events. However, in the great majority of the events, especially early cleavage divisions, the match rate was very high.

Limitations, reasons for caution:

Prospective validation is needed. Chaotic embryos with aberrant divisions and variability between annotators makes exact annotations difficult for both manual and automated annotations.

Wider implications of the findings:

Automated annotations ease the embryologists' workload and especially early events can be annotated with high accuracy. Furthermore, non-annotated events can still be annotated manually, increasing the accuracy of the data. Move into the use of automated annotations is a natural progression for a clinic utilising timelapse systems, such as ours.

O-172 Continuous flow of pre-mixed gas is not required to maintain culture medium pH in a benchtop incubator.

D. Mortimer[1], S. Geelhood[2], S. Olds[2]

[1]Oozoa Biomedical Inc., President, West Vancouver- BC, Canada
[2]Blood Cell Storage Inc, SAFE Sens, Seattle, U.S.A.

Study question:

Do benchtop incubators require continuous gassing with pre-mixed gas to maintain culture medium pH?

Summary answer:

Intermittent gassing can be used to maintain culture medium pH.

What is known already:

The equilibration and maintenance of culture medium pH depends on providing the correct partial pressure of carbon dioxide (pCO_2) inside the incubator. In compact benchtop incubators this achieved using a continuous supply of pre-mixed gas: 6.0% CO_2 / 5.0% O_2 / balance N_2 when working with typical culture media containing 25 mM bicarbonate and at 37°C at sea level (atmospheric pressure 760 mmHg), i.e. pCO_2 = 45 mmHg. However, the explicit need for a continuous supply of this gas has not been previously established.

Study design, size, duration:

This was an observational experimental study using the SAFE Sens real-time pH monitoring system (BCSI, Seattle, WA, USA) installed into a Planer/Origio BT37 compact benchtop incubator (Cooper Surgical, Trumbull, CT, USA).

Participants/materials, setting, methods:

Planer's BT37 Toolbox software was used to program 10-minute gas flow events (15ml/min/chamber) every 30, 60 or 90 minutes, abbreviated as 10:20, 10:50 and 10:80 respectively. Sensors were loaded with 125µl of Universal IVF Medium and covered with 75µl of Oil for Tissue Culture (both Cooper Surgical); pH readings were logged every minute for up to 72h per experiment. Control pH values were measured using a Siemens RapidLab 348 blood gas analyzer.

Main results and the role of chance:

Stability of pH measurements over a 4-hour steady state period (SDs of >200 measurements) were very similar: 0.0036, 0.0042, 0.0044 and 0.0039 (control, 10:20, 10:50 and 10:80 intermittent gassing respectively). Stable pH readings, averaged at 24–25h, were 7.35, 7.36, 7.42 and 7.44, respectively), all with 95% ranges of ±0.01. Given the stable medium pH levels achieved, and their low variability over time, these results do not support the necessity for a continuous supply of pre-mixed gas. However, periods of >60 minutes between gas flows should be avoided because the data indicate a lower effective pCO_2 beyond 1h, as indicated by the higher pH levels. In the 10:80 cycle it was also observed that a lid opening followed by the incubator's normal gas purge cycle caused a noticeable pH dip from 7.44 to 7.41 over a 4h period followed by a slow rise back to the stable level.

Limitations, reasons for caution:

Intermittent gas flow control is not available in all benchtop incubators that use pre-mixed gas. Surrogate sensors replicate microdroplet culture, open culture systems are expected to have differing results. Sensor cups monitor medium separate from embryo culture dishes, and CO_2 absorption in the sensors might differ from culture drops.

Wider implications of the findings:

After allowing for essential post-opening purges, the adoption of an intermittent flow rate pattern reduces pre-mixed gas usage: the 10:20 and 10:50 intermittent flow protocols can reduce gas consumption by ~68% and ~79% respectively, optimizing culture conditions while providing significant operational savings.

SELECTED ORAL COMMUNICATIONS

SESSION 50: THE LUTEAL PHASE

Tuesday 25 June 2019 Haydn 1 15:15 - 16:30

O-173 A large prospective trial in unselected population confirms that low serum progesterone on the day of embryo transfer impairs pregnancy outcome in artificial cycles.

E. Labarta Demur[1], G. Mariani[2], S. Paolelli[2], C. Vidal[2], J. Giles[2], J. Bellver[2], F. Cruz[2], A. Marzal[2], P. Celada[2], I. Olmo[2], P. Alamá[2], J. Remohí[2], E. Bosch[2]

[1]IVI RMA Valencia, Human Reproduction, Valencia, Spain
[2]IVI-RMA Valencia, Human Reproduction, Valencia, Spain

Study question:

Which is the threshold of serum Progesterone the day of embryo transfer in artificial endometrium preparation cycles that significantly reduces the chances of ongoing pregnancy?

Summary answer:

Patients with serum Progesterone levels <8.8 ng/mL the day of embryo transfer had significantly lower ongoing pregnancy rate than the rest of patients.

What is known already:

Recent retrospective studies have suggested a relationship between serum Progesterone (P) levels on the mid-luteal phase and pregnancy outcome in artificial cycles when using vaginal progesterone. Our group published the first prospective trial analyzing this topic and found that those patients with serum P levels <9.2ng/ml on the day of embryo transfer had 20% less chances of ongoing pregnancy ($p<0.05$) in a sample of 211 oocyte donation recipients' patients with strict inclusion criteria. Our aim is to analyze if these results are applicable to the general population under same preparation protocol, due to the significant clinical impact of the results.

Study design, size, duration:

Prospective cohort study including 1166 patients undergoing embryo transfer after an artificial endometrial preparation cycle with estradiol valerianate and vaginal micronized progesterone (400 mg/12 hours).

The study was performed between September 2017 and November 2018.

Sample size was calculated to detect a 10% difference (40-50%) between 2 groups according to serum P levels, in a two-sided test with a statistical power of 80% and a confidence level of 95%.

Participants/materials, setting, methods:

Patients undergoing a blastocyst transfer with an artificial cycle with their own or donated eggs, age <50, BMI <30 Kg/m^2, with a triple layer endometrium >6.5 mm, and being transferred 1-2 good quality blastocysts; in a private infertility centre.

Serum P determination was performed immediately before the embryo transfer. Primary endpoint was ongoing pregnancy rate beyond the 12thweek of pregnancy. The timeframe between last dose of exogenous progesterone and the embryo transfer was recorded.

Main results and the role of chance:

A total of 1155 patients could finally be analysed (pregnancy outcome is not available in 11 patients). The mean age was 39.6±4.6; BMI: 23.7±4.2;Endometrial thickness: 8.8±1.6 mm. A mean of 1.2±0.3 blastocysts were transferred. Ongoing pregnancy rate (OPR) was 53.1±5.0% in the whole population.

Mean serum P the day of ET was 12.0±5.8 ng/mL. The OPR according to the 10 percentiles (p) of serum P levels were: <p10: 34.2%; p10-20: 41.3%; p20-30: 43.0%; p30-40: 56.1%; p40-50: 53.8%; p50-60: 63.4%; p60-70: 59.8%; p70-80: 59.8%; p80-90: 51.7%, >p90: 61.8% (p=0.000). Women with serum P levels <8.8 ng/mL (percentile 30) had a significantly lower OPR compared to the rest of patients: 39.8% vs. 58.0%, RR (95% CI): 0.69 (0.59-0.79); p<0.0001.

After adjusting for all potential confounders (age, BMI, endometrial thickness, serum E2, number of embryos transferred, origin of oocytes), having a serum P<8.8 ng/mL remained as a significant negative factor for ongoing pregnancy; OR (95% CI)= 0.39 (0.28-0.53), p=0.000.

The timeframe between the last dose of vaginal progesterone and embryo transfer was not correlated neither with the serum P levels nor the ongoing pregnancy rate.

Limitations, reasons for caution:

Only women with micronized vaginal progesterone were included in the study, thus, extrapolation to other ways of progesterone administration needs to be validated.

Wider implications of the findings:

This large study has found the optimal threshold of serum P values the day of embryo transfer that needs to be reached in artificial endometrial preparation cycles to optimize the outcome.

Trial registration number:

NCT03272412

O-174 Cabergoline versus calcium gluconate infusion in the prevention of ovarian hyperstimulation syndrome. A randomized controlled trial

H. El-Shaer[1,2], U. Fouda[1,2], G. Youssef[1], A. Hanafy[1], H. Nabil[1], W. Mehrem[3]

[1] *Cairo University- Faculty of medicine, Obstetrics and Gynecology Department, Giza, Egypt*

[2] *Riyadh fertility and reproductive health center, Assisted conception unit, Giza, Egypt*

[3] *Al Gazeera hospital, Assisted conception unit, Giza, Egypt*

Study question:

Is calcium gluconate infusion more effective than cabergoline in the prevention of ovarian hyperstimulation syndrome (OHSS) in IVF patients at risk for developing OHSS ?

Summary answer:

Calcium gluconate infusion is as effective as cabergoline in the prevention of OHSS in IVF patients at risk for developing OHSS.

What is known already:

Several animal and human studies highlighted the role of vascular endothelial growth factor (VEGF) in the pathogenesis of OHSS. The use of cabergoline (which inhibits VEGF receptor 2 phosphorylation and signaling) and calcium gluconate infusion (which inhibits VEGF synthesis) in the prevention of OHSS has been investigated in several studies. A recent Cochrane review revealed that cabergoline was associated with a lower incidence of moderate/severe OHSS compared with placebo (11.83% Vs 33.88%). A randomized controlled study revealed that calcium gluconate infusion was associated with a lower incidence of moderate/severe OHSS compared with placebo (1% Vs 12%).

Study design, size, duration:

Between October 2016 and December 2018, this randomized controlled study recruited 170 patients who were stimulated using the long luteal GnRH agonist protocol and at high risk for developing OHSS. Patients with more than 18 follicles (> 11mm) and serum estradiol ≥ 3000 pg/ml on the day of HCG administration were considered at risk for OHSS. The study was conducted at Riyadh fertility and reproductive health center, Giza, Egypt and Al Gazeera hospital, Giza, Egypt.

Participants/materials, setting, methods:

Patients were randomized in a 1:1 ratio to cabergoline group and calcium gluconate group. In cabergoline group , 0.5 mg of cabergoline was administered once daily p.o for 8 days starting on the day of HCG administration. In calcium gluconate group, intravenous calcium gluconate (10%,10 ml in 200 ml of physiologic saline) was administered daily for 4 days starting on the day of ovum pickup.

Main results and the role of chance:

Six patients in cabergoline group and eight patients in calcium gluconate group developed moderate OHSS. One patient in each group developed severe OHSS. The incidence of moderate/severe OHSS was comparable between both groups (8.24% Vs 10.59%, P value = 0.599, OR= 0.76, 95% CI [0.269 - 2.138]). Both groups did not differ statistically in the age, body mass index, basal FSH, antral follicle count, anti-Müllerian hormone level, cause of infertility and duration of infertility. Both drugs were well tolerated and there were no adverse effects occurring in both groups. The number of retrieved oocytes , fertilization rate, quality of embryos transferred and number of embryos transferred were comparable between both groups. The implantation, clinical pregnancy and ongoing pregnancy rates were similar in the two groups (16.91% Vs. 15.84%, P = 0.771, 35.29% Vs. 32.94%, P = 0.746, 30.59% Vs. 28.24% , P = 0.736, respectively).

Limitations, reasons for caution:

The main limitations of the current study are the open label design and lack of measurement of serum levels of calcium, renin, angiotensin II and VEGF before and after calcium gluconate infusion.

Wider implications of the findings:

Calcium gluconate infusion and cabergoline are equally effective in minimizing the risk of OHSS. Both drugs are well tolerated, cheap and have no adverse effects on the reproductive outcomes of IVF cycle.

Trial registration number:

ClinicalTrials.gov: NCT02875587

O-175 Clinical pregnancy rates among anovulatory and oligoovulatory women after letrozole versus hormone replacement therapy in frozen-thawed embryo transfer cycles

M. Sharon - weiner[1], S. Farladansky-Gershnabel[1], A. Berkovitch[1]

[1] *Meir Medical Center, Obstetrics and Gynecology, Kfar Saba, Israel*

Study question:

Does letrozole versus HRT result in higher clinical pregnancy rate among anovulatory and oligoovulatory women in frozen-thawed embryo transfer (FET) cycles?

Summary answer:

Letrozole use among anovulatory or oligoovulatory women was associated with significantly higher clinical pregnancy rate, as compared to HRT in FET cycles.

What is known already:

The use of letrozole in FET cycles is associated with higher clinical pregnancy rates. However, the advantage of letrozole compared to HRT in FET cycles has not been evaluated specifically among anovulatory and oligoovulatory women for whom the alternative of a natural cycle without endometrial preparation is not an option.

Study design, size, duration:

This prospective study of 213 FET cycles among anovulatory and oligoovulatory women was conducted from 1/2017 through 12/2018. Since letrozole has recently become an effective alternative to HRT cycles, all patients with ovulation disorders undergoing FET, were given letrozole beginning in 1/2018, instead of HRT.

Participants/materials, setting, methods:

Letrozole was given in 86 cycles and HRT was given in 127 cycles of anovulatory and oligoovulatory women undergoing FET. The primary outcome measure was clinical pregnancy (fetal heartbeat) rate. Secondary outcome measures were rates of multiple pregnancies and miscarriages.

Main results and the role of chance:

Clinical pregnancy (fetal heartbeat) rate was significantly higher in the letrozole group as compared to the HRT group. The adjusted risk ratio for clinical pregnancy (fetal heartbeat) for letrozole as compared with HRT cycles was 1.98 (95% CI: 1.07-3.67). Miscarriage and multiple pregnancy rates did not differ significantly between groups. The adjusted risk ratio for maternal smoking for letrozole as compared with HRT cycles was 3.59 (95% CI: 1.07-12.07). No significant difference was found between groups regarding maternal age, BMI, indication for fertility treatment (male versus nonmale), peak estradiol levels, number of oocytes retrieved, number of cleavage/blastocyst embryos, number of frozen embryos and number of transferred embryos.

Limitations, reasons for caution:

A randomized prospective study design was not used to prescribe letrozole versus HRT to the study participants.

Wider implications of the findings:

These results suggest that letrozole as compared to HRT may improve clinical pregnancy rates among anovulatory and oligoovulatory women undergoing FET cycles.

Trial registration number:

not applicable

O-176 The luteal phase of double ovarian stimulation treatment (DuoStim) provides higher oocyte and blastocyst yield in unselected infertile patients: a retrospective, same-patient, cohort study

D. Bodri[1], J.C. Castillo[1], B. Moliner[1], J. Llácer[1], A. Fuentes[1], P. Cirillo[1], Á. Llaneza[2], J. Ten[1], A. Bernabeu[1], R. Bernabeu[1]

[1] *Instituto Bernabeu, Assisted Reproduction Unit, Alicante, Spain*
[2] *Instituto Bernabeu, Assisted Reproduction Unit, Madrid, Spain*

Study question:

What are the differences in stimulation and laboratory outcome variables between the follicular and luteal phases of double ovarian stimulation (DuoStim) in unselected infertile patients?

Summary answer:

Luteal phase of Duostim achieved higher follicular recruitment, oocyte and blastocyst yield. Fresh oocytes from aged infertile patients had better developmental competence than vitrified ones.

What is known already:

After it was first presented in the reproductive literature (Kuang, 2014), double ovarian stimulation has gradually gained in popularity, but was only applied in low responders or for fertility preservation in cancer patients. So far only few, small-sized studies have evaluated DuoStim and observations regarding laboratory and clinical outcomes are still preliminary. Furthermore, cost-sparing strategies including accumulation by oocyte vitrification were still not investigated in conjunction with DuoStim treatment.

Study design, size, duration:

All consecutive patients (n=69) who initiated DuoStim treatment during January - December 2018 were included in this retrospective analysis. Stimulation characteristics and laboratory outcomes variables were compared between the follicular (first) and subsequent luteal (second) stimulation phases. Clinical outcomes were evaluated for those patients who underwent (n=23) subsequent frozen-thawed embryos replacement (FER).

Participants/materials, setting, methods:

Recombinant and/or urinary gonadotropins (up to 300 IU daily) and GnRH antagonists were used in both stimulations with 0-6 (mainly 2-3) days gap between phases. Oocyte maturation was triggered with a GnRH agonist (triptorelin 0.2 mg) in the first, and rhCG or dual trigger in the second phase. Mature eggs were frozen during the egg accumulation phase(s) and fertilized together with fresh retrieved eggs at the final stimulation; cultured to until blastocyst-stage and electively vitrified.

Main results and the role of chance:

Sixty-nine patients underwent 73 treatment cycles. Mean female age was 38.1±3.5 (range: 24-43 years) with 67% having low ovarian reserve. Main indications were oocyte accumulation/embryo freezing in low (n=46) or normo-responder (n=14) patients, PGT-A (n=18) or fertility preservation (n=5). There were no significant differences in stimulation duration (9.9±2.3 versus 10.3±2.6, p=0.3) or total gonadotropin dose (2851±1025 versus 3047±1035, p=0.25). Total DuoStim treatment duration was 26.3±4.3 (range: 16-38 days). Follicular (>13 mm) recruitment (5±3 vs 6.7±4.1, p=0.003), the number of retrieved total (3±2.7 vs 5.3±4.3, p=0.0002) and mature (2.6±2,1 vs 4.7±3.5, p=0.0001) oocytes and blastocysts vitrified (0.7±0.9 vs 2±1.7, p=0.0003) was significantly higher in the luteal phase. More cases of no-oocytes retrieved occurred in the follicular-phase stimulation (15% vs 5%, p=0.05). The average survival rate of frozen oocytes from the first stimulation phase was 90%. Fertilization (43% vs 66%, p=0.002) and blastocyst formation rates per fertilized eggs (33% vs 55%, p=0.03) were higher for fresh oocytes. So far 10 clinical/ongoing pregnancies (43%) were achieved in 23 patients who have undergone subsequent FER. A 38-year-old, low-responder patient has undergone three consecutive stimulation attempts ("TripleStim") lasting a total of 49 days with increasing oocyte yield in each phase (0, 5 and 9 eggs).

Limitations, reasons for caution:

Due to the retrospective nature of this study patients were not included according to prospectively established inclusion criteria resulting in a heterogenous cohort. Due to the recent study period, not all frozen oocytes and/or blastocysts were utilized limiting conclusions on clinical outcomes.

Wider implications of the findings:

Although so far DuoStim was mainly used in aged low-responder patients, its indications could be extended to other groups who could benefit from an increased oocyte yield: intermediate-aged (36-39 years) patients with suboptimal ovarian response, PGT-A candidates or used as "cycle-rescue" following unexpected low oocyte yield or no oocytes retrieved.

Trial registration number:

O-177 Luteal serum progesterone levels cannot be predicted in IVF patients - A prospective study of 432 IVF/ICSI cycles

L. Thomsen[1], U.S. Kesmodel[2], P. Humaidan[1]

[1] *Department of Clinical Medicine- Aarhus University- Denmark., The fertility Clinic- Skive Regional Hospital- Denmark., Skive, Denmark*
[2] *Department of Clinical Medicine- University of Copenhagen- Denmark., The fertility Clinic- Herlev Hospital- Denmark., Herlev, Denmark*

Study question:

Is it possible to predict the early luteal serum progesterone (P4) level of IVF patients receiving a fresh embryo transfer?

Summary answer:

The corpus luteum (CL) function after trigger is highly individual and the luteal serum P4 level cannot be predicted based on general patient characteristics.

What is known already:

Luteal P4 levels seem to influence the reproductive outcome following fresh embryo transfer (ET). A recent study has shown that both very low (<60 nmol/l) and very high (>400 nmol/l) serum P4 levels in the early luteal phase reduce the chance of pregnancy. Monitoring of luteal P4 levels and an individualization of luteal phase treatment according to serum P4 levels may improve the chance of live birth. To avoid monitoring the total patient cohort, it would be beneficial if patients with the risk of suboptimal luteal P4 levels could be identified prior to ET based on known patient characteristics.

Study design, size, duration:

Prospective study of 432 patients undergoing IVF treatment and fresh ET. Patients were recruited from Danish fertility centers from May 2014 to June

2017. Patients were co-treated in a GnRH-antagonist protocol or a long GnRH-agonist protocol and triggered for final oocyte maturation with either a bolus of hCG or GnRH-agonist. Identical luteal phase support regimens were used in all patients. Serum P4 levels were measured during the early luteal phase (2-3 days following oocyte retrieval).

Participants/materials, setting, methods:

Maternal age, maternal BMI, number of final follicles, type of ovulation trigger and the day of P4 monitoring were included in a linear regression model to explore whether these parameters could predict the subsequent luteal serum P4 level with sufficient accuracy for clinical usage. In a second model, additional information in terms of protocol type, duration of stimulation, smoking, total gonadotropin dose and type of gonadotropin was added.

Main results and the role of chance:

Significant individual differences in CL function were seen, also in patients with similar characteristics. In patients with the same number of final follicles (11), the same protocol (GnRH antagonist) and the same regimen for final oocyte maturation (GnRH agonist), the inter-patient luteal P4 level varied from 68 to 566 nmol/l. Using a linear regression model, including maternal age, BMI, day of P4 monitoring and type of ovulation trigger as independent variables, the adjusted R-squared was 0.48. Adding protocol type, duration of stimulation, smoking, total gonadotropin dose and type of gonadotropin only increased the R-squared to 0.49. Thus, even though a wide range of patient parameters are known, the statistical model only explains approximately 50% of the random variation seen in the data. The remaining variation is caused by biological differences in corpus luteum function between patients. Using the regression model and the present data set, the prediction interval (PI) for early luteal P4 levels (nmol/l) in a patient with known age, BMI, final number of follicles and type of trigger was 95% PI [45;421]. This clearly demonstrates that the prediction of luteal serum P4 levels based on patient characteristics is troublesome and has no clinical relevance.

Limitations, reasons for caution:

The findings of this study should be confirmed in future larger trials with the possibility to include additional significant covariates in the statistical model.

Wider implications of the findings:

If patients with suboptimal corpus luteum function should be identified for the individualization of treatment, the circulating serum P4 level must be measured in the total patient cohort as the corpus luteal function is highly individual and cannot be predicted by patient characteristics nor by responses to treatment.

Trial registration number:

NCT02129998 (Clinicaltrials.gov).

[8]Harvard Medical School and Brigham and Women's Hospital, Channing Division of Network Medicine, Boston, U.S.A.

Study question:

Is adherence to specific dietary patterns associated with testicular function in young men?

Summary answer:

Adherence to high fat unhealthy Western dietary pattern was associated with impaired testicular function while prudent diet high in fruits and vegetables was positively associated.

What is known already:

Sperm count has been declining in the Western countries over the past few decades, and determining the risk factors for this is crucial. Coinciding with the decline in sperm count has been a decline in diet quality. A number of studies have examined the role of diet on semen quality but data on how adherence to different diet patterns influences testicular function is scarce among men in northern Europe. In addition, the population recruited in these studies have been relatively small and selective.

Study design, size, duration:

We assessed diet, semen quality, reproductive hormones, and lifestyle factors among 2,935 healthy young Danish men presented to a compulsory medical examination to determine their fitness for military service between 2008 and 2017.

Participants/materials, setting, methods:

Dietary patterns were identified by principal component analysis (PCA). We measured testicular function as conventional semen quality parameters (semen volume, sperm concentration, total count, percentages of motile and morphologically normal spermatozoa), and serum concentrations of reproductive hormones (LH, FSH, testosterone, Estradiol, SHBG, inhibin B). We used multivariable quantile regression to estimate the association between diet patterns and testicular function.

Main results and the role of chance:

We identified four dietary patterns: the "Western" pattern characterized by intake of pizza, chips, processed and red meats, snacks, refined grains, high-energy drinks, and sweets; the "Prudent" pattern characterized by intake of fish, chicken, vegetables, fruit, and water; the "Smørrebrød" pattern characterized by intake of cold processed meats, whole grains, mayonnaise, cold fish, condiments, and dairy; and the "Vegetarian" pattern characterized by intake of vegetables, soymilk, and eggs. After adjusting for confounders, the median sperm count for men in the highest quintile of adherence to the "Western" pattern was 25.6 (95% CI: -42.3,-8.86) million lower than that of men in the lowest quintile (P-trend=0.005) . Conversely, the median sperm count of men in the highest quintile of adherence to the "Prudent" pattern was 42.8 (22.9, 62.7) million higher than that of men in the lowest quintile (P-trend<0.0001). Adherence to the "Prudent" pattern was associated with the highest sperm count followed by adherence to "Vegetarian" and "Smørrebrød" patterns; adherence to the "Western" pattern was associated with the lowest sperm count. The "Western" pattern was associated with lower inhibin-B (P-trend=0.006) and higher free testosterone concentrations (P-trend<0.0001), while the "Prudent" pattern was associated with lower estradiol (P-trend=0.001) and higher SHBG concentrations (P-trend=0.04).

Limitations, reasons for caution:

This was a cross-sectional study, which limits our ability to determine causality.

Wider implications of the findings:

Our findings support the growing evidence that adhering to generally healthy diet patterns, including local variations, is associated to higher sperm counts and more favorable markers of sperm function.

Not applicable

O-179 Prenatal exposure to paternal smoking and semen quality in the adult offspring

S. Tøttenborg[1], K.K. Hærvig[1], B.B. Høyer[2], A. Giwercman[3], K.S. Hougaard[4], C. Ramlau-Hansen[2], I.O. Specht[5], G. Toft[6], J.P.E. Bonde[1]

[1]Bispebjerg Fredereiksberg Hospital, Department of Occupational and Environmental Medicine, Copenhagen, Denmark
[2]Aarhus University, Department of Public Health- Section for Epidemiology, Aarhus, Denmark
[3]Lund University, Molecular Reproductive Medicine- Department of Translational Medicine, Lund, Sweden
[4]National Research Centre for the Working Environment, National Research Centre for the Working Environment, Copenhagen, Denmark
[5]Bispebjerg Fredereiksberg Hospital, The Parker Institute- Research Unit for Dietary Studies, Copenhagen, Denmark
[6]Aarhus University, Department of Clinical Medicine- Department of Clinical Epidemiology, Aarhus, Denmark

Study question:
Is prenatal exposure to paternal smoking related to adult offspring semen parameters independently of prenatal exposure to maternal smoking?

Summary answer:
Paternal smoking is associated with lower sperm concentration and total sperm count and more non-progressive sperm independent of maternal smoking and other confounding factors.

What is known already:
The negative impact of maternal smoking during pregnancy on offspring semen quality is well established. Evidence is emerging that also preconception paternal smoking can induce epigenetic alterations in the sperm genome which can be transmitted to the cells of the offspring. Two recent studies investigating offspring semen quality in relation to prenatal exposure to parental smoking found that paternal smoking was associated with lower sperm counts independently of maternal smoking. However, these studies lacked information on key confounders, relied on retrospectively collected smoking information, and had small populations. Larger follow-up studies with extensive confounder information are needed to corroborate findings.

Study design, size, duration:
Population-based follow-up study of 536 young men aged 19 years from the Fetal Programming of Semen Quality (FEPOS) cohort, a sub-cohort of sons to mothers enrolled in the Danish National Birth Cohort (DNBC) during 1996-2002. Semen parameters were assessed at the Department of Occupational and Environmental Medicine at Bispebjerg Hospital in Copenhagen and the Department of Occupational Medicine at Aarhus University Hospital in Aarhus from April 2017 through May 2018.

Participants/materials, setting, methods:
Parental smoking information was based on maternal report around gestational week 16. Semen and testicle size were analyzed according to WHO-recommendations. Incidence rate ratios of semen volume, sperm concentration, count, and motility were calculated using negative binomial regression, difference in morphology with linear regression, and risk of testicle size< 12 ml with logistic regression, adjusting for maternal smoking and age, pre-pregnancy BMI, alcohol and caffeine consumption, paternal age, household occupational status, and son's abstinence time.

Main results and the role of chance:
In adjusted analyses, sons of fathers who smoked daily had a 15% lower sperm concentration (IRR 0.85, 95%CI 0.69;1.04), and 21% lower total sperm count (IRR 0.79, 95%CI 0.62;1.02), but same semen volume as compared to sons of paternal never smokers. While the differences in percentages of progressive and immotile sperm were not statistically significant, a 21% increase in non-progressively motile sperm was observed for sons of father's who smoked compared to those who never smoked (IRR 1.21, 95%CI 1.01;1.46). Although not statistically significant, analysis suggested that paternal daily smoking was associated with a 16% higher risk of having small testicle size as compared to paternal never smoking.

Limitations, reasons for caution:
Paternal and maternal smoking relied on mother's self-report and was not cotinine verified. Further, paternal smoking was assessed around gestational week 16 and may be less frequent than pre-conceptional smoking, though studies have shown a high correlation between pre-and postconceptional smoking.

Wider implications of the findings:
This study corroborates previous findings that paternal smoking affect offspring sperm concentration and total sperm count independently of maternal smoking. In our study, the association was also independent of other prenatal risk factors for adult semen quality including parental age, alcohol and caffeine consumption, pre-pregnancy BMI, and household occupational status.

O-180 Only high-risk human papillomavirus in semen is associated with high sperm DNA fragmentation index in primary infertile men

P. Capogrosso[1], L. Boeri[2], E. Ventimiglia[3], W. Cazzaniga[3], F. Chierigo[3], E. Pozzi[3], F. Montorsi[3], A. Salonia[3]

[1]San Raffaele Scientific Institute, Urology, Milan, Italy
[2]IRCCS Policlinico Milano, Urology, Milano, Italy
[3]IRCCS Ospedale San Raffaele, Urology, Milano, Italy

Study question:
We aimed to assess the impact of the presence of HPV in semen over the seminal parameters and SDF values in primary infertile men

Summary answer:
HPV seminal infection, in particular infections involving exclusively HR genotypes, was associated with impaired sperm progressive motility and SDF values

What is known already:
Human papillomavirus (HPV) is commonly present in semen sample. However, whether the presence of HPV in semen is actually associated with impaired semen parameters and sperm DNA fragmentation (SDF) values has yet to be elucidated

Study design, size, duration:
Cross sectional study of 729 infertile men

Participants/materials, setting, methods:
Comorbidities were scored with the Charlson Comorbidity index (CCI). Serum hormones and sperm DNA fragmentation index (SDF; SDF $\geq$30% was defined as pathologic) were measured in every patient. Semen analysis was based on 2010 WHO reference criteria. Amplification by nested polymerase chain reaction (PCR) was used to detect HPV-DNA sequences in semen samples. Descriptive statistics and linear regression models tested the association between HPV presence and clinical and seminal characteristics in the whole cohort

Main results and the role of chance:
The overall HPV positivity was 15.5% (113/729). Of all, 78/729 (10.7%) and 35/729 (4.8%) patients had high-risk (HR) HPV+ and low-risk (LR) HPV+, respectively. HPV16 was the most prevalent type (22.1%), followed by HPV43 (10.6%), HPV56 and HPV42 (both 8.8%). No differences were found in terms of clinical and hormonal characteristics between patients with or without seminal HPV. Sperm progressive motility was lower (16% vs. 22%; p=0.01) while SDF values were higher (35.9% vs. 28.3%; p=0.005) in HPV+ than in – HPV patients. HR HPV+ men had lower sperm progressive motility (12.5% vs. 22%; p=0.007) and higher SDF values (40.3% vs. 28.3%; p=0.003) than -HPV. Univariable linear regression analysis showed that HR HPV+ was associated with impaired sperm progressive motility (p=0.002) and SDF values (p=0.003). At multivariable analysis, age (beta -0.36), FSH levels (beta -0.51) and testicular volume (beta 0.66) were associated with impaired sperm progressive motility (all p$\leq$0.04). Conversely BMI, CCI, smoking habits and HPV status were not. Only age (beta 0.4; p=0.02) and FSH (beta 1.38; p=0.01) were associated with SDF, after accounting for BMI, CCI, testicular volume, smoking habits and HPV status.

Limitations, reasons for caution:
Retrospecrive design

Wider implications of the findings:
These findings outline the role of an accurate investigation of seminal HPV presence over the diagnostic work-up of primary infertile men

Trial registration number:
NA

O-181 Human sperm morphology as a marker of its nuclear quality and epigenetic status: implications for oocyte injection.

M. Bendayan[1], L. Caceres-Sanchez[1], J. Selva[1], L. Alter[1], J. Firmin[1], K. Fathallah[1], S. Bouba[1], V. Duranthon[2], A. Bonnet-Garnier[2], F. Boitrelle[1]

[1]*CHI de Poissy-St-Germain-En-Laye, Service de Biologie de la Reproduction -, Poissy, France*

[2]*UMR Bdr, INRA ENVA Université Paris Saclay, 78350- Jouy en Josas, France*

Study question:

Is there any morphological characteristic of one alive spermatozoon that could predict its nuclear quality and its epigenetic status.

Summary answer:

Observed under high-magnification, spermatozoa with vacuoles present retained histones H3 and the mark H3K4me3. Spermatozoa with no vacuole present higher degree of protamination and H3K27me3.

What is known already:

In human sperm, histones are replaced by protamines during spermiogenesis to allow chromatin condensation. During this replacement, multiple epigenetic events can occur (such as post-translational histone modifications PTMs). Observed under high-magnification, alive spermatozoa with vacuoles were associated to low chromatin condensation levels and vacuoles were defined as DNA – free structures. These results have suggested a difference in terms of sperm nuclear quality between vacuolated ones and those with no vacuole. Nothing was known about epigenetic marks of these spermatozoa.

Study design, size, duration:

Between January and September 2018, we studied sperm samples of 20 infertile patients with differing sperm profiles. Epigenetic marks, known to be present on human spermatozoa and known as potentially implied in embryo development of animals were selected. Firstly, we performed immunostaining of epigenetic marks at one-cell (sperm) scale. Then, we assessed epigenetic profiles of a total of 4000 alive spermatozoa in function of the presence of one vacuole or not.

Participants/materials, setting, methods:

For each sperm sample, 200 alive normal spermatozoa were selected under high-magnification (100 without vacuole and 100 with a vacuole occupying >15% of head-area). For each sample, we have analysed by specific immunofluorescence two nucleoproteins: Protamine and Histone H3 and eight epigenetic marks (PTMs): H3K4me1, H3K4me2, H3K4me3, H3K9me1, H3K9me2, H3K9me3, H3K27me3 and H4k20me2. A total of 4000 spermatozoa were assessed. Three-dimensional deconvolution microscopy enabled us to reconstruct images of each sperm nucleus and epigenetic patterns.

Main results and the role of chance:

The degree of histone-replacement differs from one spermatozoa to another. Spermatozoa with vacuoles were significantly more prone to retain histone H3 and H3K4me3 than spermatozoa with no vacuole. Morphologically normal spermatozoa without vacuole presented a significantly higher degree of protamination (P2) and retained significantly more H3K27me3 than vacuolated spermatozoa. These epigenetic profiles suggest that vacuolated spermatozoa have an immature chromatin closest to spermatids which could have, according to literature data, negative impacts on embryo development. 3D visualization of vacuolated spermatozoa showed that protamins were located at the basement of vacuoles while H3, H3K4me3 and H3K9me1 (all related to DNA decondensation) filled these area, described until now as DNA – free spaces. These results argue in favour of a nuclear nature of sperm vacuoles, more precisely as an epigenetic nature of sperm vacuoles that should be considered as good individual markers of chromatin non-condensation in one human spermatozoon. Thus, this is the first time here that a morphological characteristic of alive spermatozoa could be linked to epigenetic marks.

Limitations, reasons for caution:

The impact of these marks on embryo development until blastocyst-stage (as suggested by literature) should be proved in further studies.

Wider implications of the findings:

This study was the first to identify the epigenetic pattern of one alive spermatozoon according to its morphology. Selection of an alive spermatozoon, knowing its epigenetic status before oocyte injection, becomes possible. To avoid spermatozoa with vacuole allows to deselect spermatozoa with bad nuclear quality.

[11]*Andrology, Cairo University, Cairo, Egypt*

Study question:

Which are the reference ranges and the clinical, hormonal and seminal correlations of the ultrasound parameters of the male genital tract in healthy-fertile men?

Summary answer:

The reference ranges and clinical, hormonal, seminal correlations of the male genital tract ultrasound parameters in healthy-fertile men have been assessed by the EAA project.

What is known already:

Infertility affects up to 12% of all men. Despite much progress, mainly in genetics, its etiology remains obscure in about half of cases. To fill this gap, imaging of the male genital tract has progressively expanded, providing useful information in the assessment of male genital tract abnormalities. However, sonographic imaging of the male genital tract still suffers from a lack of standardization, and often tends to produce subjective and vague diagnoses. This is the main reason why the European Academy of Andrology has promoted a multicenter study (see http://www.andrologyacademy.net/studies) aimed at defining the anatomic and functional characteristics of healthy-fertile men.

Study design, size, duration:

Cohort, multicentric, international (11 EAA Centers), observational study. Sample size estimated according to the Clinical and Laboratory Standard Institute Guidelines (2000) as 200 subjects. Duration of the project: 36 months. Study design: evaluation of at least 200 healthy-fertile men according to Standard Operation Procedures (http://www.andrologyacademy.net/studies) performed within the same day: 1)personal and medical history; 2)physical examination; 3)hormonal and glyco-metabolic evaluation; 4)scrotal and transrectal ultrasound before and after ejaculation; 5)semen analysis (according to the WHO, 2010).

Participants/materials, setting, methods:

Evaluation using clinical and ultrasound Standard Operation Procedures of at least 200 healthy-fertile men in Outpatient Clinic of 11 EAA Centers. The inclusion criteria were: 1.mens aged >18 years; 2.partners of a pregnant woman in the second or third trimester of pregnancy, or men who fathered a child during the last year, under natural conception; 3.capacity to give consent for study participation. The exclusion criteria were: previous or current systemic diseases and/or medications affecting fertility.

Main results and the role of chance:

We enrolled 248 healthy-fertile men (35.3±5.9 years). Data on 248 scrotal and 188 transrectal ultrasound evaluations are available. The main results are the following: 1)Production, for the first time, of normative values and reference ranges of the organs of the entire male genital tract assessed by color-Dopper ultrasound. 2)Evaluation of the main fertiliy, life-style, medical history and physical examination characteristics of healthy-fertile men, showing median time to pregnancy as 3 months; current smokers and alcohol consumption in 25% and 35%, respectively; physical activity in 50%; absent history of cryptorchidism; mumps in 30% but without orchitis; history of genito-urinary infections in 15%. 3)Positive associations between mean testis volume and sperm concentration and progressive motility (but not normal morphology), confirmed after adjusting for confounders (age, waistline, calculated free testosterone, #EAA centers) (adj.r=0.229, p<0.0001 and adj.r=0.154, p=0.02, respectively). 4)Negative associations between mean testis volume and LH and FSH levels (but not testosterone levels), confirmed in adjusted models (adj.r=-0.363, p<0.0001 and adj.r=-0.197, p<0.005, respectively). 5)Varicocele prevalence 38%. 6)Positive associations between prostate volume, age and body mass index (both p<0.005), but not with testosterone levels. 7)Positive association between seminal vesicles emptying volume documented by ultrasound and semen volume, confirmed in adjusted model (adj.r=0.493, p<0.0001).

Limitations, reasons for caution:

The population studied is made of healthy-fertile men, but fertile men may be not healthy by definition. In addition, investigator meetings have been organized to standardize the clinical and ultrasound method to be followed by the EAA Centers: other sonographers should follow Standard Operation Procedures (http://www.andrologyacademy.net/studies) to standardize their results.

Wider implications of the findings:

This study will: 1)allow a better understanding of male infertility, by comparison of cohorts of infertile men with a true control group of healthy-fertile men; 2)allow the categorization of risk factors (e.g. smoking, alcohol, sedentary, criptorchidism); 3)allow a different management of male genital tract abnormalities (e.g. varicocele).

Trial registration number:

SESSION 52: ART FROM THE POINT OF VIEW OF SAFETY

Tuesday 25 June 2019 Haydn 2 15:15 - 16:30

O-183 Long-term risk of ovarian tumours after assisted reproductive technology

M. Spaan[1], A.W. Van den Belt-Dusebout[1], C.B. Lambalk[2], H.H. Van Boven[3], C.W. Burger[4], F.E. Van Leeuwen[1]

[1]Netherlands Cancer Institute, Epidemiology, Amsterdam, The Netherlands
[2]Amsterdam UMC, Department of Obstetrics & Gynecology, Amsterdam, The Netherlands
[3]Netherlands Cancer Institute, Pathology, Amsterdam, The Netherlands
[4]Erasmus University Medical Center, Department of Gynecologic Oncology, Rotterdam, The Netherlands

Study question:

Does assisted reproductive technology (ART) increase the risk of invasive and borderline ovarian tumours?

Summary answer:

After a median follow-up of 22 years, the risk of invasive ovarian cancer is not increased.

What is known already:

Despite the large number of women treated with ART every year, evidence about the long-term risk of ovarian tumours after ART is lacking. Previous studies, with a median follow-up of 4 to 17 years, showed inconsistent results with respect to invasive ovarian cancer, while for borderline ovarian tumours an increased risk was found in several reports.

Study design, size, duration:

Long-term risk of ovarian tumours was assessed in the OMEGA study, a nationwide historical cohort with prospective follow-up. The cohort includes 30,636 women who received ovarian stimulation for ART (ART group) between 1983 and 2001 in one of the 12 Dutch IVF centers and 9,969 women who underwent subfertility treatments other than ART (non-ART group) between 1980 and 2001. Median follow-up amounted to 22 years.

Participants/materials, setting, methods:

Detailed information on subfertility cause and treatment was collected from the medical records. Data on reproductive and lifestyle factors were obtained from the women through a questionnaire. Cancer incidence was ascertained through linkage with the Netherlands Cancer Registry (1989-July 2018). Ovarian cancer risk in the cohort was compared between the ART group and non-ART group using multivariable time-dependent Cox regression analyses.

Main results and the role of chance:

After a median follow-up of 22 years 143 invasive ovarian cancers were observed in the entire cohort, 108 in the ART group (36/10,000) and 35 in the non-ART group (35/10,000). The risk of ovarian cancer in ART-treated women was not increased (hazard ratio (HR): 1.03, 95% confidence interval (CI) 0.70-1.52) compared with the non-ART group. In addition, no trend emerged with a higher number of ART cycles (1-2 cycles HR:1.23, 95% CI 0.79-1.91, 3-4 cycles HR:0.82, 95% CI 0.51-1.32, 5-6 cycles HR:0.77, 95% CI 0.40-1.50, >7 cycles HR: 1.50, 95% CI 0.80-2.80). The risk did also not increase after long follow-up (>25 years: HR: 1.03, 95% CI 0.37-2.88).

As expected, parous women had a reduced risk of ovarian cancer (HR: 0.57, 95% CI 0.41-0.80) compared with nulliparous women. Although there was no significant interaction between parity and ART, ovarian cancer risk tended to be slightly increased in parous women treated with ART compared to parous women not treated with ART (HR: 1.40, 95% CI 0.50-1.51), while among nulliparous women ART-treatment did not increase ovarian cancer risk (HR:0.87, 95% CI 0.80-2.42).

Limitations, reasons for caution:

Risk of borderline tumours could not yet be analysed because data collection through the nationwide network and registry of histo- and cytopathology in the Netherlands (PALGA) is currently being completed. The final results, including the risk of borderline ovarian tumours, will be available for presentation at the ESHRE conference.

Wider implications of the findings:

This large study, with an internal comparison group of subfertile women not treated with ART, importantly contributes to knowledge of the long-term risks of ART. The reassuring results with respect to invasive ovarian cancer can be used to inform couples who are contemplating to start or continue with ART.

O-184 No decreased chance of a live born child in women with epilepsy after assisted reproduction treatment: a nationwide cohort study

M.D. Larsen[1], L.R. Jølving[1], J. Fedder[2], B.M. Nørgård[1]

[1]Odense University Hospital and University of Southern Denmark, Research Unit of Clinical Epidemiology., Odense, Denmark
[2]Odense University Hospital and University of Southern Denmark, Centre of Andrology and Fertility Clinic, Odense, Denmark

Study question:

We assessed the chance of a live birth following assisted reproductive technology (ART) treatments in women with epilepsy compared to women without epilepsy receiving ART.

Summary answer:

Women with epilepsy receiving ART treatment did not have a decreased chance of a live birth per embryo transfer compared to other women.

What is known already:

In the general population up to 10–15% of all women have problems of infertility. Studies within this area have indicated that ART treatments are less effective in women with chronic inflammatory bowel disease and rheumatoid arthritis, than in infertile women in the general population. Some evidence

has suggested a role of inflammation in the pathophysiology of epilepsy, but in general epilepsy is not regarded as an autoimmune disease. The efficacy of ART in women with epilepsy has never been examined, and therefore, we want to study the chance of a live born child after ART in women with epilepsy.

Study design, size, duration:

This nationwide cohort study comprised all embryo transfers in Denmark from 1995 to 2017 including follow-up on pregnancies until November 2018. Women undergoing ART treatment included 2,693 embryo transfers in 916 women with epilepsy (the exposed cohort), and 200,259 embryo transfers in women without epilepsy (the unexposed cohort).

Participants/materials, setting, methods:

We used multilevel logistic regression analyses to compute crude and adjusted relative risk estimates (prevalence OR with 95% CI) for live births following ART treatments in women with epilepsy relative to women without epilepsy, and the model accounted for multiple embryo transfers in the same woman. We adjusted for Charlson Comorbidity Index, women's age at the time of embryo transfer, calendar year of infertility treatment, type of infertility treatment, and cause of infertility.

Main results and the role of chance:

There were 631 live births in the epilepsy cohort (by 535 women), and 48,336 live births in the non-epilepsy cohort (by 40,290 women). The cause of infertility in the epilepsy cohort referred to as a female factor in 22.7% of the cases and a mixture of factors in 44.2% of the cases. Among embryo transfers in patients with epilepsy, the median duration of epilepsy at the time of embryo transfer was 15 years (25%–75% percentiles: 8–22 years). The odds ratio for a live born child in women with epilepsy, relative to women without epilepsy undergoing ART, was 0.94 (95% CI 0.85-1.05) and adjusted 0.92 (95% CI 0.83-1.02).

Limitations, reasons for caution:

In this large register-based nationwide study, we cannot obtain information on clinical details on disease severity or types of seizures. These preliminary results are not adjusted for medication.

Wider implications of the findings:

This is the first population-based study to examine the impact of epilepsy on the efficacy of ART. The chance of a live birth per embryo transfer in women with epilepsy was similar to women without epilepsy. This finding is novel, and it is reassuring for women with epilepsy.

Trial registration number:

The study was approved by the Danish Data Protection agency (j. nr. 2012-58-0018, 17/37434).

O-185 Time trends in pregnancy complications over three decades of assisted reproduction technology (ART) – a registry-based study from the Committee of Nordic ART and Safety

S. Petersen[1], M. Gissler[2], C. Bergh[3], B.O. Åsvold[4], L.B. Romundstad[5], A. Tiiteten[6], S.C. Rasmussen[7], M. Petzold[8], A.B. Pinborg[9], U.B. Wennerholm[3], A.K. Henningsen[9], S. Opdahl[1]

[4]Norwegian University of Science and Technology, K.G. Jebsen Center for Genetic Epidemiology Department of Public Health and Nursing Faculty of Medicine and Health Sciences, Trondheim, Norway

[5]Norwegian Institute of Public Health, Centre for Fertility and Health, Oslo, Norway

[6]University of Helsinki and Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland

[7]Amager and Hvidovre Hospital, Department of Clinical Microbiology, Copenhagen, Denmark

[8]University of Gothenburg, Swedish National Data Service & Health Metrics Unit, Gothenburg, Sweden

[9]Rigshospitalet Copenhagen University Hospital, The Fertility Clinic, Copenhagen, Denmark

Study question:

Do trends in occurrence of pregnancy complications differ for assisted reproductive technology (ART) and spontaneously conceived pregnancies during three decades of ART treatment?

Summary answer:

ART pregnancies follow the same trends for pregnancy complications as the background population, except for placenta previa, where risk has increased over time.

What is known already:

ART conception comprises an increasing proportion of birth cohorts in the Nordic countries. Perinatal health in ART pregnancies has improved over time, approaching health in the background population. Risk of pregnancy complications is higher after ART compared to spontaneously conceived (SC) pregnancies. Whether this excess risk has remained stable over time, is unknown.

Study design, size, duration:

Registry-based cohort study including nation-wide data from four Nordic countries. In total, 6,830,578 pregnancies resulting in delivery between 1988 and 2015 were included. Among these, 146,998 (2.2%) were ART pregnancies.

Participants/materials, setting, methods:

Data were collected from several national health registries in Denmark, Finland, Norway and Sweden, including ART, medical birth, and patient registries, and linked using the unique identification number for residents. We used logistic regression with post-estimation to estimate absolute risks and risk differences (RDs) over time for hypertensive disorders in pregnancy (HDP), placental abruption and placenta previa, adjusting for parity, maternal age and country. We repeated analyses for singleton and twin pregnancies, separately.

Main results and the role of chance:

The risk of each pregnancy complication was consistently higher in ART compared to SC pregnancies across the study period, with the exception of HDP in twin pregnancies, where risks were similar. In a sub-sample with information on maternal body mass index and smoking in pregnancy, adjustment for these factors did not influence the results.

Risk of HDP increased over time in twin pregnancies for both conception methods (RD 1.73 percentage points [pp] per 5 years, 95% confidence interval [CI] 1.35 to 2.11 for ART and 0.75 pp, 95% CI 0.61 to 0.89 for SC). No clear trend was found for HDP in singletons pregnancies. Risk of placental abruption decreased over time in all groups (RD -0.16 pp, 95% CI -0.19 to -0.12 and -0.06 pp, 95% CI -0.06 to -0.05 for ART and SC, respectively, for singletons and multiple pregnancies combined). The risk of placenta previa increased over time among both ART singletons (RD 0.21 pp, 95% CI 0.14 to 0.27) and twins (RD 0.30 pp, 95% CI 0.16 to 0.43), but remained stable in SC pregnancies. Trends for placenta previa persisted when restricting analyses to primiparous women and to placenta previa with caesarean section.

Limitations, reasons for caution:

Results may be influenced by changes in registration practice over time for placental complications, although registration practice is similar for ART and SC pregnancies. Residual confounding cannot be excluded.

Wider implications of the findings:

Risks of pregnancy complications are consistently higher in ART. Trends in HDP and placental abruption follow those in the background population. The increasing risk of placenta previa over time in ART pregnancies diverges from a stable risk in the background population and warrants further investigation.

ISRCTN11780826

O-186 Reduced multiple birth after 85,559 eSET over 233,548 non-eSET cycles, but twinning rate in eSET cycles is above expected levels

P. Hinstridge[1], G. Bahadur[1], R. Homburg[2], J. Bosmans[3], J. Huirne[4], A. Srikantharajah[2], J. Kanna[5], P. Racich[6], A. Al-Habib[1], I. Karapanos[1], E. Jauniaux[7]

[1]North Middlesex University Hospital, Reproductive Medicine Unit, London, United Kingdom

[2]Homerton University Hospital, Homerton Fertility Unit, London, United Kingdom

[3]Vrije Universiteit Amsterdam, Health Sciences, Amsterdam, The Netherlands

[4]VU University Medical Center, Gynaecology, Amsterdam, The Netherlands

[5]Royal Derby Hospital, Gynaecology, Derby, United Kingdom

[6]University of Oxford, Linacre College, Oxford, United Kingdom
[7]University College London, Institute for Women's Health, London, United Kingdom

Study question:
What is the prevalence of multiple births after elective single embryo transfer (eSET)?

Summary answer:
There was significant reduction of twins with eSET (1.4%) compared to non-eSET (20.7%) after 85,559 eSET and 233,548 non-eSET cycles. Triplets occurred in both groups.

What is known already:
Prevalence of multiple pregnancies with zygotic splitting after SET was 1.36% after 937 848 single embryo transfer cycles in Japan. UK data is from HFEA database.

Several risk factors for zygotic splitting include manipulations of the zona pellucida for example assisted hatching, ICSI, embryo biopsy leading to herniation of blastomeres through the zona and embryo splitting during blastocyst expansion. Extended blastocyst culture can weaken intracellular bonding in the inner cell mass, leading to zygote splitting. Genetic factors, ovarian stimulation, embryo quality and maternal age are potential risk factors. Some dizygotic pregnancies or triplets from sexual intercourse cannot be ruled out.

Study design, size, duration:
A retrospective observational study was performed, based on 85,559 eSET and 233,548 non- eSET treatment cycles registered on the UK HFEA database from 2012-2016. Additional data on associated risks was gained under the Freedom of Information act (FOI). Data submission to the HFEA is a mandatory requirement.

Participants/materials, setting, methods:
Numbers of eSET and non- eSET treatment cycles registered on the UK HFEA database from 2012-2016 were obtained from the large UK regulated HFEA database coupled to FOI request for information on risk aligned to IVF practices. The level of twins and triplets from each was compared and comparative z-statistical analyses were performed. Incidences of < 5 triplets or quadruplets were not further analysed as it potentially breaches HFEA laws on patient identification.

Main results and the role of chance:
For the 233,548 non eSET cycles there were 54,460 births (23.3%/cycle) and 11,498 multiple births (21.1%). In contrast, from 85,559 eSET cycles the birth rate was 31,585 (36.9%/cycle) and multiple births numbers of 448 (1.4%). The twin births from non-eSET were 20.7% whereas in eSET this was 1.4%. The triplet rate for non-eSET was 0.4% whereas for eSET cycles this was described numerally as < 5 so as not to potentially identify patients. Likewise quadruplets occurred minimally in the non-eSET cycles. From the stakeholders and patients perspective 76.7% of non-eSET treatment cycles failed whereas in the eSET group this was 63.1% failure.

The rate of multiple pregnancy as a proportion of all births was significantly lower following eSET than following IVF without eSET [eSET: 1.42% (1.29-1.55); non-eSET: 21.11% (20.77-21.46). Absolute difference: 19.69% (19.33-20.06). Relative risk: 14.88 (13.56-16.34) p<0.001].

The proportion eSET increased significantly between 2012 and 2016: [2012: 19.85% (19.53-20.17; 2016: 34.65% (34.29-35.01). Absolute difference: 14.80% (14.32-15.28). Relative risk: 1.75 (1.71-1.78) p<0.001]

In eSET cycles there were no quadruplets but there were insignificant levels of triplets.

The practice of non-eSET vs eSET was 2.7 fold higher respectively, with e SET twins higher than background monozygotic twinning rate.

Limitations, reasons for caution:
Although, as expected, eSET is significantly better towards reducing twins compared to non-eSET cycles, it is still higher than the 0.40–0.45% universal monozygotic twinning prevalence. IUI as first line treatment option offers an alternative strategy for lessening the multiple births, several risk factors and numerous associated costs with IVF.

Wider implications of the findings:
Although, as expected, eSET is significantly better towards reducing twins compared to non-eSET cycles, it is still higher than the 0.40–0.45% universal monozygotic twinning prevalence. IUI as first line treatment option offers an alternative strategy for lessening the multiple births, several risk factors and numerous associated costs with IVF.

O-187 Association between oocyte number retrieved with neonatal outcome after freeze-all strategy

W. Yun[1]
[1]Shanghai ninth hospital, Reproduction, Shanghai, China

Study question:
Is there a relation between the number of oocytes retrieved and neonatal outcomes following IVF/ICSI treatment for patients using a freeze-all strategy?

Summary answer:
There is an increased risk of very preterm birth (VPTB, <32 weeks gestation) in women with a low number (1-3) of oocytes retrieved.

What is known already:
Recent studies have found that there is an increased risk of PTB (<37 weeks gestation) and low birthweight (LBW, <2500g) following IVF in women with a high number(>20) of oocytes retrieved in fresh ET cycles. Still others found that there is an association of oocytes retrieved with placenta praevia. However, the association between the number of oocytes retrieved and neonatal outcomes in freeze-all strategy cycles is unknown.

Study design, size, duration:
This retrospective cohort study included 14170 women with singleton deliveries achieved after freeze-all strategy conducted between November 2006 and December 2017, in China. Only the first delivery from one episode of ovarian stimulation were calculated.

Participants/materials, setting, methods:
Patients were categorized into five groups according to the number of oocytes retrieved:1-3, 4-9, 10-15, 16-20 or >20 oocytes. A number of ten to fifteen oocytes was used as a reference. The number of oocytes retrieved was analyzed as a continuous variable as well as categorized variable. Logistic regression analysis of the association between ovarian response (quantified as numberof oocytes retrieved) and outcomes of preterm birth (PTB), VPTB and low birthweight(LBW) was performed.

Main results and the role of chance:
The gestational age, birthweight z-scores, risk of PTB, LBW and congenital malformations did not differ significantly between the groups. There was a significantly higher risk of VPBT among women with a poor ovarian response (≤3 oocytes) compared with women with a normal response (10–15 oocytes) (1.5% vs 0.8%), crude odds ratio (OR) 2.001, 95% confidence interval (CI) 1.159–3.465, P=0.03;adjust OR 1.799, 95%CI 1.027–3.153, P=0.040.

Limitations, reasons for caution:
As with any retrospective study, unknown confounders may affect outcomes.

Wider implications of the findings:
In the absence of ovarian stimulation, a higher number of oocytes retrieved was not associated with adverse neonatal outcome. However, women with low ovarian response associated with a higher risk of VPTB. Factors that may underlie the unfavourable outcomes warrant further research.

Trial registration number:
Not applicable.

O-188 Mitochondrial DNA mosaicism in early human development

J. Mertens[1], **M. Regin**[1], **N. De Munck**[2], **K. Sermon**[1], **H. Van de Velde**[3], **C. Spits**[1]
[1]Vrije Universiteit Brussel, Reproduction and Genetics, Jette, Belgium
[2]IVI Middle East Fertility Clinic, IVI Medical Center, Abu Dhabi, United Arab Emirates
[3]UZ Brussel, Center for Reproductive Medicine, Jette, Belgium

Study question:

Do day-3 human preimplantation embryos show mitochondrial DNA mosaicism?

Summary answer:

90% of embryos carry variants unique to one blastomere, showing that mitochondrial DNA mosaicism is already present at day three of human development.

What is known already:

In the past years it has become evident that all the cells in one human being are not as genetically homogenous as previously assumed. Historically, the mitochondrial genome was known to show heterogeneity by different family members carrying the same variants in different frequencies and with diversity across tissues. By now, this diversity has been further refined to the level of the single cell, and often individuals consist of different cell populations that differ substantially in their variants and their mutational burden. Conversely, the timing of the appearance of these cell lineages has not yet been identified.

Study design, size, duration:

We hypothesized that mitochondrial DNA mosaicism begins during preimplantation development. We studied 19 top-quality day-3 embryos, donated by 8 couples, resulting in all but two embryos having at least one sibling in the study cohort. The embryos were surplus to ART treatment and donated after informed consent. The embryos were disaggregated and 119 single blastomeres were deep sequenced for a large part of the mitochondrial DNA.

Participants/materials, setting, methods:

The zona pellucida was removed using pronase, and the blastomeres were isolated by briefly incubating them in Ca^{2+}- and Mg^{2+}- free medium. The single blastomeres were collected in alkaline lysis buffer and long-range PCR was used to generate amplicons of 13 Kbp. Deep massive parallel sequencing was carried out on an Illumina NovaSeq platform and the reads were aligned with reference genome (NC_012920.1) using BWA-MEM. Variants >2% were further analyzed with mtDNA server and MuTect.

Main results and the role of chance:

Fifteen of the 19 embryos carried the same heteroplasmic variant in all of their blastomeres. These had a load ranging between 2-49% and showed a mean difference in frequency from blastomere to blastomere of 3%. Of these variants, 61% were in the hypervariable region and 39% in protein coding regions, of which 60% non-synonymous. Only one pair of sibling embryos showed the same variant but at different loads. All other variants were specific to each embryo. In 17 embryos, we found variants that were unique to one of their blastomeres (33-85% of the blastomeres of one embryo). Of these 147 unique variants, 48% were found in the RNA coding region, 17% in the hypervariable and 35% in protein coding sequences (65% of which non-synonymous). Most of these variants had a low load (±5%), except for 16 variants that had a load over 10% and up to 49%. These variants may be the result of asymmetric distribution of mutant mitochondria and show that the first events of mitochondrial somatic bottleneck are indeed occurring as early as day three of human development.

Limitations, reasons for caution:

These findings apply to non-disease related variants and should be taken with caution if trying to extrapolate to, for instance, preimplantation genetic diagnosis for mitochondrial disease. For pathogenic variants at high loads, different forms of segregation may apply.

Wider implications of the findings:

This is the first study of this kind in the human and shows that it is very likely that the cell lineages found in the adult start originating in the early developmental stages.

not applicable

O-189 Human granulosa cells are of very young DNA methylation age following a different epigenetic drift than other somatic cell types

K.W. Olsen[1], A. Cardona[2], A. Chi-Ho Chan[3], R. Borup Helweg-Larsen[3], J.R.B. Perry[2], E.R. Hoffmann[3], N. La Cour Freiesleben[4], A. Zedeler[5], M.L. Groendahl[1]

[2]University of Cambridge Addenbrooke's Hospital Cambridge, Medical Research Council Epidemiology Unit, Cambridge, United Kingdom

[3]Institute of Molecular and Cellular Medicine- Faculty of Health and Medical Sciences- University of Copenhagen, Center for Chromosome Stability, Copenhagen, Denmark

[4]VivaNeo Fertility Clinics, Stork IVF, Copenhagen, Denmark

[5]Hvidovre Hospital- Copenhagen University Hospital, Fertility Clinic, Copenhagen, Denmark

Study question:

Does the DNA methylation age (DNAm age) in mural granulosa cells from human ovarian follicles differ from the chronological age of the women?

Summary answer:

The DNAm age of granulosa cells from preovulatory follicles is substantially younger compared to the chronological age of the women.

What is known already:

A multi tissue age predictor based on of 353 CpG sites was developed by Steve Horvath in 2013 suggesting that age-associated DNA methylation changes are shared between cell-types and independent of mitotic activity.

Several studies have shown age-associated hypermethylation in specific genes. Furthermore, higher DNAm age compared to chronological age is associated with a higher risk for all-cause mortality.

In reproduction, the DNAm age of cumulus cells have shown to be younger than the chronological age in infertile women with normal and poor response to ovarian stimulation (Scott et al. 2018).

Study design, size, duration:

This study is a multicenter cohort study based on retrospective analysis of prospectively collected data and material derived from healthy women undergoing IVF or ICSI treatment following controlled ovarian stimulation with antagonist protocol. The granulosa cells were collected from 64 women between September 2016 and January 2018 in in the public fertility clinics at the Copenhagen University Hospitals in Herlev and Hvidovre, and in the private fertility clinic, Stork IVF.

Participants/materials, setting, methods:

Granulosa cells were obtained from women with varying ovarian reserve status (defined from age dependent anti-Müllerian hormone levels) by isolation from pooled follicles immediately after oocyte retrieval. DNA from the granulosa cell aggregates were extracted and analysed with the Illumina EPIC array, at the Human Genotyping Facility Genetic Laboratory, Dept. of Internal Medicine Erasmus MC Rotterdam. Subsequently the DNAm age was calculated using Steve Horvath's age predictor.

Main results and the role of chance:

The DNAm age in the granulosa cells are considerable younger (4-12 years of age, mean: 6.6 years) than the chronological age (26-43 years of age, mean: 33.0 years). There was no correlation between DNAm age and the chronological age of the women (p-value = 0.44), suggesting that the somatic cells of the follicle follow a different epigenetic drift compared to other somatic cell types. Stratification by ovarian reserve status (diminished, normal and high) had no effect on the results.

Limitations, reasons for caution:

The granulosa cells are collected during ovarian stimulation which may influence DNA methylation. As DNA was extracted from granulosa cells from pooled 3-5 follicles we were not able to address if variation in DNAm age is present between follicles in the same women.

Wider implications of the findings:

An accelerated ageing of the somatic cells of the follicle seems not to be involved in the age dependent decline in oocyte competence. This young DNAm age of granulosa cells may reflect that DNAm aging is 'on hold' in the years as pre-granulosa cells before primordial follicle activation.

O-190 Asn680Ser single nucleotide polymorphism in the follicle stimulating hormone receptor (FSHR) gene does not affect semen quality

C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], B. Petersen[1,2], M. Canas[2], M. Mattila[1], C. Zamara[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil

[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil

Study question:

Are there correlations between the follicle stimulating hormone receptor (FSHR) gene Asparagine/Asn 680 Serine/Ser (2039A>G; rs6166) polymorphism and semen quality or DNA damage in sperm?

Summary answer:

There seems to be no association between FSHR Asn680Ser single nucleotide polymorphism (SNP) and semen quality or sperm DNA damage.

What is known already:

Given the significant role of FSH in fertility, genetic mutation of the FSHR gene might lead to impaired fertility. FSHR gene Asn680Ser SNP exchanges Asn for Ser in the intracellular domain of the receptor and affects the sensitivity of FSHR to FSH in women. However, in men, the impact of this SNP is unclear. Some studies have assessed the association between FSHR Asn680Ser polymorphisms and male infertility. However, the results remain inconsistent.

Study design, size, duration:

A prospective cohort study enrolled 347 men seeking fertility care. DNA was extracted from peripheral blood, and the FSHR Asn680Ser SNP was genotyped using real-time PCR with the Taqman Universal PCR Master Mix and Taqman SNP genotyping assays. For purposes of comparisons, the individuals were divided into three groups according to their genotypes: Asn/Asn; Asn/Ser; and Ser/Ser. Semen analyses were compared between genotype groups

Participants/materials, setting, methods:

A portion of each semen samples was used for analysis according to the WHO guidelines/morphological analysis by motile sperm organelle morphology examination(MSOME). The remainder of the semen samples were tested for sperm DNA fragmentation using TUNEL assays; sperm apoptosis was analysed using the annexin V assay; sperm chromatin packing/protamination was assessed using chromomycin A3(CMA3) staining; and sperm mitochondrial membrane potentia (MMP) was analysed using MitoTracker Green. At least 200 spermatozoa were examined in each evaluation.

Main results and the role of chance:

Hardy–Weinberg genotype distributions indicated concordance between the observed/expected frequencies. No correlations between FSHR Asn680Ser genotypes and potential confounders (age, abstinence time, smoking, and drinking alcohol) were observed. There was no association between FSHR Asn680Ser genotypes and general semen parameters or DNA damage in sperm. Table 1 shows the data.

Limitations, reasons for caution:

Sperm was obtained from men seeking fertility care. Generalisations of the results to the general population should be performed with caution. Differences in the genetic backgrounds of various ethnic populations should also be considered.

Wider implications of the findings:

Although an association between the FSHR Asn680Ser SNP and human fertility has been reported, there appears to be no link between the genotype and semen quality or sperm DNA damage. The genotype of this polymorphism is probably not useful in the evaluation of male infertility.

Trial registration number:

Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

O-191 Rare variants in genes involved in Integrin-linked-kinase pathway identified in patients developing severe ovarian hyperstimulation syndrome (OHSS) with a predicted low-risk of OHSS.

M.L. Groendahl[1], L. Borgwardt[2], C.M. Rossing[2], R. Borup Helweg-Larsen[3], M. Toftager[4], A. Pinborg[5], J. Bogstad[4], K. Løsl[4], A. Zedeler[4], K. Wendelboe Olsen[1]

[1]Herlev Hospital- Copenhagen University Hospital, Fertilitetsklinik, Copenhagen, Denmark

[2]Rigshospitalet- Copenhagen University Hospital, Centre for Genomic Medicine, Copenhagen, Denmark

[3]Faculty of Health and Medical Sciences- Copenhagen University, Functional Genomics and Reproductive Health Group, Copenhagen, Denmark

[4]Hvidovre Hospital- Copenhagen University Hospital, Fertility Clinic, Copenhagen, Denmark

[5]Rigshospitalet- Copenhagen University Hospital, Fertility Clinic, Copenhagen, Denmark

Study question:

Do genetic variants in patients developing severe OHSS but with predicted low risk of OHSS, provide clues to the mechanisms involved in the syndrome?

Summary answer:

Genes with variants in OHSS patients with low-risk of OHSS enrich the Integrin-linked-kinase (ILK) and Focal-adhesion-kinase (FAK) signaling pathways, both linked to VEGF signaling.

What is known already:

Severe OHSS is a systemic disorder including high vascular permeability correlated to an excessive ovarian response following ovarian stimulation (OS) and ovulation trigger with hCG. However, severe OHSS is also, though rarely, seen in women with low ovarian response to OS and in spontaneous pregnancies. VEGF is involved in the high vascular permeability. OHSS-predisposing genes have primary been confined to known and frequent of polymorphisms (i.e. *FSHR, LHR, CYP11A, AMH, VEGFR2*). Recently, a case report (severe OHSS after GnRHa trigger) focusing on rare genetic variants, suggested *VEGFR3* (official name *FLT4*) to have a role in OHSS (Stouffs et al., 2018).

Study design, size, duration:

Among participants in a prospective randomized study including 1050 women in 1st IVF cycle (2009-2013) (Toftager et al., 2016), six women with no risk factors of OHSS developing severe OHSS (grade 4 and 5, Golan classification) were selected. In the same cohort, six matched (age, diagnosis, protocol, ovarian response, estradiol level) controls (grade 0, no OHSS) were selected. In connection to oocyte retrieval, cumulus cells were isolated and snap frozen until analysis.

Participants/materials, setting, methods:

DNA was extracted from cumulus cells from six patients with OHSS (grade 4-5) and six controls (grade 0). Whole exome sequencing (WES) was performed by SureSelect library preparation and sequenced on the Illumina High-Seq2500. DNA variants call was performed in GATK 4.0 pipeline, variants and pathways filtering was done using the Ingenuity Variant Analysis tool (Qiagen). Variants were manually validated in Integrative Genomics Viewer (IGV 2.4.9), only class 3, 4 and 5 variants were included.

Main results and the role of chance:

Variants called (number: 30911) from the six patients and six controls were submitted to pathway filtering. Among the most significant enriched pathways in the OHSS group as compared to control was the ILK signaling pathway (23 genes, 24 variants, $p<0.00001$) recently connected to play a central role in VEGFR3 signaling (Urner et al., 2019). Furthermore, FAK signaling, converging signaling point between VEGFR2 and integrins and focal adhesions in endothelial cell was enriched (17 genes, 18 variants, $p<0.00001$). Genes with variants in ILK signaling were genes coding for cell junctional proteins (*ITBG2, ITBG5, ITBG7, PXN*) and protein phosphatases and kinases (*PTPA, PIK3R5, PIK3R6, PIK3C2G, PIK3R4, PIK3CD*). Each OHSS patient had two-six variant genes in the pathway, while variants were absent in the controls.

Limitations, reasons for caution:

A potential role of ILK and FAK signaling in development of OHSS needs to be validated by WES on additional OHSS in women with high risk cases and followed by functional studies.

Wider implications of the findings:

Clarification of the mechanism as well as potentially defining genetic predisposition of the high vascular permeability is important for future treatment and prevention of OHSS.

Trial registration number:

Not applicable.

O-192 Endometrial microbiome analysis using long-read nanopore sequencing technology

A. Oberle[1], L. Urban[2], M. Hengstschläger[1,3], W. Feichtinger[4], M. Feichtinger[4,5]

[1]Wunschbaby Institut Feichtinger, Department of Genetics, Vienna, Austria

[2]European Molecular Biology Laboratory, European Bioinformatics Institute- Wellcome Genome Campus, Hinxton, United Kingdom

[3]Medical University of Vienna, Institute of Medical Genetics, Vienna, Austria

[4]Wunschbaby Institut Feichtinger, Wunschbaby Institut Feichtinger, Vienna, Austria

[5]Karolinska Institutet, Department of Oncology-Pathology, Stockholm, Sweden

Study question:

In this pilot study we aim to investigate if the human endometrial microbiome can be analyzed by using a handheld third-generation nanopore DNA sequencing device.

Summary answer:

Our data suggest the feasibility of 16S rDNA amplification and sequencing the microbiome from endometrium biopsies by using long-read nanopore sequencing technology.

What is known already:

Metagenomics sequencing enlightened the fact that the healthy endometrium hosts a normal, non-infectious microbiome and is not sterile as historically thought. Recent studies suggest that the microbiome constellation contributes to fertility and pregnancy outcome. Especially the amount of *Lactobacillus* species in the endometrial microbiome influences pregnancy outcome, with higher live birth rates in *Lactobacillus*-dominated (>90%) microbiota.

Novel third-generation sequencing technologies, like the portable MinION sequencing device from Oxford Nanopore Technologies (ONT) allow real-time sequencing analysis and significantly reduce initial hardware investment costs, library preparation time and cost per sequence. Additionally, the long-reads allow full-length sequence analysis of 16S rRNA genes.

Study design, size, duration:

Here we investigate the feasibility of targeted 16S microbiome sequencing of ten endometrial biopsy samples on the Oxford Nanopore MinION device. The results were compared with RT-PCR microbiome panel analysis from DNA Technology (FEMIFLOR® Screen).

Participants/materials, setting, methods:

Endometrium biopsy was taken from patients undergoing assisted reproductive technology (ART) in our institution due to repeated implantation failure for further analysis. The biopsy was performed using Probet endometrial suction curette (Gynétics) and left-over material was used for this pilot study after patient's informed consent.

After DNA extraction, 16S rDNA was amplified using ONT's SQK-RAB204 kit. The sequencing was performed on the handheld MinION sequencing device and data were analyzed using EPI2ME 16S workflow.

Main results and the role of chance:

In a first step, we analyzed the feasibility of unbiased 16S rDNA sequencing with the MinION using ZymoBIOMICS™ Microbial Community Standard. By comparing different DNA extraction methods and PCR conditions, we minimized the extraction and PCR bias for equal sequencing of different gram-positive and gram-negative bacterial species. Microbiota were analyzed on genus-level.

With these optimized conditions, we were able to amplify 16S rDNA from six out of ten endometrial biopsy samples. In four of six samples *Lactobacillus* spp. was the dominant genus, with three of these showing >90% *Lactobacillus* reads. One sample was *Streptococcus*-dominated, and one was dominated with *Staphylococcus* reads. Microbiome RT-PCR analysis from DNA Technology did not lead to any reliable results due to low bacterial load in all six samples, which were reliably amplified for nanopore sequencing. This highlights the importance of optimized 16S amplification protocol and the necessity of highly sensitive detection methods like high-throughput sequencing for the analysis of low bacterial load tissues.

These results open new avenues for endometrial microbiome analysis for assessing IVF-outcome chances. Our study proofs that it is possible to reliable detect and analyze bacterial specimen even in tissues with low bacteria infiltration by using 16S amplification and long-read nanopore sequencing.

Limitations, reasons for caution:

Nanopore sequencing technology is fast, cost-effective and much progress has been made recently. Nevertheless, sequencing still produces high error rates what currently enables assessment of microbiota only down to genus level.

Additionally, not all endometrium samples could be amplified. This is possibly due to low bacterial load in these samples.

Wider implications of the findings:

This study is a proof of concept for the feasibility of rapid, cost-effective and easy endometrial microbiome screening for human reproduction.

Clinical impact of endometrium microbiome sequencing for pregnancy outcome, especially for ART treatment is still under debate and needs to be further investigated in prospective clinical trials.

O-193 Encapsulation of mice immature testicular tissue in alginate supplemented with nanoparticles delivering a necrosis inhibitor improved spermatogonial survival and seminiferous tubule integrity in autografts

F. Del Vento[1], M. Vermeulen[1], J. Poels[2], C. Wyns[2]

[1]Université Catholique de Louvain, Andrology, Bruxelles, Belgium
[2]Cliniques Universitaires Saint-Luc, Andrology, Bruxelles, Belgium

Study question:

Can we improve the outcome of immature testicular tissue (ITT) autotransplantation using tissue engineering techniques that involve localized and sustained delivery of a necrosis inhibitor?

Summary answer:

Seminiferous tubule integrity and spermatogonial survival were improved in 21 day grafts of mice ITT encapsulated in alginate supplemented with nanoparticles delivering necrosis inhibitor NecroX-5™.

What is known already:

Anticancer therapy often induces gonadal damage leading care providers to develop fertility preservation measures. For prepubertal boys, cryostorage of ITT containing spermatogonial stem cells is so far the only option to give them a hope for future fatherhood. Fertility restoration using frozen-thawed human ITT has not been achieved yet but autotransplantation appears to be a promising strategy based on non-human primate data. Unfortunately, spermatogonial loss is a constant observation in ITT transplantation experiments, although ITT encapsulation in 1% alginate containing nanoparticles delivering VEGF (vascular-endothelial growth factor) improved tissue vascularization and doubled spermatogonial survival compared to non-encapsulated tissue.

Study design, size, duration:

ITT pieces recovered form 15 mice were encapsulated within a matrix of 1% alginate supplemented with PLGA/PEG (Poly(D,L-lactide-co-glycolide) poly(ethylene glycol)) nanoparticles (Nps) delivering NecroX-5™, a necrosis inhibitor. One fragment per mice was auto-transplanted orthotopically for 21 days and grafts were compared to non-encapsulated and alginate-encapsulated ITT auto-grafts.

Participants/materials, setting, methods:

1mm^3 testicular fragments were obtained from 15 NMRI (naval medical research institute) prepubertal mice after bilateral orchidectomy. Orthotopic auto-transplantation of non-encapsulated, alginate-encapsulated and alginate/Necrox-5™ Nps- encapsulated ITT was carried out for 21 days. Grafts were evaluated on hematoxylin-eosin histological sections using a scoring system for seminiferous tubule integrity and after immunohistochemical staining using promielocytic leukemia zinc-finger (PLZF) , active caspase-3 and malondialdehyde as markers of undifferentiated spermatogonia, apoptotic cells and lipid peroxidation, respectively.

Main results and the role of chance:

Histological evaluation of grafts showed that when an alginate tissue embedding matrix supplemented with Nps delivering NecroX-5™ was used, the number of seminiferous tubules scored as intact (as cells adhesion to the basement membrane, cell cohesion and absence of sclerosis were observed) was increased compared to both non-encapsulated (p=0,0068) and alginate-encapsulated grafts (p=0,0036). The number of undifferentiated spermatogonia was also increased in grafts supplemented with NecroX-5™ Nps compared to alginate- encapsulated (p=0.0009) and non-encapsulated tissue (p<0.0001), as well as in alginate- encapsulated compared to non-encapsulated grafts

(p<0.0001). No statistical significant difference was found when the results obtained in the three groups were compared for both active-caspase 3 positive cells and malondialdehyde positive cells.

Limitations, reasons for caution:

Several questions need to be answered before a translation to clinical practice could be considered. Experiments involving animal tissue should be replicated using human tissue. Moreover, no information was obtained concerning the reproductive potential of surviving spermatogonia, nor on genetic and epigenetic consequences on tissue engineered grafts.

Wider implications of the findings:

Supplementation of an alginate matrix with Nps containing a necrosis inhibitor allowed improved mice ITT auto-transplantation outcome. Application of tissue engineering involving tissue embedding and controlled delivery of growth factors and other molecules using nanoparticles represents a powerful tool for future perspectives to restore fertility with cryostored ITT transplantation.

Trial registration number:

not applicable

O-194 Pubertal development after testicular tissue biopsy for fertility preservation in pre- and peripubertal boys having received gonadotoxic treatment

A. Braye[1], A. Ferster[2], I. Gies[3], E. Goossens[1]

[1]Vrije Universiteit Brussel VUB, Reproduction- Genetics and Regenerative Medicine RGRG - Biology of the Testis BITE, Brussels, Belgium

[2]Hôpital Universitaire des Enfants Reine Fabiola HUDERF, Department of Hemato-Oncology, Brussels, Belgium

[3]Universitair Ziekenhuis Brussel UZB, Division of Pediatric Endocrinology- Department of Pediatrics, Brussels, Belgium

Study question:

Does a testicular tissue biopsy procedure at pre- or peripubertal age affect the pubertal development of young boys on the long-term?

Summary answer:

FSH and testosterone serum levels and bone age seem affected by the biopsy procedure; whereas testicular volume, LH, INHB, AMH and bone density are not.

What is known already:

Male infertility due to gonadotoxic treatment and the search for an adequate fertility preservation strategy becomes clinically more relevant because of the improved survival rate of children with cancer or haematological disorders. The only fertility preservation option for pre- and peripubertal boys who do not produce mature spermatozoa yet, is to undergo a testicular tissue biopsy (TTB) followed by banking before spermatogonial stem cell loss. Although recent evidence demonstrates that immediate adverse effects of the biopsy procedure are rare (1%), nothing is known on the effects on the long-term.

Study design, size, duration:

Testicular volume, LH, testosterone, FSH, INHB and AMH serum levels, bone age and bone density were retrospectively collected from patients' medical records between 2002 and 2017 at Universitair Ziekenhuis Brussel. Because Tanner stages were not available, data were coded according to patients' age at measurement and compared between boys who underwent TTB (biopsy group) and those who did not (control group) to identify possible association between TTB at pre- or peripubertal age and pubertal development.

Participants/materials, setting, methods:

109 pre- and peripubertal boys needing gonadotoxic treatment with >80% risk of later fertility problems were offered TTB and banking. Exclusion criteria were testicular cancer diagnosis, substitution treatments for testosterone and mature spermatozoa present in the semen sample. Seventy-two boys were diagnosed with cancer and 37 with haematological disorders. Prader orchidometer, the Greulich & Pyle method and z-scores were used for the measurement of testicular volume, bone age and bone density respectively.

Main results and the role of chance:

The testes of 63 boys were biopsied, while 46 boys had chosen not to cryopreserve their testicular tissue and served as control. TTB was performed in 52 prepubertal boys (< 12 years) and 11 peripubertal boys (12-16 years). Up to five years and seven months after the biopsy procedure, no statistically significant difference in testicular volume was found between the biopsied and the contralateral non-biopsied testis in both pre- and peripubertal boys. The number of boys showing normal FSH serum levels was significantly decreased in the biopsy group compared to the control group (68% vs. 94%; p=0.006). For testosterone, significantly more boys showed low serum levels after the TTB procedure (52% vs. 6%; p<0.001). No statistically significant differences were observed for the serum levels of LH, INHB and AMH. Less boys had a delayed bone age after TTB (17% vs. 50%; p=0.038). The TTB procedure had no impact on the bone density.

Limitations, reasons for caution:

Because this retrospective study revealed plenty missing data in clinical files, no firm conclusions could be made. A prospective study could obtain a more representative picture of long-term effects of TTB. This study proves the need for an improved and standardized follow-up protocol for boys undergoing TTB for fertility preservation.

Wider implications of the findings:

This was the first study investigating long-term effects of TTB at pre- or peripubertal age on pubertal development of boys with cancer or haematological disorders. A more standardized follow-up after TTB will allow better counseling of patients interested in fertility preservation and optimize selection of patients eligible for fertility preservation.

Trial registration number:

Not applicable.

O-195 Fertility of women with Rheumatoid Arthritis (RA) : The inflammatory activity of the pathology is negatively correlated with AMH serum level.

C. Valdeyron[1], M. Soubrier[2], B. Pereira[3], A. Constantin[4], J. Morel[5], P. Gaudin[6], B. Combe[7], A.S. Gremeau[1], L. Dejou-Bouillet[1], J.L. Pouly[1], F. Brugnon[8]

[8]CHU Estaing Hospital Clermont Ferrand University, Service Biologie de la Reproduction- AMP/CECOS, Clermont Ferrand, France

Study question:

Is there an impact of Rheumatoid Arthritis and its treatment on the ovarian reserve to evaluate if fertility preservation would be necessary for these patients?

Summary answer:

Rheumatoid Arthritis (RA) activity is negatively correlated with AMH serum level.

What is known already:

Patients with RA have a higher prevalence of infertility compared with general population. Inflammation related to the pathology and the treatments of RA seem to be the main hypothesis to explain the infertility of these patients. Nevertheless, the tangible link of these different factors with the decline of women's fertility has never been clearly demonstrated.

Study design, size, duration:

Patient data and serum analysis were derived from the French national prospective cohort ESPOIR (Etude et Suivi des POlyarthrites Indifférenciées Récentes). Enrolled patients (n= 106, 18 to 37 years old) with the ACR/EULAR2010 criteria for RA didn't receive any medication at the time of enrolment (T0). Patients were examined and AMH serum level was measured at T0, 6(T6), 12(T12), 24(T24) and 36(T36) months after the diagnosis.

Participants/materials, setting, methods:

The measurement of serum AMH level was performed with electrochemiluminescence method (analyseur Cobas® e411). The impact of RA inflammatory activity (evaluated by DAS28 score and level of CRP) and treatments (methotrexate only/or with other medications) was evaluated at each time of our study.

Main results and the role of chance:

We observed a gradual decrease of AMH serum level of patients over time similar with the decrease curve described for the healthy women in the literature (Kelsey *et al*.,2011). AMH serum level of the RA patients compared with the values considered as normal graduated by age did not show any significant difference at T6, T12, T24 and T36 ($p > 0.05$). We did not observe an impact of the treatments on AMH serum level whatever the type of medication performed (methotrexate only/or with other medications). We showed an inverse correlation between AMH variation and inflammation parameters (DAS28: $r = -0.27$, $p = 0.003$; CRP: $r = -0.16$, $p = 0.06$).

Limitations, reasons for caution:

The evaluation of the ovarian reserve should be completed by an ultrasound at the 5th day of the cycle as well as an additional hormonal assessment.

Wider implications of the findings:

This study is the first to study AMH serum level follow up of a large cohort of young RA patients during 36 months. The quick limitation of inflammation seems necessary to limit alterations of ovarian reserve. Oocytes and/or ovarian tissue don't seem necessary if inflammation is quickly controlled.

Trial registration number:

Clinical trial registration number is in progress.

O-196 Fertility preservation by ovarian tissue freezing in patients with genetic and chromosomal disorders

L.S. Mamsen[1], R.A. Anderson[2], E.E. Telfer[3], M. McLaughlin[4], T.W. Kelsey[5], E. Ernst[6], K.T. Macklon[7], A.M. Lund[8], S.G. Kristensen[1], D.A. Gook[9], C.Y. Andersen[1]

[9]Royal Women's Hospital, Reproductive Services and Melbourne IVF, Victoria, Australia

Study question:

Should ovarian tissue cryopreservation (OTC) be considered in girls and young women with genetic and chromosomal disorders that may cause premature ovarian insufficiency (POI)?

Summary answer:

OTC may be considered in patients with galactosemia, thalassemia and in a highly selected group of patients with mosaic Turner syndrome (TS).

What is known already:

Genetic and chromosomal disorders such as TS, galactosemia, and thalassemia are often associated with poor ovarian function. The main reproductive effect of these disorders is POI, and the prevalence of spontaneous pregnancy is low. Further, these diagnoses are often associated with increased risk during pregnancy. A few studies have detected follicles in ovarian biopsies from adolescent girls with TS and in young girls with galactosemia, and some centers offer OTC for these patients. However, the speed at which the follicle pool is depleted and the subsequent fertility potential of these follicles has not been clarified.

Study design, size, duration:

This retrospective study included 15 girls and young women with TS (aged 5 to 22 years), 6 patients with galactosemia (aged 0.3 to 11 years), 11 patients with thalassemia (aged 3 to 17 years) and 42 control patients (aged 2 to 26 years), who had one ovary removed for fertility preservation for other reasons prior to gonadotoxic treatment. All patients underwent OTC between the years 2002 and 2017.

Participants/materials, setting, methods:

A total of 74 girls and young women aged 0.3 to 26 years (mean age 13.6 years), who underwent OTC for fertility preservation were included in this study. Follicle density (follicles/mm^3), morphology and health were assessed in ovarian cortex biopsies from patients with genetic/chromosomal disorders and compared to controls.

Main results and the role of chance:

Follicles were found in 60% (9/15) of the biopsies from TS ovaries; 8 girls with a mosaic karyotype and one 45,X. In 78% (7/9) of the ovaries with follicles, the mean follicle density was -0.7 standard deviations below age-related predicted density of the control group. There was a high rate of abnormal follicle morphology in the TS ovaries. In girls with galactosemia, morphological normal follicles were found in 83% (5/6) of the biopsies and the mean density was -0.2 standard deviations below age-related predicted density of the control group. No follicles were detected in the ovary from an 11.7-year-old girl with galactosemia. In girls with thalassemia follicles were detected and the densities were within the 95% CI of the control group. 5 follicle specific proteins were expressed similarly in ovaries with genetic and chromosomal disorders and in control ovaries.

One women with thalassemia had her tissue grafted and conceived following IVF treatment and delivered a healthy baby where the oocyte derived from the transplanted tissue.

These findings suggest that OTC may be considered for highly selected patients with genetic/chromosomal disorders. It is important to note that frozen/thawed ovarian tissue has not yet been grafted to women with TS or galactosemia.

Limitations, reasons for caution:

The pathophysiology of the genetic/chromosomal disorders leading to an accelerated follicle loss is unknown and it is currently unknown to what extent transplanted ovarian tissue can sustain fertility.

Wider implications of the findings:

The benefits of OTC may be limited to a highly selected group of patients with genetic/chromosomal disorders, in whom a sizeable pool of normal follicles is present at OTC and where endocrine assessment does not indicate POI, and if other health issues do not preclude pregnancy.

Approved by the ethics committee of Copenhagen and Frederiksberg (H-2-2011-044)

O-197 Secondary follicle rescue feasibility and in vitro follicle culture after initiation of treatment with cyclophosphamide in prepubertal mice – Implications for fertility preservation

A. Anastácio[1], L. Viñals Ribé[1], X. Hao[1], K.A. Rodriguez-Wallberg[1,2]

[1]Karolinska Institutet, Department of Oncology and Pathology, Stockholm, Sweden

[2]Karolinska University Hospital, Department of Reproductive Medicine, Stockholm, Sweden

Study question:

How a recent treatment with cyclophosphamide (CPA) affects the feasibility of isolation of secondary follicles for culture aiming fertility preservation vs untreated controls?

Summary answer:

Follicle isolation, culture and oocyte maturation were feasible after CPA treatment, although significantly smaller follicle size and reduced maturity rate were obtained vs controls.

What is known already:

Clinical guidelines recommend the application of fertility preservation methods before cancer treatment, however, in some cases, this is not possible. Up to

date, there is a lack of knowledge about the growth dynamics of ovarian follicles in vitro after cancer therapy initiation.

Study design, size, duration:

Experimental controlled study using mice. Prepubertal B6CBA/F1 females 12 days old were randomly distributed to CPA treatment (n=18) or control (n=8). CPA 50, 75 or 100mg/kg was injected intraperitoneally. The mice were sacrificed by cervical dislocation after 3 days and ovaries collected. Secondary follicles were isolated and cultured for 12 days up to oocyte maturation according to the method described by Cortvrindt [1].

Participants/materials, setting, methods:

Main outcome variables included the number of isolated follicles obtained per ovary, follicle growth estimated by mean diameter throughout the culture, survival at day 12 of culture, expulsion of the cumulus-oocyte complex (COC) and metaphase II (MII) oocytes ratios. Comparison between groups was performed using Chi-square test with Yate's continuity correction and Welch's ANOVA test. The results were considered significantly different for $p<0.05$.

Main results and the role of chance:

The size of secondary follicles isolated and put in culture was similar among the groups. However, on day 12 the size of follicles obtained from CPA-treated ovaries was significantly smaller (575.2mm ±253,0; 560,4mm ±225,0 and 600,1mm ±205,4 in the 50, 75 or 100mg/kg, respectively) than in the controls (666,5mm ±191,0) ($p<0,01$ for all). In all groups follicle survival ratio was high (>80%). There was a trend towards decreasing COC expulsion rates in association with increasing CPA dose received ($p=0.07$). The MII oocyte ratio was reduced in all CPA-treated groups vs control ($p<0,01$).

Limitations, reasons for caution:

The data presented herein are based on morphological follicle characteristics observed during culture. Further investigation of molecular markers would improve the knowledge on the mechanisms of cytotoxic drugs affecting follicle development and oocyte viability.

Wider implications of the findings:

Secondary follicles could be retrieved from pubertal mice ovaries after CPA-treatment. Comparable numbers of follicles could be isolated, survival and COC expulsion were not affected by CPA treatment. However, the final size of the follicles and the MII oocyte ratio were significantly reduced in follicles obtained from CPA-treated ovaries.

SESSION 55: NON-INVASIVE APPROACHES FOR PREDICTING EMBRYO PLOIDY

Tuesday 25 June 2019 Haydn 1 17:00 - 18:00

O-198 The blastocyst score, integrating morphologic grade and day of blastocyst development, is a predictor of blastocyst ploidy

N. Zaninovic[1], Q. Zhan[1], Z. Ye[1], R. Clarke[1], Z. Rosenwaks[1]

[1]Weill Cornell Medicine, The Center for Reproductive Medicine and Infertility, New York- NY, U.S.A.

Study question:

Can the blastocyst score (BS), which comprises numeric values for blastocyst expansion, inner cell mass (ICM), trophectoderm (TE), and day of blastocyst development, predict ploidy?

Summary answer:

A numeric blastocyst score, integrating blastocyst (BL) morphologic grades and speed of development (D5 or D6), can be used as a predictor of ploidy status.

What is known already:

Preimplantation genetic testing for aneuploidy (PGT-A) has been shown to enhance the implantation rate per transfer and decrease the miscarriage rate, particularly in advanced maternal age patients. However, the technique is invasive, sometimes inconclusive, and expensive. Non-invasive blastocyst morphology (grade) and morphokinetics have been shown to be associated with implantation, suggesting a possible correlation with ploidy, as reported in several studies. Moreover, blastocysts developed on D5 exhibit higher implantation and euploidy rates compared to D6 blastocysts. The use of blastocyst quality and its developmental speed as a way to determine ploidy should be validated.

Study design, size, duration:

This is a retrospective cohort study conducted in an academic institution from November 2011 to June 2017. A total of 11,364 biopsied blastocysts from 2,309 IVF cycles (female age, 21-48; avg. 36.8±4.7) were included. Embryos were biopsied on days 5 or 6, contingent on reaching the expanded blastocyst stage, and tested using aCGH/SNP or NGS.

Participants/materials, setting, methods:

Blastocyst scores were based on a modified Gardner grading. Numerical blastocyst grades of 1-4 were given individually for expansion, ICM, and TE (1 being the best) based on clinical implantation rates. The blastocyst score was calculated as the sum of the blastocyst grades and development day (D5 or D6; a value of 2 was added for D6 blastocysts). Logistic regression analysis was used to estimate the odds ratio between scores with a 95% CI.

Main results and the role of chance:

To predict blastocyst euploidy, the following factors were significant (ranked in descending order of significance): age of female patient (oocytes), blastocyst score, and blastocyst developmental day (D5 or D6). The oocyte source (donor vs. autologous) and the method of fertilization (ICSI vs. IVF) were not significant. Blastocyst euploidy decreased by 0.86 times (95% CI, 0.84-0.87) per year of advancing age. Blastocysts from 21-year-old oocytes were 66.7 times more likely to be euploid than those from 48-year-old oocytes (95% CI, 50.1-84.4). The blastocyst score showed a linear correlation with euploidy rate in all female age groups. For each numerical rise in blastocyst score, embryos were 0.83 times less likely to be euploid (95% CI, 0.82-0.85). The embryo with the best blastocyst score (score 3) had euploid probability 12.9 times higher than the worst-scored one (score 17; 95% CI, 10.6-15.9). Euploid prediction for patients <35 years old with the best blastocyst score was 80%. In comparison, euploid prediction in 40-year-old patients with the same blastocyst score was 40%.

Limitations, reasons for caution:

This study is limited by its retrospective nature. PGT-A was performed on different platforms.

Wider implications of the findings:

This study underscores the importance and the role of evaluating blastocyst morphology and developmental speed. The numeric blastocyst score can be used as a non-invasive predictor of euploidy and a tool for patients considering undergoing PGT-A.

O-199 Morphokinetics may provide a useful adjunct for selecting Euploid embryos with a high chance of implantation

Y.Y. Lim [1], M.S.R. Lim [1], J.J. Chen [1], P.S. Wong [2]

[1]Sunfert International Fertility Centre - Bangsar South, PGT Department, Bangsar South- Kuala Lumpur, Malaysia

[2]Sunfert International Fertility Centre - Bangsar South, Clinical, Bangsar South- Kuala Lumpur, Malaysia

Study question:

Can a universal morphokinetic model based on Known Implantation Data (KID) increase the chance of selecting euploid embryos with a higher implantation potential, than just morphology.

Summary answer:

Selecting euploid embryos with higher morphokinetic scores by a universal time-lapse algorithm gives a higher probability of implantation than selection by morphology.

What is known already:

PGT-A is increasingly used to select chromosomally normal blastocysts, however despite advances in genetic testing techniques, pregnancy rates of euploid embryos are still around 60%. When multiple euploid embryos are available, further selection must be applied. Morphokinetic models have been developed by correlating embryo development pace and morphology, with Known Implantation Data (KID) of transferred blastocysts. Several studies have shown that morphokinetic scores can be used to select untested blastocysts with higher implantation potential. Few studies have examined the adjunct use of

morphokinetics to select higher implantation potential euploid embryos, instead of morphology alone.

Study design, size, duration:

This retrospective analysis embryos were cultured in the EmbryoScope time-lapse system (Vitrolife A/S) and evaluated for morphokinetics, morphology and ploidy. KIDScore D5 v2.0 scores were generated in the EmbryoViewer Software. Blastocysts were categorized into three KIDScore groups: Poor, Fair, Good according to score range (2-5.9, 6.0-7.9 and 8.0-9.9, respectively). Morphological scoring was performed using Gardner score. Following trophectoderm biopsy on day 5 or day 6, PGT-A was performed using NGS platform (VeriSeq protocol, Illumina).

Participants/materials, setting, methods:

Between October 2017 and December 2018 we analysed a total of 1498 embryos from patients between ages 20 to 50 (mean age 30.564). Euploid blastocysts for frozen embryo transfer were selected by morphology only. Mosaics and aneuploid blastocysts were not selected for transfer. For this subset of 200 transferred embryos the different scoring options were compared to implantation rates. Statistical significance of implantation data was calculated using chi square test.

Main results and the role of chance:

The analysis of the ploidy status for all embryos showed that increasing Day 5 KIDScore categories (poor / fair / good) were correlated with an increasing rate of euploid embryos (48.1% / 51.7% / 63.3%; $P<0.05$) and a decreasing rate of aneuploid embryos (25.6% / 35.7% / 41.6%), whereas the rate of mosaic embryos ranged from 10.2% to 12.5% and was not different. A similar result was found for morphology alone versus ploidy.

Implantation rates for euploid embryos of all morphology types in the KIDScore categories good / fair / poor were 73.9%, 59.5% and 47.7%, respectively. Within the different KIDScore subgroups the embryos with good morphology alone gave implantation rates of 58.7% (KIDScore good), 43.2% (KIDScore fair) and 27.3% (KIDScore poor), respectively. Comparing morphology only versus KIDScore only showed implantation rates of 63.5% versus 73.9% for good morphology score versus good KIDScore, 59.6% versus 59.5% (fair/fair) and 27.3% versus 47.7% (poor / poor), thus showing that in the direct comparison subselecting euploid embryos by KIDScore gave better or equal results compared to subselection by morphology only scoring.

Limitations, reasons for caution:

These data are from a single center. Larger numbers and verification in another center are needed.

Wider implications of the findings:

In cases where multiple Euploid embryos are available for transfer, morphokinetic analysis may identify other viability factors, which are not related to chromosomal status and morphology alone and therefore be a valuable adjunct to PGT-A for selecting embryos with the highest implantation potential.

O-200 Slow embryo development predicts higher aneuploidy rates among high grade blastocysts but does not influence pregnancy outcomes in euploid blastocyst transfer cycles

J. Tan[1], R. Harjee[1], C. Jing[2], A. Kan[1], G. Nakhuda[2]

[1]*University of British Columbia, Obstetrics & Gynecology, Vancouver, Canada*
[2]*Olive Fertility Centre, Obstetrics & Gynecology, Vancouver, Canada*

Study question:

Does blastocyst formation rate predict rates of embryo aneuploidy, independent of morphologic grading, and subsequent pregnancy outcomes in euploid frozen blastocyst transfer cycles?

Summary answer:

Early blastocyst development only predicts higher euploidy rates among high-grade embryos in women <40-years-old and does not correlate with pregnancy outcomes in euploid transfer cycles.

What is known already:

Current strategies for embryo assessment primarily rely on either non-invasive morphologic parameters that have limited accuracy for determining embryo viability or invasive embryo biopsy techniques for pre-implantation genetic testing (PGT-A). Although previous studies found an association between blastocyst morphology and euploidy rate, there is conflicting evidence regarding the value of embryo development rate as a non-invasive marker for predicting embryo aneuploidy and implantation potential of euploid embryos. Understanding the role of embryo development rate and blastocyst morphology in PGT-A cycles may help improve to embryo selection and optimize cycle management and clinical outcomes.

Study design, size, duration:

A retrospective cohort study was conducted at an academic fertility center and included 535 patients undergoing in-vitro fertilization (IVF) and preimplantation genetic testing for aneuploidy (PGT-A) between 2014-2018. 2305 embryos were biopsied on either day 5 (n=481) or day 6 (n=1824) depending on rate of embryonic growth and blastocyst expansion. A standard infertility evaluation was performed within 12 months of treatment and the decision to undergo PGT-A was a joint discussion between patient and physician.

Participants/materials, setting, methods:

Euploid rate was the primary outcome of interest and was calculated according to the day of biopsy and stratified by morphologic grading (good: 5/6AA-BB, average: 5/6BC-CC, poor: 3/4BB-CB) and patient age. Secondary outcomes included implantation (IR) and ongoing pregnancy rate (OPR) in subsequent euploid transfer cycles. Implantation rates were calculated based on a positive pregnancy test after embryo transfer while OPR was defined by the presence of a viable fetal heart rate >7 weeks' gestation.

Main results and the role of chance:

A higher euploidy rate was observed among day 5 compared to day 6 blastocysts overall (53.01 vs. 39.75%, $p<0.0001$). As expected, aneuploidy rates increased with maternal age and no difference in euploid rates was observed among day 5 vs. 6 blastocysts in women ^{3}41-years-old (33.33 vs. 23.17%, p=0.22). A significantly higher euploid rate was also observed among high grade embryos compared to low grade embryos (47.43% vs. 28.23%, $p<0.0001$); however, day 5 biopsied blastocysts demonstrated a significantly higher euploid rate compared to day 6 biopsied blastocysts among high grade embryos (55.15% vs. 44.87%, p=0.0002), while no difference in euploid rates was observed among lower grade embryos (23.68 vs. 28.64%, p=0.64).

Overall, no significant difference in IR or OPR between day 5 and day 6 blastocysts was observed (72.41 vs. 70.91% and 71.42 vs. 65.63%, respectively). High grade embryos demonstrated improved IR compared to lower grade embryos (73.20 vs. 62.50%, p=0.047) but OPR were not significantly different (69.35 vs. 55.00%, p=0.10). Using regression logistic analysis to stratify embryos by morphologic grade and day of biopsy, high grade embryos biopsied on day 5 yielded similar IR and OPR compared to day 6 (72.29 vs. 73.47%, p=0.87, and 71.67 vs. 68.06%, p=0.57, respectively).

Limitations, reasons for caution:

The retrospective nature of this study is its major limitation and a prospective randomized design would be required to validate these results. Live birth outcomes were also not reported in this dataset.

Wider implications of the findings:

Contrary to previous studies, our results demonstrate that early blastocyst formation is only associated with higher euploidy rates among high-grade embryos in women <40-years-old. Early embryo development does not predict improved pregnancy outcomes in PGT-A cycles, but may be a useful embryo selection adjunct to morphologic grading in non-biopsied cycles.

[4]*Womens College Hospital, Gynecology, Toronto, Canada*
[5]*University of Torornto, Obstetrics and Gynecology, Toronto, Canada*
[6]*University of Torornto, Physiology, Toronto, Canada*
[7]*University of Torornto, Institute of Medical Sciences, Toronto, Canada*

Study question:
Does blastocyst morphology influence the concentration of cell-free DNA isolated from embryo culture-conditioned media(ECCM) and blastocoel fluid(BF), as well as the accuracy of non-invasive preimplantation genetic aneuploidy-testing(NIPGT-A) using this DNA?

Summary answer:
Cell-free DNA concentration in embryo culture-conditioned media (ECCM) and blastocoel fluid (BF) and the accuracy of NIPGT-A are not affected by blastocyst morphology grade.

What is known already:
Recently cell-free embryonic-DNA(cfeDNA) has been found in both BF and ECCM. These studies showed that the BF, ECCM or combined ECCM and BF could be potentially used for non-invasive aneuploidy and monogenic disease detection. However, this approach needs to be optimized before it could be routinely used clinically. This includes a better understanding of the nature of the cfeDNA releasing from human embryonic cells into BF and ECCM. Previous studies have reported that the concentration of cfeDNA correlates with apoptotic events. Therefore, lower quality blastocysts may have a higher rate of apoptosis and, as result, a higher quantity of cfeDNA.

Study design, size, duration:
This is a prospective study where we analysed the amount of amplified DNA and results from next generation sequencing (NGS) from 71 combined ECCM and BF samples and their corresponding 71 trophectoderm (TE) biopsy samples derived from fresh blastocysts (n= 71). The embryos were obtained from 21 patients undergoing PGT-A cycles between October 2018 and December 2018 with age ranging from 29-42 years (37.0 ± 3.3).

Participants/materials, setting, methods:
Embryos were zona-breached on d4 and transferred into fresh 15µl-droplets of Global-HP HSA medium. Morphology of Day5/6 full/expanded blastocysts was assessed based on the simplified SART scoring system: good (≥BB:-AA,AB,BA,BB) (n=35), and moderate/low quality (<BB:–AC,CA,BC,CB,CC) (n=36). Both ECCM and BF were collected as one NIPGT sample after pulse-laser collapse of the blast. The corresponding TE-samples were used as controls. Whole genome amplification (WGA) products were assessed with the Qubit3.0-Fluorometer, BioAnalyzer™ and VeriSeq™ PGS-NGS kit.

Main results and the role of chance:
WGA-DNA was detected in all NIPGT-A (n=71) and TE (n=71) samples. The mean amount of NIPGT-A sample WGA-DNA was lower for good quality blastocysts compared with moderate/low quality blastocysts 13.9 ± 0.9 ng/µl (5.1-30.0 ng/µl) vs. 15.7 ± 1.0 ng/µl (6.3-36.0 ng/µl), respectively, however the difference was not statistically significant. Average size of WGA-DNA fragments of NIPGT samples from good quality blasts was 746.9±42.6bp, and 736.9±26.9bp from moderate/low quality blasts. Informative NIPGT-A results were obtained from 98.6% TE biopsies (70/71) and from 88.7% NIPGT-A samples (63/71). Concordant rate for ploidy status (euploid/aneuploid) between NIPGT and TE biopsy samples for good (31/31, 100%) and moderate/low (32/32, 100%) quality blastocysts was not statistically different. NIPGT-A correctly determined the gender of embryos and aneuploidy in all NIPGT samples. Considering the amount of NIPGT-A WGA DNA from different blastocysts and the size of NIPGT-A WGA DNA fragments (not close to nucleosomal size), it is likely that cell apoptosis is not the only mechanism for DNA to be released into BF and ECCM from the ICM and TE. Therefore, other mechanisms for release of embryonic DNA, which are either passive or active or both, are likely involved.

Limitations, reasons for caution:
This study was limited to the number of samples. The amount of possible maternal contamination of non-invasive samples due to residual cumulus-corona radiata cells could be further decreased, and there is a room for additional optimization of the techniques for isolation, amplification and analysis of embryonic DNA from NIPGT-A samples.

Wider implications of the findings:
Our findings provide evidence that ECCM combined with BF has great potential for use with NIPGT-A. Also, NIPGT-A samples can be used as a backup source of embryonic DNA in case of inconclusive NGS results from the TE biopsy, potentially avoiding re-biopsy.

O-202 Climacteric status at the age of 46: impact on metabolic outcomes in population-based study

S. Savukoski[1,2], H. Mäkelä[1,2], J. Auvinen[2,3], J. Jokelainen[4], K. Puukka[2,5], T. Ebeling[2,6], E. Suvanto[1,2], M. Niinimäki[1,2]

[1]*Department of Obstetrics and Gynaecology, Oulu University Hospital, Oulu, Finland*
[2]*Medical Research Centre Oulu, Oulu University Hospital and University of Oulu, Oulu, Finland*
[3]*Centre for Life Course Health Research, University of Oulu, Oulu, Finland*
[4]*Centre for Life Course Epidemiology and Systems Medicine, University of Oulu, Oulu, Finland*
[5]*NordLab Oulu, Oulu University Hospital, Oulu, Finland*
[6]*Department of Internal Medicine, Oulu University Hospital, Oulu, Finland*

Study question:
Does earlier climacterium impair cardiovascular risk-associated metabolic outcomes in women?

Summary answer:
Being climacteric at the age of 46 was associated with unfavorable changes in metabolic features, as compared to preclimacteric controls.

What is known already:
Several adverse changes in cardiovascular disease (CVD) risk factors during menopausal transition have been described in earlier studies: increased waist circumference, higher total cholesterol and low-density lipoprotein, altered concentrations of inflammatory markers, increased fat mass, central fat accumulation, and higher blood pressure. Many studies have suggested that EM (early menopause) and POI (premature ovarian insufficiency) increase the risk of cardiovascular morbidity.

Study design, size, duration:
A prospective cohort study including 2685 women of the Northern Finland Birth Cohort 1966 (NFBC1966). Cohort members have been followed since antenatal period with questionnaires and clinical examinations. This study was based on clinical examinations at the ages of 14, 31 and 46, on laboratory samples taken at the ages of 31 and 46 and on a follow-up questionnaire at the age of 46.

Participants/materials, setting, methods:
Study subjects were divided into two groups: climacteric cases and preclimacteric controls, by their menstrual anamnesis and FSH values at the age of 46. Between these groups, cardiovascular risk-associated anthropometric, hormonal and metabolic parameters were compared. The analyses were adjusted for age at menarche, parity, smoking, level of education, and physical activity. The possible effect of HRT (hormone replacement therapy) on outcomes was taken into account by including and excluding HRT users in respective sub-analysis.

Main results and the role of chance:
There were 381 climacteric and 2304 preclimacteric women in the study population. Women who were climacteric at the age of 46 had lower BMIs (body mass index) (P = 0.029), testosterone levels (P = 0.018) and FAIs (P = 0.009) at the age of 31. At the age of 46, they had less skeletal muscle (P < 0.001), a higher fat percentage (P = 0.016), higher cholesterol levels (total cholesterol [P < 0.001], low-density lipoprotein [LDL-C] [P < 0.001], high-density lipoprotein [HDL-C] [P = 0.022], and triglycerides [P = 0.008]) and higher alanine aminotransferase (ALT) (P=0.023) and gamma-glutamyltransferase (GGT) (P < 0.001) levels compared to preclimacteric women. Waist circumference, WHR, BP and hs-CRP levels did not differ between the groups. 111/381 of the climacteric women were using hormone replacement therapy (HRT). In sub-analysis that excluded the HRT-users, triglycerides, HDL-C and body fat percentage did not differ between the groups.

Limitations, reasons for caution:

Data concerning menstrual anamnesis and hormonal medications were based on self-reporting. In the sub-analysis excluding HRT users, the difference in body fat percentage and HDL-C became insignificant, even though the means of those parameters did not change, probably due to the smaller number of study subjects included in the analyses.

Wider implications of the findings:

Medical professionals should be aware of the impairing effect of climacteric transition on metabolic features, and that women who reach climacterium earlier may be more at risk for adverse long-term health consequences.

O-203 Does one size fit all? Female age impacts the number of oocytes retrieved to maximise fresh live birth rates: an analysis of 256,643 cycles

N. Zhang[1], Y.J. Law[1], C. Venetis[1], G. Chambers[1], H. Katie[1]

[1]University of New South Wales, National Perinatal Epidemiology and Statistics Unit NPESU, Sydney, Australia

Study question:

What is the number of oocytes retrieved to maximise live birth rates (LBR) after fresh assisted reproductive technology (ART) cycles for women of different ages?

Summary answer:

The maximal LBR was observed at 6-11, 11-16, 9-17 and 15-17 oocytes for women less than 30, 30-34, 35-39 and 40-44 years old, respectively.

What is known already:

Previous studies have shown that the number of oocytes retrieved is an important prognostic factor in fresh ART cycles. While some have advocated that large oocyte yields lead to increased LBR, others have suggested an excessive response results in impaired endometrial receptivity and decreased oocyte quality, leading to decreased LBR. High yields have also been associated with an increased risk of developing ovarian hyperstimulation syndrome (OHSS). Although previous studies have attempted to determine an optimal number of oocytes, most have not investigated the potential effect-modifying role of female age and whether this number changes for women of different ages.

Study design, size, duration:

This is a retrospective population-based registry study, with full ascertainment of cycles, using data extracted from the Australian and New Zealand Assisted Reproduction Database (ANZARD). The study included 129,023 women undergoing 256,643 fresh autologous cycles with at least one oocyte retrieved, performed from January 2009 to December 2015.

Participants/materials, setting, methods:

Live birth (LB) was defined as ≥1 liveborn baby at ≥ 20 weeks gestation. The secondary outcome was the incidence of ovarian hyperstimulation syndrome (OHSS) requiring hospitalisation. Generalised estimating equation (GEE) regression models were fitted to model LB with the number of oocytes as the primary independent variable and adjusted for confounders. An interaction term between the number of oocytes retrieved and female age was included to evaluate the potential effect-modifying role of age.

Main results and the role of chance:

Overall, the median age of patients was 36 years and the median number of oocytes retrieved was 8.

The number of oocytes remained a statistically significant predictor (P<0.001) of LB after adjusting for female age, parity and fresh cycle count. Compared with the reference category of 10-14 oocytes, the retrieval of 1-4 oocytes (adjusted odds ratio-AOR 0.46, 95% CI: 0.44-0.48) and 5-9 oocytes (AOR 0.85, 95% CI: 0.83-0.88) had lower odds of LB. At greater oocyte yields, the adjusted odds of LB reached a plateau followed by a decline when >20 oocytes were retrieved (15-19 oocytes: 0.96 (95% CI: 0.92-0.99), 20-24 oocytes: 0.73 (95% CI: 0.70-0.77) and ≥ 25 oocytes: 0.43 (95% CI: 0.40-0.47)).

Following stratification by female age, the predicted probability of LB was found to peak at different oocyte yields. Overall, the maximal LBR was observed at 6-11, 11-16, 9-17 and 15-17 oocytes for women less than 30, 30-34, 35-39 and 40-44 years old, respectively.

The risk of OHSS requiring hospitalisation increased significantly with the number of oocytes retrieved, being 1.1% with the retrieval of 15 oocytes and reaching 6.4% with the retrieval of ≥ 25 oocytes.

Limitations, reasons for caution:

The present study is subject to the potential presence of confounding bias due to unmeasured variables, including ovarian stimulation protocols. Due to the observational nature of the study, a cause-effect relationship between the number of oocytes retrieved and LBR should not be assumed.

Wider implications of the findings:

The results from this study highlight that ovarian stimulation protocols should be informed by female age. Younger women require less oocytes retrieved to maximise LBR in fresh cycles which in turn reduce OHSS occurrences.

O-204 Ovarian Reserve and Exposure to Environmental Pollutants (ORExPo study)

A. La Marca[1], M. Simoni[2], M. Michelangeli[3], A. Casonati[3], R. Grassi[3], B. Enrica[4], S. Daniele[2]

[1]University of Modena and Reggio Emilia- and Clinica Eugin, Mother-Infant Department, Modena, Italy

[2]Unit of Endocrinology, Department of Biomedical- Metabolic and Neural Sciences-University of Modena and Reggio Emilia, Modena, Italy

[3]Hopenly srl, Hopenly srl, Reggio Emilia, Italy

[4]Department of Laboratory Medicine and Pathology Azienda USL of Modena, Department of Laboratory Medicine and Pathology Azienda USL of Modena, Modena, Italy

Study question:

to assess the association existing between environmental pollutants and AMH. The hypothesis is that exposure to pollutants may be associated to an age-independent decrease in AMH, suggesting decreased ovarian reserve.

Summary answer:

AMH serum levels are significantly affected by high levels of air pollution.

What is known already:

Many chemicals present within the environment, as well as natural and artificial components of our diet, have the potential to interfere with the physiological role of hormones, interfering with hormone biosynthesis, signalling or metabolism. In the last years AMH, a protein secreted by granulosa cells, has emerged as a reliable marker of ovarian reserve. The influence of age and smoking on AMH serum levels is largely accepted, although a clear effect of environment was not demonstrated so far.

Study design, size, duration:

A longitudinal, observational, retrospective, real-world big data trial was performed. All laboratory AMH measurements of women living in the area surrounding the city of Modena performed from January 2007 to October 2017 at the Central Laboratory of Modena Hospital were extracted and collected in a large database.

Participants/materials, setting, methods:

The study design did not foresee any inclusion/exclusion criteria, since the database was formed by the entirety of data produced by the laboratory. AMH was measured with commercial assay. A computing data warehouse was created, in which AMH data were connected to patients' age and residential address. The database was completed, including environmental data and considering the place where each patient lived for geo-localization. The environmental exposure considered daily particulate matter (PM) and NO2 values.

Main results and the role of chance:

1,463 AMH measurements were collected for 1,318 women. Serum AMH levels (mean 1.94 ng/mL and median of 0.90 ng/mL) were inversely related to patients' age (Rho=-0.437, p<0.001), although not related to age in patients younger than 25 years (Adjusted R- squared 0.068 p=0.055). On the contrary, AMH was inversely related to age after 25 years of age (Adjusted R-squared 0.120, p<;0.001).

AMH was inversely related to environmental pollutants, such as PM10 (Rho=-0.088, p=0.001), PM2.5 (Rho=-0.062, p=0.021) and NO2 (Rho=-0.111, p<0.001). This association was age–independent. No relationships were found between AMH and environmental temperatures.

Limitations, reasons for caution:

The study was based on a retrospective analysis. The assay for the AMH measurement has been revised during the study period and this may introduce variability in absolute values for the hormone

Wider implications of the findings:

It is well known that there is a large genetic component in the ovarian reserve, but other factors may influence the extent of the follicular pool such as environmental factors. Results of this study strongly suggest that environmental factors may modify the downward dynamics of AMH and ovarian reserve.

na

O-205 Chronic elevation of serum Progesterone levels and ovarian macrocysts in infertile and/or amenorrheic women: think of Cytochrome P450 oxidoreductase deficiency!

A. Dumont[1], G. Papadakis[2,3], J. Bouligand[4], N. Pitteloud[2], J. Young[3], D. Dewailly[1]

[1]Centre Hospitalier Régional Universitaire. Hopital Jeanne de Flandre, Department of endocrine gynecology and reproductive health, Lille, France

[2]Centre Hospitalier Universitaire Vaudois, Service d'endocrinologie diabétologie et métabolisme, Lausanne, Switzerland

[3]Hôpitaux Universitaires Paris Sud. Hopital Bicêtre, Service d'Endocrinologie Adulte, Paris, France

[4]Hôpitaux Universitaires Paris Sud. Hopital Bicêtre, Service de génétique moléculaire pharmacogénétique et hormonologie, Paris, France

Study question:

Can Cytochrome P450 oxidoreductase deficiency (PORD) be revealed lately in adult women through infertility and/or cycle disorder?

Summary answer:

PORD was biologically and genetically confirmed in 4 women with chronically elevated serum progesterone (P) levels who were referred for infertility and/or cycle disorder.

What is known already:

PORD is a rare autosomal recessive genetic disease most often revealed by ambiguous genitalia and/or skeletal abnormalities in infants and children. It is responsible for a decrease in the activity of P450 enzymes including *CYP21A2*, *CYP17A1* and *CYP19A1*.

Very few undiagnosed cases were described in adults where PORD was often misdiagnosed as Polycystic Ovary Syndrome (PCOS) or non-classical 21-Hydroxylase deficiency (NC-CAH). Little is known about fertility and pregnancy outcomes in such cases with late-onset PORD.

Study design, size, duration:

In this series we report 4 patients recruited in 3 different institutions between January 2017 and September 2018.

Participants/materials, setting, methods:

4 patients (P1, P2, P3 and P4) aged 19, 30, 36 and 38, respectively, were included in this study. They all underwent full clinical examination, basal hormonal assessment, ACTH stimulation test, pelvic ultrasound and sequencing of the *CYP21A2* and *POR* genes. When possible, a family study was performed.

In Vitro Fertilization (IVF) with conventional procedures followed by frozen embryo transfer was performed in P3 and P4, under glucocorticoid therapy

Main results and the role of chance:

All patients had irregular cycles or amenorrhea. None had hyperandrogenism. P1 had a supsicion of Shprintzen syndrome (craniosynostosis). Basal estradiol and total testosterone levels were low (<0.15 and <0.5 nmol/L, respectively). Serum FSH and LH levels were normal to moderately elevated. P and 17 hydroxyprogesterone (17OHP) levels were increased (3.11 to 35.23 and 5.7 to 11.6 nmol/L, respectively). The P, 17OHP, 21-deoxycortisol and corticosterone rises 60 min after ACTH stimulation were largely excessive (4.8 to 31.5-fold, 3.6 to 11.5-fold, 5 to 70-fold and 2.6 to 14.1-fold, respectively). Conversely, basal serum cortisol levels were low-normal, with weak rises under ACTH (1.2 to 2.6-fold). In all patients, pelvic ultrasound showed ovarian bilateral macrocysts. All 4 patients were homozygous or compound heterozygotes for *POR* gene (NM_000941.3) mutations. P1: c.859G>C, p.(Ala287Pro) homozygous ; P2: c.1648C>T, p.(Arg550Trp) and c.1826_1849del, p.(Leu612_Leu619del) ; P3: c.1324C>T, p.(Pro442Ser) and c.1249-1G>C ; P4: c.1825C>T, p.(Gln609*) and c.1859G>C, p.(Trp620Ser).Despite low E2 levels at ovulation triggering, pregnancy was obtained in P2 and P3 after IVF and frozen embryo transfer under hydrocortisone that was continued throughout pregnancy. P3 presented hypertension, preeclampsia and partial adrenal insufficiency. P2 had a normal twin pregnancy. The male (P4) and the twin female (P3) newborns were healthy.

Limitations, reasons for caution:

Hormonal assessment and ultrasound were done in 3 different institutions while genetic testings were done in 2 units.

Wider implications of the findings:

The diagnosis of PORD must be considered in infertile women with chronic anovulation, elevated P levels and ovarian macrocysts, after exclusion of NC-CAH. Genetic counseling must be provided to the patients, as beside reproductive issues, PORD may induce adrenal deficiency, disordered sex development, and skeletal malformations in the offspring.

SESSION 57: THE INFLUENCE OF ENDOMETRIOSIS ON PREGNANCY RATES AND METHODS FOR IMPROVEMENT

Tuesday 25 June 2019 Haydn 2 17:00 - 18:00

O-206 Implantation after embryo transfer (ET) of equal quality embryos is impaired in endometriosis compared to male subfertility patients: a matched case-control study

E. Decroos[1], C. Deboever[1], B. Schoot[2], C. Blank[2], P. De Sutter[1]

[1]Ghent University Hospital, Reproductive Medicine, Ghent, Belgium

[2]Catharina Hospital Eindhoven, Gynaecology, Eindhoven, The Netherlands

Study question:

Investigating the uterine receptivity in IVF (In vitro fertilisation)/ICSI (Intracytoplasmic sperm injection) cycles following equal quality ET, compared between endometriosis patients and male factor subfertility.

Summary answer:

Implantation and subsequent IVF/ICSI outcomes in endometriosis showed to be significantly lower compared to outcomes after equal quality ET in a male subfertility population.

What is known already:

Endometriosis is a benign, gynaecological disease affecting approximately 10% of the female population, with prevalences peaking during reproductive life. Endometriosis is often accompanied by different degrees of adenomyosis, and can be visible in up to 79% of these women. Both pathologies are frequently associated with subfertility. Most studies focused on ovarian dysfunction and impaired oocyte and embryo characteristics, while no major impact on uterine receptivity is considered.

Study design, size, duration:

First fresh IVF/ICSI cycles resulting in a single embryo transfer on day 5, performed in Ghent University hospital, were included. In this subfertile population of 1053 subjects, 121 women with endometriosis and 361 patients undergoing IVF/ICSI because of male subfertility were eligible. 118 endometriosis cases were matched 1:1 to 118 male subfertile controls stratified by female age (±1 year), parity (±1 delivery) and embryo quality (identical ALPHA grading categories).

Participants/materials, setting, methods:

A retrospective matched case-control study was executed between 01/07/2015 and 31/08/2017 at the Department for Reproductive Medicine in Ghent University Hospital. Endometriosis was diagnosed by laparoscopy, transvaginal ultrasound or magnetic resonance imaging and was classified according the revised American Society for Reproductive Medicine (rASRM) score into grade I/II (34.7%) vs. grade III/IV (65.3%). Male subfertility was defined by the World Health Organization (WHO) criteria (5th edition).

Main results and the role of chance:

A multiple logistic regression (MLR) model was generated using the Enter method, including the matching variables and variables showing a significant

difference during univariate tests, including stimulation protocol, IVF/ICSI application and dysmenorrhea, to correct for possible confounding. A significant difference between the endometriosis and male subfertility population was found for positive HCG test on day 16 (p=0.047; OR=2.077;CI=[1.009;4.276]), clinical pregnancy rate (p=0.038;OR=2.265;CI=[1.048; 4.893]), ongoing clinical pregnancy rate (p=0.046;OR=2.292;CI=[1.016;5.173])) and live birth rate (p=0.043; OR=2.502;CI=[1.029;6.087]). However, undiagnosed co-existent adenomyosis can have an important attribution to the impaired IVF/ICSI outcomes observed in this study. Other factors contributing to the role of chance were minimized by matching and by controlling for confounding by applying MLR. Besides, case and control populations were highly comparable on characteristics of reproductive capability (AMH, age male, age female and number of previous IVF/ICSI cycles).

Limitations, reasons for caution:

Due to the tertiary hospital setting, a higher frequency of co-existent subfertility diagnoses in women with endometriosis can play an important role in the reported impaired IVF/ICSI outcomes. It needs further research to what extent a combination of adenomyosis with endometriosis is associated with the impaired fertility chances.

Wider implications of the findings:

These results are only valid for IVF/ICSI cycles due to possible positive/negative influences of the IVF/ICSI process, whereby results can not be extrapolated to the general population. This study confirmed that an altered uterine receptivity is present in women with endometriosis, complementary to the existing knowledge on ovarian disease.

O-207 Short-term down-regulation of Gonadotropin-releasing hormone agonists does not improve pregnancy rate and live birth rate in frozen embryo transfer cycles in patients with endometriosis

Z. Wen[1], L. Yubin[2], Q. Mai[1]

[1]the Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University., the Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University., Guang dong, China

[2]the Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University, the Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University, guangdong, China

Study question:

Does Gonadotropin-releasing hormone agonists (GnRH-agonist) down-regulation increase pregnancy rate (PR) and live birth rate (LBR) in frozen embryo transfer (FET) cycles in women with endometriosis

Summary answer:

Down-regulating GnRH-agonist for less than three months does not increase the PR and the LBR in FET cycles in women with endometriosis including adenomyosis

What is known already:

According to the 2014 ESHRE guidelines for management of women with endometriosis, the prolonged down-regulation of GnRH-agonists prior the controlled ovarian hyperstimulation and the in-vitro fertilization treatment increases the chance of pregnancy in women with endometriosis.That is because of the suppression of hostile peritoneal microenvironments and improve the endometrium receptivity in women with endometriosis. However, whether the pre-treatment with GnRH-agonist prior the FET would increase the PR and LBR in women with endometriosis including adenomyosis is still unknown

Study design, size, duration:

This retrospective cohort study has been performed between January 2016 to January 2018. The selected female patients with endometriosis or adenomyosis have undergone frozen embryo-transfer (FET) at the Reproductive Medicine Center of The First Affiliated Hospital of Sun Yat-sen University

Participants/materials, setting, methods:

This study has included 911 patients with endometriosis or adenomyosis undergone 1286 FET cycles,376 cases have down-regulated GnRH-agonist ,while 909 cases were natural cycles (NC) or hormone replacement treatment (HRT) (NC/HRT group). In GnRH-agonist down-regulation group, patients were injected 3.75mg triptorelin14 days to 3 months before the use of estrogen. If the down-regulation duration is more than 1 month, patients have 3.75mg triptorelin every 28 days. SPSS 20 was used to analyze statistics

Main results and the role of chance:

Analysis of data includes the base line of age, basic FSH, BMI, embryo transfer number and the endometrial thickness did not found any significant differences.

Both In <38-year-old patients group and in ≥38-year-old patients group with endometriosis, PR and LBR in the GnRH-agonist down-regulation group and in NC/HRT group were found no statistically significance(52.44% and 42.38% VS 46.80% and 40.10%;P=0.147;0.612;23.5% and 20.0% VS 25.41% and 16.47%; P=0.589;0.349)

Both In <38-year-old patients group and in ≥38-year-old patients group with adenomyosis,PR and LBR in the GnRH-agonist down-regulation group and in NC/HRT group were found no statistically significance(43.61% and 27.53%VS 48.89% and 18.42%; P=0.589;0.349;12.5% and 5%VS31.80% and 22.22%;P=0.159;0.170).

We further analyzed data of the GnRH-agonist down-regulation groupusing median down-regulation duration (DRD). In patients with endometriosis, when DRD < 1 month, PR and LBR were 50.00% and 40.65%, respectively, when DRD ≥ 1month, PR and LBR were 45.78% and 37,30%, respectively. No significant difference was found as compared to NC/HRT group (PR=43.71%, LBR=37.07%). In patients with adenomyosis, when DRD < 1.5 month, PR and LBR were 40.30% and 22.41%, respectively, when DRD ≥1.5m, PR and LBR were 34.00%,15.56%. No significant difference was found as compared to NC/HRT group (PR=43.28%,LBR=19.64%)

Limitations, reasons for caution:

This is a retrospective cohort study, the selection bias is inevitable and the duration of GnRH agonist down-regulation was not uniform in each group. The total number of adenomyosisis 185 cycles which is relatively few and may cause false negative answer.

Wider implications of the findings:

Our research indicated that a short-term GnRH agonistspretreatment of less than three months prior FET does not increasethe PR and the LBR of women with endometriosis or adenomyosis. Whether long-term down-regulation of GnRH agonistswill benefit the outcome of FET is beyond studied

Trial registration number:

The study has no external funding. There are no competing interests.

O-208 Long-term gonadotrophin-releasing hormone agonist (GnRHa) therapy before in vitro fertilisation (IVF) for improving fertility outcomes in women with endometriosis: a Cochrane systematic review and meta-analysis

E. Georgiou[1], P. Melo[1], P. Baker[2], H.N. Sallam[3], A. Arici[4], J.A. Garcia-Velasco[5], A.M. Abou-Setta[6], C. Becker[7], I.E. Granne[8]

[5]Instituto Valenciano de Infertilidad Madrid, IVI Madrid, Madrid, Spain

[6]University of Manitoba, Knowledge Synthesis Platform- George and Fay Yee Centre for Healthcare Innovation, Winnipeg, Canada

[7]University of Oxford, Nuffield Department of Women's & Reproductive Health, Oxford, United Kingdom

[8]University of Oxford, Nuffield Department of Women's & Reproductive Health, Oxford, United Kingdom

Study question:

Does long-term GnRHa therapy versus no GnRHa pre-treatment before standard IVF in women with endometriosis improve reproductive outcomes?

Summary answer:

There is evidence of an increase in the clinical pregnancy rate with GnRHa therapy before IVF and no evidence of an increased complication rate.

What is known already:

Endometriosis has a negative impact on fertility through mechanisms that are currently not well established. Women with endometriosis often require

IVF to increase their chances of pregnancy. Studies have suggested that surgical treatment of endometriosis may improve IVF outcomes whereas surgical treatment to ovarian endometriomata could negatively impact ovarian reserve. Long-term GnRHa treatment, which is known to improve endometriosis pain via pituitary suppression, has been proposed as an alternative to surgical intervention. Studies have suggested that GnRHa use prior to IVF may also improve reproductive outcomes compared to standard IVF protocols although efficacy and safety have not been well established.

Study design, size, duration:

A Cochrane systematic review and meta analysis was performed. Electronic searches of the Cochrane Gynaecology and Fertility Specialised Register of Controlled Trials, CENTRAL, MEDLINE, EMBASE, PsycINFO and CINAHL were conducted to January 2019 to identify relevant randomised controlled trials (RCTs). In addition, the following trial registers were searched for RCTs: www.clinicaltrials.gov and www.who.int/trialsearch/Default.aspx.

Participants/materials, setting, methods:

Participants: Infertile women diagnosed with endometriosis via laparoscopy-/laparotomy undergoing IVF or intracytoplasmic sperm injection (ICSI).

Intervention: GnRHa therapy for minimum 3 months before standard IVF/ICSI.

Comparison: standard IVF/ICSI only.

Two independent authors screened studies and extracted data. Risk ratios (RR) were calculated for dichotomous data and mean differences (MD) for continuous data, with 95% confidence intervals (CI). Heterogeneity was examined via the I^2 statistic. Primary analysis was conducted on data per woman randomised.

Main results and the role of chance:

Seven studies were included, incorporating 496 women. Eight studies are awaiting classification and two are ongoing studies.

On comparing long-term GnRHa therapy before IVF/ICSI to standard IVF/ICSI, there was no evidence of a difference in the primary outcomes of live birth rate (RR 7.31, 95% CI 0.97 to 55.29, one RCT, n = 67, I^2 not applicable) or complication rate (RR 0.64, 95% CI 0.16 to 2.57, one RCT, n = 116, I^2 not applicable).

There was evidence of an increase in the clinical pregnancy rate (RR 1.31, 95% CI 1.05 to 1.64, seven RCTs, n = 488, I^2 = 16%) and mean number of oocytes (MD 1.09, 95% CI 0.32 to 1.86, five RCTs, n = 333, I^2 = 73%) with GnRHa therapy. There was no evidence of a difference in the multiple pregnancy rate (RR 0.22, 95% CI 0.01 to 4.40, one RCT, n= 61, I^2 not applicable), miscarriage rate (RR 0.36, 95% CI 0.02 to 8.39, one RCT, n = 60, I^2 not applicable) or mean number of embryos (MD -0.20, 95% CI -1.68 to 1.28, one RCT, n = 119, I^2 not applicable). No studies were found that looked at ectopic pregnancy or fetal abnormality rates.

Limitations, reasons for caution:

The quality of some of the included studies as well as the significant degree of heterogeneity are the major limitations of this systematic review. In particular, live birth rate data are currently based on the results from one small single-centre RCT with wide confidence intervals.

Wider implications of the findings:

The clinical pregnancy rate appears to be higher with GnRHa therapy before IVF/ICSI in women with endometriosis. Further high-quality RCTs are required to determine whether this impacts on live birth rate and to more closely examine potential complications.

Trial registration number:

Not applicable.

O-209 Uterine administration of CXCL12 (SDF-1) increases pregnancy rates in mice with induced endometriosis

A.C. Rosa-e-Silva[1], J.C. Rosa-e-Silva[2], R. Mamillapalli[3], H.S. Taylor[4]

[1]*School of Medicine of Ribeirão Preto- University of São Paulo, Gynecology and Obstetrics, Ribeirao Preto, Brazil*

[2]*School of Medicine of Ribeirão Preto - University of São Paulo., Gynecology and Obstetrics, Ribeirao Preto, Brazil*

[3]*Yale University - School of Medicine- New Haven, Obstetrics- Gynecology and Reproductive Sciences, New Haven, U.S.A.*

[4]*Yale University - School of Medicine, Gynecology and Obstetrics- School of Medicine of Ribeirão Preto, New Haven, U.S.A.*

Study question:

Does CXCL12 (SDF-1) injected in the uterus, increase Bone Marrow Derived Stem Cells migration to the endometrium and improve fertility in mice with induced endometriosis?

Summary answer:

CXCL12 injection improves pregnancy rates in mice with endometriosis (30%increase), with no association between fertility improvement and a higher migration of BMDSCs to the uterus.

What is known already:

Stem cells migration plays a critical role in the pathogenesis of endometriosis.Using a mouse model of bone marrow transplantation (BMT) with marked cells (donor GFP+), we have previously demonstrated that the presence of endometriosis reduced the migration of BMDSCs to the uterus, with high concentration of these cells engrafting the lesion instead. Impaired BMDSCs cell migration to the uterus could explain the lower pregnancy rates seen in women with endometriosis. The administration of stem cell chemotaxic molecules to the uterus could potentially improve fertility.

Study design, size, duration:

Cross sectional study with 40 C57BL/6 female wild type mice that underwent BMT with BM from C57BL/6 GFP+ female donors. After 4 weeks the animals underwent surgery to induce experimental endometriosis or a sham control surgery (N=40). Each group was then subdivided to receive a single injection of CXCL12 (SDF-1) or placebo in both uterine horns, composing four study groups. Three weeks after surgery the animals were caged with proven males (C57BL/6) to assess fertility.

Participants/materials, setting, methods:

Endometriosis was induced by suturing endometrial tissue on the peritoneal cavity. Injection of CXCL12 or placebo in the uterine horns was done during a second laparotomy. For breeding, one male was placed with four females for four weeks. The reproductive outcomes were evaluated. Animals were euthanized in diestrus after delivery and embryo implantation markers were evaluated by immunohistochemistry (Hoxa11, $\alpha V\beta 3$ integrin and PR). Quantification of GFP+ BMDSCs in the uterus was also evaluated by immunofluorescence.

Main results and the role of chance:

Four study groups were composed: Endometriosis+CXCL12 (Edt+CX), Endometriosis+Placebo (Edt+Pl), Sham+CXCL12 (Sh+CX) e Sham+Placebo (Sh+Pl). The placebo treated endometriosis groups had lower pregnancy rates than the Sham groups (50% vs 100%; $p<0.0001$). There was a 28% increase in pregnancy rates in the endometriotic mice treated with CXCL12 (Edt-CX) (78%) in relation to the Edt-Pl group (50%) ($p<0,0001$). This increase was not associated to a higher engraftment of GFP+ BMDSCs in the uterus that persisted in the postpartum period ($p>0.05$); a transient recruitment prior to or during pregnancy was not evaluated. However, there was a significant increase in the abundance of PR and $\alpha V\beta 3$ integrin in the Edt+CX group when compared to Edt+Pl group ($p<0.0001$ and $p=0.005$, respectively).

Limitations, reasons for caution:

These experiments were performed in a murine model.

Wider implications of the findings:

CXCL12 (SDF-1) improves pregnancy rates of mice with endometriosis. The mechanism of action includes induction of molecules involved in endometrial receptivity. CXCL12 has potential as a therapeutic agent in women with endometrioisis and infertility.

Trial registration number:

Not applicable.

O-210 Reprotoxicity tests performed by manufacturers of IVF disposable devices lack transparency and sensitivity

L. Delaroche[1], P. Oger[2], E. Genauzeau[1], P. Meicler[2], F. Lamazou[2], C. Dupont[3], P. Humaidan[4]

[1]Hôpital Privé de Parly II- 21 rue Moxouris, Centre de Biologie Médicale - Laboratoire d'Assistance Médicale à la Procréation, 78150 Le Chesnay, France
[2]Hôpital Privé de Parly II- 21 rue Moxouris, Centre d'Assistance Médicale à la Procréation, 78150 Le Chesnay, France
[3]APHP- Hôpital Tenon- 4 rue de la Chine, Service de Biologie de la Reproduction - CECOS, 75020 Paris, France
[4]The Fertility Clinic, Skive Regional Hospital Faculty of Health Aarhus University Resenvej 25, 7800 Skive, Denmark

Study question:
Can the reprotoxicity tests performed by manufacturers of disposable devices for IVF laboratories be trusted?

Summary answer:
Reprotoxicity tests used for IVF disposable devices lack standardization and sensitivity for detecting toxic substances. Hence, users should be cautious when choosing IVF devices

What is known already:
Many components used in IVF laboratories, such as culture media and disposable consumables may impair human embryonic development. Consequently, it is necessary to screen all reagents and materials used that will be in contact with gametes and embryos. Numerous reprotoxicity tests have been developed as objective quality control tools independent of clinical factors, e.g. Mouse Embryo Assay (MEA), Human Sperm Survival Assay (HSSA), Limulus Amoebocyte Lysate (LAL) test, biocompatibility and sterility tests. However, presently this field is not regulated, and there is no consensus defining the methodology used or the thresholds applied in quality control tests.

Study design, size, duration:
Through a questionnaire manufacturers of IVF disposable devices were contacted during the period November to December 2018 to explore and compare the methodology of the MEA, HSSA and LAL tests performed to ensure the overall quality of raw materials and final products used in IVF laboratories; we focused in specific on dishes, catheters, tubes, needles, pipettes, straws, syringes, and cones.

Participants/materials, setting, methods:
We approached 9 major IVF companies (Cook Medical, CooperSurgical, Biocare, Merck Serono, Vitrolife, CCD, BD, ThermoScientific, CryoBioSystem) and asked for details about methodology of the MEA, HSSA and LAL tests performed to validate the absence of toxicity in the IVF disposable devices. All specific parameters like mouse strains, number of embryos used, culture conditions (media, temperature, atmosphere, pH), subcontracting, and thresholds were registered and compared between the companies for the MEA, HSSA and LAL tests.

Main results and the role of chance:
There were significant differences in the methodology and thresholds of the reprotoxicity bioassays used by different manufacturers to test their IVF disposable devices. The MEA was performed either with frozen or non-frozen, 1- or 2-cell mouse embryos from different strains. Fifteen to 30 embryos were cultured either in micro-drops or in wells with or without protein supplementation under 5% or 20% O_2. The objectives varied from 70 to 80% of blastocysts or fully expanded blastocysts within 96h sometimes a quantifying the inner cell mass and trophectoderm cells. The HSSA was performed with donor sperm, using gradient centrifugation or swim-up at a final concentration from 4 to 60 M/mL. The sperm incubation with the tested device was performed during 24h at room temperature, 27°C or 32°C. The total motility or the progressive motility were assessed with a threshold of 70%. For LAL test, the extraction mode and the measurement method varied (kinetic turbidimetric or chromogenic tests). Importantly, being aware of the lack of sensitivity of some reprotoxicity tests, some manufacturers developed more sensitive tests using new technologies such as time-lapse or Computed Automated Sperm Analysis (CASA). More detailed results of this study will be presented at the conference.

Limitations, reasons for caution:
Until now 9 IVF industrial companies were approached in this study, however, our results call for the inclusion of a larger number of benchmarked manufacturers.

Wider implications of the findings:
Our study confirms the heterogeneity of the reprotoxicity tests performed by manufacturers when validating their IVF disposable devices. Professionals should call for and request standardization and a future higher degree of transparency as regards reprotoxicity testing from supplying companies.

O-211 Low frequency of exogenous DNA template-mediated repair of double strand breaks in human embryos

N. Marti Gutierrez[1], D. Liang[1], S.W. Park[2], A. Koski[1], H. Ma[1], H. Darby[1], Y. Lee[1], R. Ahmed[1], T. Hayama[1], C. Van Dyken[1], Y. Li[1], E. Kang[1], P. Amato[3], J.S. Kim[2], S. Mitalipov[1]

[1]Oregon Health & Science University, Center for Embryonic Cell and Gene Therapy, Portland, U.S.A.
[2]Institute for Basic Science, Center for Genome Engineering, Daejeon, Korea- South
[3]Oregon Health & Science University, Division of Reproductive Endocrinology, Portland, U.S.A.

Study question:
Repair frequency of DNA double strand breaks (DSBs) by non-homologous end joining (NHEJ) vs. homology directed repair (HDR) with synthetic DNA template in human embryos.

Summary answer:
Repair by NHEJ is the dominant pathway ranging from 95-99%, while the incidence of HDR is much lower (1-5%) when targeting homozygous loci.

What is known already:
CRISPR-Cas9 can be designed to target a specific genomic region in human embryos and induce a DSB. Embryos quickly respond to such DNA damage and repair DSBs by either NHEJ or HDR using the provided exogenous single-stranded oligodeoxynucleotide (ssODN) as a template. NHEJ is detrimental for most therapeutic purposes since it generates small indel mutations often leading to gene inactivation. In contrast, HDR provides means for repair of heritable mutations and thus is critical for development of germline gene therapy.

Study design, size, duration:
Pre-tested CRISPR-Cas9 was injected into human zygotes to target heterozygous MYH7 (g.15819 C>T; NG_007884.1) and homozygous wild-type (WT) MYBPC3 (g.9836, NC_000011.10) loci. A total of 88 injected zygotes were cultured for 3 days and individual blastomeres of cleaving embryos were isolated and target regions were analyzed by sequencing.

Participants/materials, setting, methods:
One sperm and seven oocyte donor volunteers were recruited. Selected sgRNA for both loci, Cas9 protein and ssODNs were co-injected into zygotes 18 hours after fertilization. Each blastomere from injected and control embryos was disaggregated, whole genome amplified and target regions genotyped by Sanger sequencing.

Main results and the role of chance:
DSBs at the heterozygous *MYH7* locus were repaired by NHEJ in 55% (50/91) of embryonic cells resulting in additional indel mutations, while the remaining 45% (41/91) of DSBs were repaired by gene conversion using the intact maternal MYH7 allele as a template. No samples with ssODN-mediated HDR were detected. Targeting of homozygous *MYBPC3* locus resulted in repair by NHEJ in 93% (110/118) of cases leading to indel mutations either in one or both alleles. HDR using the exogenous ssODN was seen in 7% (8/118) of cells with both alleles repaired in only 4 blastomeres.

These results demonstrate that gene conversion is one of the major repair pathways in human heterozygous embryos for the target region. However, HDR with ssODN is low or absent. Repair by NHEJ dominates when targeting homozygous loci.

Limitations, reasons for caution:
Human embryos demonstrate limited HDR via conventional ssODN and exogenous templates of different sizes and design should be tested.

Wider implications of the findings:
Our study provides prospects for development and application of future germline gene therapy

Trial registration number:
not applicable

O-212 Risk factors for Monozygotic Twinning (MZT) in Frozen Embryo Transfer (FET) Cycles

D. Vaughan[1], A. Penzias[2], D. Sakkas[3]

[1]*Beth Israel Deaconess Medical Center/Harvard Medical School, Reproductive Endocrinology and infertility, Boston, U.S.A.*
[2]*Boston IVF, Reproductive Endocrinology and Infertility, Boston, U.S.A.*
[3]*Boston IVF, Embryology, Boston, U.S.A.*

Study question:

Is there a difference in the incidence of monozygotic twinning between individual infertility centers in FET cycles and, if so, can it be explained?

Summary answer:

Individual IVF centers are independent risk factors for MZT in FET cycles. There are likely multiple intrinsic factors contributing to this difference.

What is known already:

The incidence of MZT is greatly increased among infertility patients undergoing fresh IVF cycles compared to the general population (0.7-13% versus 0.45%, respectively), but the reason for this remains unclear. Several risk factors have been proposed and, of those, prolonged embryo culture (blastocyst transfer) appears to be the most significant independent risk factor for MZT. The use of FET cycles is increasing annually, coinciding with an increased utilization of preimplantation genetic testing for aneuploidy (PGT-A) and a hypothesis of a more physiologic uterine environment. There is limited data in the literature on risk factors for MZT in FET cycles.

Study design, size, duration:

This was a retrospective, multicenter, cohort study. Using an electronic medical record system (eIVF, PracticeHwy), clinical pregnancy data (confirmation of a gestational sac(s) and presence of a fetal pole with a heartbeat(s) on ultrasound) was obtained from single embryo transfer (SET) FET cycles from June 1st, 2004 to December 31st, 2016. 122,531 IVF cycles were identified in the database. Our analytic sample comprised 4,991 SET thaw cycles. Of these, 151 (3%) resulted in MZT.

Participants/materials, setting, methods:

Four large infertility centers in the U.S (both academic and private) were included in the study. Only cycles using homologous oocytes were included in the final analysis. Monozygotic pregnancies were identified when the number of fetal heart beats (FHB) seen on ultrasound exceeded the number of embryos transferred (≥2 FHB). A logistic regression analysis was performed to ascertain independent risk factors for MZT within our cohort.

Main results and the role of chance:

The mean (±SD) patient age in the cohort was 37±5 years. 216/4991 patients (4%) had a single cleavage stage embryo transfer and 4775/4991 (96%) had a single blastocyst transfer.

In the logistic regression we controlled for patient age at cycle start, day of embryo transfer, PGT-A performed, media type, freezing technique and clinic number.

Firstly, we examined the media type in which the embryos were cultured. There was not a significant independent difference in the incidence of MZT in those cultures in single step (2961/4991, 59%) or sequential media (2030/4991, 41%), (p=0.35).

Cryopreservation technique performed- slow freeze (5%) or vitrification (95%), also did not have an independent association with MZT rates (p=0.63).

However, when we examined incidence of MZT amongst different clinics in FET cycles we noted a significant difference (range 1.7-4.6%). This difference was significant and independent of all factors examined and listed above in 2 of the 3 clinics (p<0.01), with the largest clinic serving as a reference.

Of note, patient age at cycle start, day of embryo transfer and embryo biopsy for PGT-A were not found to be significant, independent risk factors for MZT in our cohort.

Limitations, reasons for caution:

A limitation of the study is its retrospective nature. We examined data from four infertility centers over a 12-year period. Undoubtedly there have been changes in practice over this period. Without access to genetic information confirming zygosity of pregnancies, it is impossible to be certain of the incidence of MZT.

Wider implications of the findings:

With increasing utilization of FET cycles, it behooves us to counsel patients on the risk of MZT. This risk varies between clinics and each individual clinic should continuously monitor their respective MZT rates over time and investigate potential causative factors in time periods where an increased incidence is seen.

Trial registration number:

O-213 Monozygotic splitting and multiple births following embryo biopsy: analysis of 149 182 single embryo transfers

S.K. Sunkara[1], B. Antonisamy[2], M.S. Kamath[3]

[1]*King's College London, Division of Women's Health, London, United Kingdom*
[2]*Christian Medical College, Department of Biostatistics, Vellore, India*
[3]*Christian Medical College, Department of Reproductive Medicine, Vellore, India*

Study question:

Does embryo biopsy increase the risk of monozygotic splitting following ART?

Summary answer:

The present study demonstrated an increased risk of monozygotic splitting with embryo biopsy and warrants validation by further research.

What is known already:

Multiple pregnancies resulting from transfer of multiple embryos is an iatrogenic adverse outcome following ART. Single embryo transfer (SET) has been promoted to avoid the risk of multiple pregnancies. Extended embryo culture has facilitated SET by allowing for better embryo selection. There has been evidence for increased risk of monozygotic twinning following blastocyst transfers. There have also been speculations that certain other ART procedures are associated with a risk of monozygotic twinning. With the expanding use of preimplantation genetic testing (PGT) it is of interest, whether interventions such as embryo biopsy affect the risk of zygotic splitting and monozygotic twinning.

Study design, size, duration:

Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of ART in the UK. The HFEA has collected data prospectively on all ART performed in the UK since 1991. Recent data from 2001 to 2016 comprising a total of 149 182 SET cycles (4 544 following PGT and 144 638 following autologous IVF) were analysed.

Participants/materials, setting, methods:

Data on women undergoing SET either with embryo biopsy for PGT or autologous IVF between 2001-2016 were analysed to compare the risk of zygotic splitting and monozygotic twins. Zygotic splitting was established when two or more gestational sacs were identified on ultrasound following SET. Twins following SET were considered as being monozygotic. Logistic regression analysis was performed adjusting for potential confounders; female age, IVF or ICSI, day of embryo transfer and fresh or frozen transfers.

Main results and the role of chance:

The live birth rate following SET was 31.9% (95% CI 30.5% - 33.2%) for PGT cycles and 28.9% (95% CI 28.6% - 29.1%) following IVF. The incidence of zygotic splitting following PGT involving embryo biopsy was 2.4% (95% CI 1.7% - 3.3%) versus 1.4% (95% CI 1.3% - 1.5%) following IVF (without embryo biopsy). The incidence of monozygotic twins/ multiple births was 2.2% (95% CI 1.5% - 3.1%) with PGT versus 1.4% (95% CI 1.2% - 1.5%) with IVF. There was a significantly higher risk of monozygotic twinning/ multiples with embryo biopsy cycles versus IVF, unadjusted odds ratio (OR) 1.72, 95% CI 1.24 - 2.38. After adjusting for potential confounders such as female age category, IVF or ICSI, day of embryo transfer and fresh or frozen transfers, there was a trend towards an increased risk, adjusted odds OR 1.55, 95% CI 0.98 - 2.46.

Limitations, reasons for caution:

Limitations with observational data would apply to this study including residual confounding. This is the first study to address this study question, the results need validation by further studies, particularly given the low event rates with monozygotic twinning.

Wider implications of the findings:

The risk of zygotic splitting associated with embryo biopsy during PGT is useful information for clinicians to counsel patients.

Trial registration number:

Not applicable

O-214 Why are frozen oocytes still frozen? A five year follow up of women after social egg freezing

A. Tsafrir[1], T. Miron-Shatz[2], T. Eldar-Geva[1], M. Gal[1], A. Weintruab[1], J. Hyman[1], D. Goldberg[3], H. Levi[1], N. Dekel[1], O. Schonberger[1], N. Srebnik[1], K. Rotshenker-Olshinka[1], E. Zivi[1], R. Nabulsi[1], H. Holzer[1]

[1] *Shaare Zedek Medical Center, IVF Unit- Department of Obstetrics and Gynecology, Jerusalem, Israel*

[2] *Ono Academic College, Center for Medical Decision Making, Kiryat Ono- Israel, Israel*

[3] *Clalit Health Services, fertility clinic- Central district, Modi'in Illit, Israel*

Study question:

While social oocyte freezing is gaining popularity, it remains unclear why usage rates of frozen oocyte are low.

Summary answer:

Five years after freezing, most women either attempted conception naturally or with fresh oocytes, or chose to defer pregnancy due to lack of partner.

What is known already:

According to studies with short term follow-up periods, less than 10% of women who froze oocytes tried to conceive using those oocytes.

Study design, size, duration:

An anonymous internet based survey for all women who underwent social oocyte freezing in one unit in the preceding four to seven years. The participants completed the survey independently, responding to both open and closed - ended questions.

Participants/materials, setting, methods:

Patient records and laboratory data were used to create a comprehensive database of all cycles of social oocyte freezing performed in our unit since this procedure was first approved in Israel in 2011. Women treated during the years 2011-4 were contacted by phone between August 2018 and January 2019. Links for an online survey using a secure web application were emailed to women who agreed to participate in the study.

Main results and the role of chance:

87 women who underwent social oocyte freezing during 2011-4 were invited to participate, and 61 women responded (70%). The main reason for oocyte freezing was lack of interest in pregnany without a partner (85%). Age at freezing was 37.1± 2.3 (range 30-41) and 42.5±2.6 (range 35-48) at time of participation in the study. Time from first cycle of oocyte freezing to participation was 5.4±1.2 years (range 4-7).

During the follow–up period, 39 women (64%) tried to conceive, with husband or partner (66.6%), or with donor sperm (33.3%). Of these, 22 women achieved a live birth (36% of all respondents, 56% of those who tried to conceive). 13 respondents reported using their frozen oocytes (21%), and 4 had a livebirth or ongoing pregnancy using those oocytes (30% of women who used the frozen oocytes). The reasons for not using frozen oocytes included: becoming pregnant spontaneously or with fresh oocytes (37.5%), lack of interest in pregnany without a partner (33.3%), still trying without the frozen oocytes at time of the study (18.8%), or lack of interest in pregnancy for other reasons (10.4%).

Limitations, reasons for caution:

Potential bias regarding women who chose to respond, who possibly had better reproductive outcomes than those who did not. Follow-up period and age of participants do not reflect full potential of natural fertility and of frozen oocytes since most participants did not use their oocytes at time of study.

Wider implications of the findings:

The current study could help fertility professionals provide improved counselling and advice to women considering fertility preservation options.

Trial registration number:

not applicable.

O-215 Nudging to promote elective single embryo transfer (eSET): A randomized controlled experiment

C. Suwandee, MD[1], R. Pawa[2], L. Udomsrisumran[2], S. Kiatpongsan, M.D.- Ph.D.[2]

[1] *Chulalongkorn University, Obstetrics and Gynecology, Bangkok, Thailand*

[2] *Chulalongkorn University, Population Studies, Bangkok, Thailand*

Study question:

Our study evaluates the effect of a novel approach based on a behavioral economic theory—nudging— to promote elective single embryo transfer (eSET).

Summary answer:

Nudging technique can significantly increase preference for eSET regardless of twin preference, gender and age. Therefore, nudging can be an effective intervention to promote eSET.

What is known already:

Multiple pregnancies are associated with both maternal and fetal complications. Elective single embryo transfer (eSET) is an effective strategy to reduce multiple pregnancies; however, uptake is low. Traditional interventions (e.g., education or counseling) have not been effective.

Study design, size, duration:

A randomized controlled experiment. There were 56 participants in the control group and 52 participants in the intervention (nudging) group. We conducted the study from September to November 2018.

Participants/materials, setting, methods:

Infertile patients attending an information session at a university, teaching hospital in Bangkok, Thailand were randomized into two groups. In the control group, participants simply reported their preference for either eSET or double embryo transfer (DET). In the intervention group, eSET was presented as a default choice and participants were given a chance to opt-out.

Main results and the role of chance:

108 out of 110 participants completed the experiment (response rate = 98.1%). There were no differences between the control group and intervention group in regards to twin preference, gender, age, education and income, $p > .05$ for all characteristics.

Overall, preference for eSET was significantly higher in the intervention group compared to the control group (59.6% vs 19.6%), $p < .001$.

Subgroup analyses revealed that preference for eSET was significantly higher in the intervention group across all subgroup-comparisons. First, 46.7% vs. 10.5% in those preferring twins, $p = .001$ and 76.2% vs. 43.8% in those preferring singletons, $p = .047$. In regards to participants' gender, 70.8% vs. 24.0% in male participants, $p = .001$ and 50.0% vs. 16.1% in female participants, $p = .006$. Lastly, 57.1% vs. 17.9% in participants 36 years old and younger, $p = .005$ and 61.3% vs. 21.4% in participants 37 years old and above, $p = .002$.

Limitations, reasons for caution:

The nudging effect might be influenced by various factors and should be further tested in other contexts and settings.

Wider implications of the findings:

Nudging can be used effectively in reproductive medicine and healthcare settings. It can be an effective strategy to promote more efficient and safer care.

Trial registration number:

not applicable

O-216 Dealing with endometriosis and infertility: Partners matter as interrelation influences stress and sexual satisfaction

M. Schick[1], B. Böttcher[2], A. Germeyer[3], S. Hecht[3], M. Geiser[2], S. Rösner[3], T. Strowitzki[3], B. Toth[2], T. Wischmann[1], B. Ditzen[1]

[1] *Institute of Medical Psychology, University Hospital Heidelberg, Heidelberg, Germany*

[2] *Department of Gynecological Endocrinology and Reproductive Medicine, Medical University Innsbruck, Innsbruck, Austria*

[3]Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg University Hospital, Heidelberg, Germany

Study question:

Investigate the interrelations in couples with endometriosis and/or infertility in matters of stress and sexuality.

Summary answer:

How couples deal with the impact of endometriosis pain and infertility interrelates with the partners stress and sexual satisfaction.

What is known already:

Endometriosis is a common gynecological disorder, often associated with severe dysmenorrhea, pelvic pain and dyspareunia. It is the major cause for female infertility and has a high impact on daily life as well as sexuality. Partnership quality positively influences the course of various diseases. Furthermore, a positive relationship between partnership and perceived stress can be found in reproductive treatment, with resilient partnerships being able to buffer high levels of stress associated with treatment. However, studies focusing on the male part in couples with endometriosis and wish for a child are rare, and even less about the reciprocal influences in couples.

Study design, size, duration:

A quantitative study was devised, approved by the Ethics Committee of the Heidelberg Medical Faculty and Medical University Innsbruck (MUI). The study was conducted from September 2016 to August 2018 at the Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg University Hospital and from June 2017 to August 2018 at the Department of Gynecological Endocrinology and Reproductive Medicine, MUI with n=322 participants, resulting in n=140 couples.

Participants/materials, setting, methods:

Participants completed a questionnaire with 88 items regarding endometriosis, wish for a child, partnership, sexuality, pain, stress, psychosocial well-being and sociodemographic items. All women undergoing laparoscopy during their treatment at Heidelberg University Hospital and MUI and their partners were invited to participate in the study. Data were analyzed using the Actor-Partner-Interdependence Modell, which stipulates that one person's behavior does not only affect him-/herself (actor effect) but also his/her partner (partner effect).

Main results and the role of chance:

In total, n=140 couples (women: mean age: 32.6 years; men: 36.2 years) participated in the study. Mean partnership duration was 8.5 years. Of all participants, 26.5% already had children, 79.4% had a present wish for a child, on average for 3.7 years. Of all subjects, 63.6% had high school or university graduation. EM was clinically confirmed in N=104 women (74.3%). All analyses have been controlled for participant's age, duration of endometriosis and wish for a child, sex frequency and existing children.

Women and men were asked about the impact of women's endometriosis pain (IEP) in their everyday life (e.g. leisure time). Significant partner effects were evident: High stress scores in women led to high IEP in men (p=.012) and reciprocally (p=.049). Regarding sexuality, less sexual satisfaction in women led to a higher IEP in men (p=.035).

Concerning wish for a child, participants reported about their cognitions in terms of hopelessness and acceptance. The more men indicated cognitions of acceptance, the less stress women reported (p=.024). Hopeless cognitions in women led to more stress in men (p=.002) and reciprocally (p=.034). Furthermore, hopeless cognitions in women were interrelated to less sexual satisfaction in men (p=.021).

Limitations, reasons for caution:

Generalization of findings is limited due to the retrospective study design. Furthermore, participants in this sample had an above-average high educational background.

Wider implications of the findings:

The male partner should be focused when counseling or treating women with endometriosis and/or infertility. Thus talking about and improving sexual satisfaction may hold large benefits for dealing with endometriosis and infertility. Furthermore, stress reducing techniques for both partners should be addressed and enhanced actively.

O-217 How do people adjust to not realizing their parenthood goals? A test of the Three Tasks Model of Adjustment to Unmet Parenthood Goals (3TM)

S. Gameiro[1]

[1]School of Psychology, United Kingdom, Cardiff, United Kingdom

Study question:

Can the Three Tasks Model (3TM) explain the mental-health and well-being of individuals who do not realize their parenthood goals?

Summary answer:

The 3TM shows good explanatory ability, reflected in good model-fit to the data indexes and high proportions of explained variance in mental-health and well-being.

What is known already:

More and more people end their reproductive life without realizing their parenthood goals (none/less children than desired). This is associated with worse mental-health and well-being, with some individuals reporting never fully recovering. The Three Tasks Model of Adjustment to Unmet Parenthood Goals (3TM, Gameiro & Finnigan, 2017) predicts that people will try to adjust to this loss by creating meaning of their situation (meaning-making), integrating the loss in their identity and life-style (acceptance), and pursuing other life-goals (pursuit of new life-goals), and that these efforts will lead to better mental-health and more positive feelings (hedonic well-being) and life-fulfillment (eudaimonic well-being).

Study design, size, duration:

Cross-sectional online survey. To reach this non clinical heterogeneous sample the survey was advertised via fertility charities (Fertility Network, Resolve, Fertility Matters Canada, NISIG Ireland and Fertility New Zealand), forums (Fertility Friends, The Not Mom, Net Mums, Mums Net, and Health Unlocked) and Facebook and Google adds. Participants were given the chance to win one of four £50 vouchers.

Participants/materials, setting, methods:

Participants were individuals who had not met their parenthood goals and were not undergoing fertility treatment. We used well-validated and sound questionnaires (except when otherwise specified) to measure relevant 3TM variables. Determinants were age (in years), having stopped trying to conceive (no, yes), importance of parenthood (1 item scale), and perceived social-support; mediators were meaning-making (general efforts, positive re-framing), acceptance, and pursuit of new goals; and outcomes were mental-health and hedonic and eudaimonic well-being.

Main results and the role of chance:

Final sample were 420 individuals with unmet parenthood goals. 860 individuals accessed the survey and 516 (60%) met the inclusion criteria, but 86 (18.6%) were excluded because they did not fill any of the questionnaires. Average age was 35. Only 2 participants (0.5%) were men, the majority were in a relationship, had university education and were employed.

A test of the 3TM using Structured Equation Modelling (path analysis with maximum likelihood estimation) revealed a good model fit to the data ($X^2(18) = 44.936$, $p < .001$, CFI = 0.979, RMSEA = .060 [.038, .082]). The model explained 42%, 42% and 35% of variance in mental-health, hedonic and eudaimonic well-being, respectively. Older people reported higher acceptance (b=.119). Those who had stopped trying to have children and perceived more social-support reported higher positive re-framing (b=.192, .337), acceptance (b=.289, .243) and pursuit of new goals (b=.271, .332). Importance of parenthood was associated with more meaning-making general efforts (b=.139), less acceptance (b=-.291) and pursuit of new goals (-.198). Positive re-framing was associated with better eudaimonic well-being (b=.157), acceptance with higher hedonic well-being (b=.281) and pursuit of new goals with better mental-health and hedonic and eudaimonic well-being (b=.273, .223, .410).

Limitations, reasons for caution:

It was not possible to calculate the survey response rate. Individuals more affected by their inability to realize their parenthood goals might be more willing to participate, which may result in an under estimation of this population ability to adjust to this life challenge.

Wider implications of the findings:

The 3TM is useful to explain adjustment to unmet parenthood goals. Individuals who construct positive meanings of their situation experience higher life-fulfillment, individuals who are better able to accept it experience more positive

feelings, and individuals who pursue new life-goals experience better mental-health, more positive feelings and life-fulfillment.

Trial registration number:

not applicable

O-218 Outcome reporting in fertility trials: what a mess! Why we need a core outcome set

J. Wilkinson[1]

[1] *University of Manchester, Centre for Biostatistics, Manchester, United Kingdom*

Abstract text

Outcome reporting in fertility trials: what a mess! Why we need a core outcome set

Recent reviews of fertility research have revealed massive inconsistencies in how outcomes are measured and reported. In our 2016 study of outcome reporting in fertility RCTs, we identified 361 numerators (for example, number of oocytes, clinical pregnancy and live birth) and 87 denominators (for example, per cycle started, per transfer procedure, per egg collection), resulting in 815 distinct combinations. We also observed that a variety of definitions were in use for many of the numerators, compounding the problem.

This heterogeneity undermines the evidence base in a variety of ways, several of which remain generally underappreciated. Most obviously, variation in outcome measurement hampers the comparison and combination of trials in meta-analysis. Recently published work from our group highlights the consequences of this for the evaluation of reproductive medical interventions; we found that meta-analyses contained in systematic reviews published by Cochrane Gynaecology and Fertility generally contained too few participants to detect anything other than implausibly large treatment effects, with results generally being too imprecise to determine which intervention was better. This concern has practical implications, since uncertainty around the effectiveness of interventions leaves room for the exploitation of vulnerable patients. Core outcome sets represent an important part of the solution to underpowered treatment comparisons.

A lesser appreciated point is that the choice of outcome measure can undermine the validity of an individual study. Many of the outcome measures commonly used in fertility trials discard the benefits conferred by randomisation. This results in biased observational comparisons being held in higher regard than they might warrant. Examples include live birth rates calculated per embryo transfer, miscarriage rates calculated per pregnancy, oocyte yields calculated per egg collection, and perhaps neonatal outcomes such as birthweight, which are necessarily only calculable for those women who have live births. I will discuss ongoing work where we attempt to quantify the implications of using these measures for the conclusions we make, and will outline a number of imperfect solutions. Core outcome sets, accompanied by clear guidance regarding presentation and analysis, offer one way to reduce these ubiquitous errors.

O-219 COMMIT: Developing a core outcome set for infertility research

J.M.N. Duffy[1]

[1] *University of Oxford, Balliol College, London, United Kingdom*

Abstract text

Despite the escalation in research activity and an exponential rise in published papers, many of the fundamental questions in infertility remain. Potential treatments for infertility should be evaluated in randomised controlled trials. The Priority Setting Partnership for Infertility (www.phc.ox.ac.uk/infertility) has prioritised unanswered research questions relating to the evaluation of potential treatments for infertility. However, complex issues including a failure to consider the perspectives of different stakeholders when designing trials, variations in outcome measures, and outcome reporting bias, could undermine the translation of future infertility research into clinical practice. Such research waste represents a substantial barrier in improving the outcomes of people with infertility.

The challenges of poor outcome selection, measurement, and reporting can be addressed by developing, disseminating, and implementing a core set of outcomes and outcome measures which would be common to future infertility research. An international initiative, embed within the Cochrane Gynaecology and Fertility group, has developed a core outcome set for infertility using robust consensus science methods, engaging 265 health care professionals, 58 researchers, and 55 patients representing 55 different countries.

Embedding the infertility core outcome set within future randomised trials, systematic reviews, and guidelines could make a profound contribution to advancing the usefulness of research to inform clinical practice, enhance patient care, and improve outcomes.

INVITED SESSION

SESSION 61: THE UTERUS AND THE SURGEON

Wednesday 26 June 2019 Haydn 3 08:30 - 09:30

O-220 The persisting challenge of Asherman's syndrome

M.H. Emanuel[1]

[1] *University Medical Center, Gynaecology and Reproductive Medicine, UTRECHT, The Netherlands*

Abstract text

The persisting challenge of Asherman's syndrome

Dysmenorrhea or pain in Asherman's Syndrome (AS; intrauterine adhaesions [IUA] present after an intrauterine pregnancy reated procedure leading to menstrual disorders and/or subfertility) related to menstruation is often explained by the theory that myometrial contractions try to evacuate blood trapped in the uterine cavity. However in patients with AS a haematometra is uncommon. Although Asherman and others have suggested that the endometrium becomes unresponsive when outlet adhesions are present, there is remarkably little objective evidence to support this. This lack of haematometra with occlusion of the lower (isthmic) part of the uterine cavity is in contrast to other types of lower congenital genital tract occlusion such as an imperforate hymen, a partially non-communicating bicornuate or septate uterus or a partially non-communicating hemi-vagina. Even occlusion at the external cervical os after cervical surgery, often leads to haematometra, haematocolpos and haematosalpinx on the long run. Between 2003 and 2013 a first-trimester pregnancy procedure preceded AS in 371 women (58.2%) and caused adhesions of grades 1–2 (ESGE/ESHRE). In 243 (38.1%) women, a postpartum procedure caused IUA of grades 3–5. Hysteroscopic adhaesiolysis with fluoroscopy guidance was successful in normalizing uterine cavity anatomy with at least one open tubal ostium in 606 (95%) women, and restoration of menstrual blood flow occurred in 97.8%; IUA spontaneously recurred in 174 (27.3%) of these cases. High grades of adhesions were predictive of a higher chance of spontaneous recurrence of adhesions. Representive endometrial biopsies were taken immediately after restoring the normal uterine cavity anatomy during hysteroscopical adhaesiolysis. At the same time blood samples were taken to determine the serum levels of follicle stimulation hormone, luteinizing hormone, estradiol and progesterone. All endometrial biopsies, taken from women with amenorrhea as a result of AS had microscopic characteristics mainly seen during the secretorial phase. Looking at the endocrinology in these randomly in the cycle taken biopsies 1/3 of them were actually taken during the follicular phase and only 2/3 during different stages of the luteal phase. This phenomenon which we named: "endometrial secretory arrest" in AS seems to prevent haematometra and severe dysmenorrhea in most patients. Future research should focus further on the pathophysiology of this typical clinical situation (mediators, immunology, gene expression, microbioma...).

O-221 Where are the limits of surgical treatment of uterine anomalies?

INVITED SESSION

SESSION 62: SPERM DNA MATTERS

Wednesday 26 June 2019 Haydn 2 08:30 - 09:30

O-222 Sperm DNA a clinically useful prognostic?

O-223 Finding the best sperm

N. Garrido[1]

[1]*IVI Foundation- Instituto de Investigación Sanitaria La Fe- Avenida Fernando Abril Martorell- 106 - Biopolo- Torre A- Planta 1ª, Innovation, Valencia, Spain*

Abstract text

The basic sperm analysis has limited predictive value in the achievement of success in either natural or assisted conception, in part because several non-measured molecular factors within the sperm cells are crucial to succeed.

There are upper limits of assisted reproduction success. If we look carefully to the results exhibited by all ART programs, we may find two similar patterns among them: first, often a couple needs several attempts to get a child. Second, not every patient succeeds.

In some cycles, there may be no embryos to transfer or they are unable to implant. Another subsequent cycle ends up in a child, even when using the same gamete's combination. Same gamete providers-different cycles-different results.

This, together with the fact that in an ART procedure, gametes are provided by the patients and afterwards the laboratory intervenes in the preparation and selection, lead us to wonder how much this intervention affects the reproductive performance of a couple. Regarding spermatozoa, you may find from thousands to millions within an ejaculate, they are different, they behave differently, and their adequate selection may be key for reproductive success. Using one specific spermatozoon leads oocyte fertilization, develops to a good quality embryo who implants, and a child is born. Choosing another instead, may result in an embryo that is arrested or is unable to implant. . .. even within the same ejaculate. . . even within different ejaculates from the same man.

Within an ejaculate, you may find that every single sperm is theoretically unique from the genetic viewpoint. The number of genetic combinations possible exceed the number of available spermatozoa even in the best ejaculates. Their genetic, and subsequently their molecular traits are exclusive, as expected after combining maternal and paternal chromosomes during spermatogenesis, and the DNA crossover between homologous regions. This has been previously confirmed sequencing and comparing single sperm DNA, and this uniqueness makes people have different children depending on the sperm that fertilizes the oocyte. But most importantly, they can lead you to success or failure.

When sperm is selected by an operator, they may have in their hands the possibility to choose, and their selection must be made according to the best criteria and available evidence. Most importantly, several millions of spermatozoa will be ruled out (unlike oocytes, here is where the key of sperm selection potential resides).

A good sperm selection protocol may change the whole picture and improve the entire embryos' cohort quality. Good sperm-Good embryo. Bad sperm-Bad embryo.

So far, several sperm phenotypical and molecular markers of fertility have been described as being related with reproductive success: DNA integrity, membrane charge, apoptotic traits, hyaluronic acid receptors, platelet activating factor, and a long etc.., and some can also be used to select sperm individually for using them in assisted reproduction techniques. Nevertheless, robust evidence for significant improvement in reproductive performance after its application is scarce, or almost inexistent.

From ultrahigh magnification to magnetic activated cell sorting, through physiological ICSI, hypoosmotic swelling tests, electrophoresis, microfluidic devices, birefringence, etc., several papers and research projects have aimed to separate ejaculates into two sperm populations or more, which contain the good and the bad. Available information is still limited, coming mainly from the developers of each technique, without enough evidence and non-contrasted by other independent groups.

First it´s a matter of finding and defining the molecular traits that identify the best sperm to be selected (or the worse to be removed), those strongly linked with reproductive results, and then developing "sperm-friendly" and cost/effective selection techniques, to lead us to move from auto or subjective sperm selection towards smart or objective sperm selection ultimately improving reproductive results.

SESSION 63: IFS-ISAR EXCHANGE SESSION - CONTROVERSIES TO CONSENSUS IN RECURRENT IMPLANTATION FAILURE

Wednesday 26 June 2019 Haydn 4 08:30 - 09:30

O-224 Probing deep into RIF

O-225 Maternal factors in RIF

O-226 Improving embryo quality

K. Jain, M.D.[1]

[1]*KJIVF & LAPAROSCOPY CENTRE, department of reproductive medicine, DELHI, India*

Abstract text

Recurrent Implantation Failure- Improving Embryo Quality

Implantation a rate limiting factor in ART cycles & is a cause of concern. There is no consensual definition of RIF . common accepted definition is failure to achieve conception in three cycles in spite of transferring good quality embryos. Successful implantation depends on synchronization of multiple factors like immune quality of embryos, optimal culture conditions, receptively of endometrium & maternal system. Selecting good quality embryo & putting them at appropriate time is the mainstay of treatments in RIF.

Factors incriminated in RIF are embryo quality are suboptimal conditions compromising development, chromosomal abnormalities, zona hardening & improper timing and technique of embryo transfer.

A large proportion of patients of RIF show a high no of chromosomal anuploidy and other structural defects[maternal or paternal origin]. Routine morphological evaluation cannot distinguish between euploid or aneuploid embryos. High DNA fragmentation of sperms causes decreased implantation and chromosomal abnormality and need identification.

strategies to improve and select good quality euploid embryos to improve implantation are

1. optimizing culture condition to get a viable blastocyst to help in selecting embryos with best implantation potential. However reaching up to blastocyst stage may be challenging in elderly and poor responders because of fewer embryos and increased risk of aneuploidy.
2. Various stimulation protocols have been suggested to improve the outcome in RIF however due to lack of high quality evidence, none of the protocol seems superior to other in improving outcome in RIF.
3. Assisted hatching- zona hardening due to prolonged culture resulting in to failed implantation may be another cause of RIF. Assisted hatching has been proposed as a measure to correct the problem and thus increasing pregnancy rates in RIF. However role of assisted hatching remains controversial due to lack of any conclusive evidence.
4. Co- culture system Co- culture system with granulose cell, Homologus endometrial cells have been proposed to improve pregnancy rates in RIF however there role remains controversial.

5. PGS/ PGT- A; High order auploidy and chromosomally abnormal embryo. Leading to failed implantation is important factor in RIF. Electing euploid embryos by PGS/ PGT- A is logical choice to improve pregnancy rates in RIF. Biopsy at blastocyst stages is suggested to select euploide embryos in comparison to D3 biopsy. However there are multiple reasons for in efficiency of PGS in improving the pregnancy rate significantly, Using NGS/ array CGH is preferable than FISH to select chromosomally normal embryo.
6. Cytoplasmic transfer; procedure is still experimental and requires validation for clinical practice.
7. Newer methods for embryo selection of good quality embryo by using time lapse technique has been suggested however no robust data exists to suggest is as beneficial in RIF. When compared to conventional system analysis of spent culture media for byruvate, glucose consumption and amino acid turnover. All of them correlated with development of blastocyst viability, can be used to select the good quality embryo. Also measurement of specter profile of spent culture edia reflection of oxidative stress shows a good correlation with pregnancy outcome.

Conclusion: RIF poses a great challenge for both clinician and embryologist there are multiple measures which have been suggested to improve and select a good quality embryo to improve pregnancy outcome. Some of them like improving culture condition and blastocyst culture are applicable to all cases while rest of measure can certainly be used in selected group of patients.

O-227 Immunological Issues- Any evidence?

G. Devi[1]

[1] *Senior consultant-Gouri Hospitals ltd- Director-Ridge ivf pvt ltd, Reproductive medicine, Delhi, India*

Abstract text

RIF is defined as the failure to achieve clinical pregnancy after the transfer of two good quality embryos , in at least three fresh or frozen IVF cycles/embryotransfers (6 embryos in total) or in at least two egg donations(i.e., 4 embryos in total)

Despite growing new evidence of the involvement of immunological alterations on pregnancy outcome. There are no existing evidence-based guidelines focusing on immunological factors of RIF

Causes of RIF can be Maternal or Embryonic.One of the important maternal factors is immunologic.

Pathophysiological role of immunological factors in RIF:

1. Antiphospholipid syndrome:Inclusion of RIF as clinical criteria for APS has been proposed since aPL are pathogenic antibodies and the implantation failure could have analogous pathophysiology to that of an early miscarriage
2. Expansion of peripheral natural killer cells
3. Deregulation of uterine natural killer cells has a controversial role
4. Allorecognnition: MHC molecules and NK cells receptors: Successful implantation depends on a fine balance of NK cell activation and inhibition which might be influenced by the KIR gene frequencies of the patients and their partners
5. Untreated hypothyroidism:women with hypothyroidism have decreased chances of achieving pregnancy and optimal level of TSH prior to and during controlled ovarian hyperstimulation for IVF should be determined.
6. Cytokine imbalance

The Food and Drug Administration (FDA) provides pregnancy safety categories for immunomodulator and immunosuppressant therapies. IVIG, corticosteroids, tacrolimus and intralipid therapy are category C medications. Tacrolimus has demonstrated safety for both the mother and foetus in a number of studies. The TNFα inhibitors such as etanercept and adalimumab are classified as FDA Category B reflecting limited evidence in a small number of pregnant women and women of childbearing age, where these drugs have not shown any increase in the frequency of mal- formation or other direct or indirect harmful effects on the human foetus. Nevertheless, immunomodulator and immunosuppressive therapies for RIF and RPL have already been introduced to clinical practice with promising results.

- To conclude, defining the evidence-based immunological studies is essential for the appropriate evaluation and management of couples with RIF
- Immunological as well as haematological or hormonal factors play a relevant role in successful gestation as has been highlighted for the case of women with RM
- There is an urgent need of further validating these data with clinical trials and of standardizing both the evaluation and interpretation of immunological tests
- Research targeted to come up with better answers to improve the outcome of pregnancy and the life-quality of couples undergoing IVF is needed
- This will also impact the IVF-related costs

O-228 ICSI does not offer any benefit over conventional IVF across different ovarian response categories: a European multicenter analysis

P. Drakopoulos[1], J.A. Garcia-Velasco[2], E. Bosch[3], C. Blockeel[1], M. De Vos[1], H. Tournaye[1], N.P. Polyzos[4]

[1] *UZ Brussel, Center for Reproductive Medicine, Jette- Brussels, Belgium*
[2] *IVI- RMA Madrid, Reproductive medicine, Madrid, Spain*
[3] *IVI-RMA Valencia, Reproductive medicine, Valencia, Spain*
[4] *Dexeus University Hospital, Department of Obstetrics- Gynecology and Reproductive Medicine, Barcelona, Spain*

Study question:

Does ICSI improve reproductive outcomes compared with IVF in different ovarian response categories?

Summary answer:

There is no advantage of ICSI over IVF as insemination method for non-male factor infertility, irrespective of the ovarian response.

What is known already:

Conventional IVF and ICSI are two techniques used to inseminate oocytes in-vitro. Although ICSI was originally developed for male factor infertility there has been an increase in the use of ICSI for all causes of infertility. The rationale that ICSI is associated with a higher likelihood of fertilization and a potentially increased number of embryos is controversial. Furthermore, ICSI still remains the first choice in many centers in case of low oocyte yield. There are currently no patient-based data on the effectiveness of ICSI compared with IVF according to the number of oocytes retrieved in patients with non-male factor infertility.

Study design, size, duration:

This is a large multicenter analysis using individual patient data, conducted in 15 tertiary referral hospitals across Europe. The study included the first cycle of all patients undergoing ovarian stimulation for IVF or ICSI in a GnRH antagonist protocol from 2009 until 2014. Each patient contributed with one cycle.

Participants/materials, setting, methods:

Only patients having either IVF or ICSI for non-male factor infertility were included. Patients were divided into 4 groups based on their ovarian response: Group 1: poor responders (1-3 oocytes), Group 2: suboptimal responders (4-9 oocytes), Group 3: normal responders (10-15 oocytes), Group 4: high responders (>15 oocytes).

Main results and the role of chance:

In total, 4891 patients were analyzed, of whom 4227 underwent ICSI and 664 IVF. There was no significant difference for the insemination method (ICSI vs. IVF) used among the different ovarian response categories: 87% vs. 13%, 87% vs. 13%, 86% vs. 14%, 84% vs. 16%, for groups 1, 2, 3 and 4, respectively, p value= 0.35. Mean fertilization rate defined as the ratio of 2PN oocytes and number of oocyte-cumulus complexes was comparable between ICSI and IVF groups [61% ± 23% and 60% ± 27%, p-value = 0.9). These findings were replicated for each ovarian response group. Mean embryo utilization rate defined as the total number of transferred and cryopreserved embryos per number of fertilized oocytes was also similar in the two insemination procedure groups, irrespective of the ovarian response category. Univariate analysis demonstrated that the insemination procedure was not significantly associated with either live birth rate (LBR) or cumulative LBR (p-value = 0.38 and 0.38, respectively). Multivariate regression analysis taking into account the ovarian response category and other relevant confounders showed that the insemination method was not significantly associated with LBR or with cumulative LBR (OR=1.1 CI 0.9-1.3/ OR =1.06 CI: 0.9-1.2).

Limitations, reasons for caution:

This is a cohort analysis based on retrospective data collection. Despite our robust methodological approach, the presence of bias related to the retrospective design cannot be excluded.

Wider implications of the findings:

To our knowledge, this is the first population-based cohort study to investigate the cumulative LBR following IVF and ICSI across different ovarian response categories. The number of oocytes retrieved has no value for the selection of the insemination procedure in case of non-male infertility.

Trial registration number:

O-229 ICSI is associated with lower live birth outcomes compared to IVF in couples having their first treatment cycle: A longitudinal analysis of 285,038 treatment cycles

H. Kamali[1], I. Gamaleldin[2], P. Wilson[3], V. Akande[4]

[1]*Bristol Centre for Reproductive Medicine, Clinical team, Bristol, United Kingdom*
[2]*NIHR Academic Clinical Lecturer, University of Bristol, Bristol, United Kingdom*
[3]*Bristol Centre for Reproductive Medicine, Embryology and Andrology, Bristol, United Kingdom*
[4]*Bristol Centre for Reproductive Medicine, Medical Director, Bristol, United Kingdom*

Study question:

Is ICSI associated with improved outcomes over conventional IVF in couples undergoing their first treatment cycle?

Summary answer:

ICSI is associated with lower implantation, clinical pregnancy and live birth rates in women undergoing their first treatment cycle compared to conventional IVF

What is known already:

Currently, ICSI is the treatment of choice for couples with male factor infertility or with previous low fertilisation rates. An 'ICSI for all' approach has been suggested as the treatment of choice in all cases requiring assisted conception. However, previous studies comparing IVF and ICSI have shown inconsistent results.

Study design, size, duration:

Anonymised data on first fresh ICSI and conventional IVF treatment cycles (n=353,881) performed in the UK from years 2000 – 2016 were retrospectively obtained from the Human Fertility and Embryology Authority (HFEA). Women above 42 years old and those having donor oocytes/sperm were excluded. Primary outcome was live birth rates. Secondary outcomes were fertilisation rates, implantation rates and clinical pregnancy rates. Outcomes were adjusted for age, number of oocytes collected, and number of embryos transferred.

Participants/materials, setting, methods:

Following exclusion, complete data was available for 285,038 cycles. Poisson regression with restricted cubic splines was used to model events and rates. Covariates included year of treatment, age groups, cause/type of male infertility and total embryos transferred. In the subgroup analysis, we incorporated second order interactions among covariates to estimate the rate ratio within; each age group, in those with and without male factor infertility and at different time periods (year 2000,2010 and 2016).

Main results and the role of chance:

A total of 146,991 women had IVF and 138,047 women had ICSI. The overall live birth rates were 30% for ICSI and 29% for IVF. The adjusted analysis showed higher fertilisation rates in ICSI compared to IVF (68% vs 64%, RR:1.08 95% CI 1.08-1.08, p<0.001). However, the likelihood of implantation (27% vs 28%, RR:0.96, 95% CI 0.95-0.98, p<0.001) and clinical pregnancy (49% vs 50%, RR:0.98, 95% CI 0.97-0.99, p<0.001) were lower in ICSI compared with IVF. Although the observed rate of live birth was higher in ICSI compared to IVF, following adjustment the likelihood of live birth was lower in the ICSI group (RR:0.98, 95% CI 0.97-0.99, p<0.001). Sub-group analysis comparing ICSI to IVF persistently showed lower live birth outcomes in cycles with non-male factor infertility (RR:0.96, 95% CI 0.94-0.98, p<0.001). These findings were consistent across different age groups and different time periods.

Limitations, reasons for caution:

As a retrospective study, our analysis depends on previously recorded data, therefore certain variables (such as clinic specific protocols and duration of infertility) could not be collected. The reported cause of infertility is based on the treating clinician's classification and may be inconsistent

Wider implications of the findings:

In couples having their first fresh treatment cycle, ICSI offers no advantage over IVF in terms of live birth outcomes. These findings are consistent across different age groups and different time periods. The routine application of ICSI for treating couples with non-male factor infertility offers no benefit over conventional IVF.

O-230 Effect of the use of Polyvinylpyrrolidone (PVP)-coated injection pipette during intracytoplasmic sperm injection on clinical outcomes

T. Okimura[1], K. Uchiyama[1], T. Kobayashi[2], K. Kato[2]

[1]*Kato Ladies Clinic, IVF laboratory, Tokyo, Japan*
[2]*Kato Ladies Clinic, Department of Gynecology, Tokyo, Japan*

Study question:

Does the use of Polyvinylpyrrolidone (PVP) for coating injection pipette during intracytoplasmic sperm injection (ICSI) procedure influence embryonic and pregnancy outcomes?

Summary answer:

The application of PVP-coated injection pipettes for ICSI procedure may influence negatively embryonic outcomes.

What is known already:

ICSI is a well-established and accepted method for infertility treatment. Most centres use Polyvinylpyrrolidone (PVP) routinely during the ICSI procedure to improve the safety of the procedure, such as easier oocyte manipulation and sperm immobilization. Although there is evidence that the exposure of spermatozoa to PVP had detrimental effect on sperm structure and function, there is an inadequate emphasis on the potential hazards of PVP on clinical outcomes. Additionally, the effects of coating the pipette with PVP prior to ICSI on embryonic and pregnancy outcomes have not been investigated.

Study design, size, duration:

A retrospective cohort study of 951 cycles with 1,385 oocytes was conducted between April 2015 and January 2016. It consisted of 417 cycles (598 oocytes, mean age: 40.2 ±4.0 years) in which ICSI using PVP-coated injection pipette was performed (PVP-ICSI) and 534 cycles (787 oocytes, mean age: 40.2 ±4.2 years) in which ICSI using non-PVP coated pipette was performed (non-PVP-ICSI). Embryonic and pregnancy outcomes following single vitrified-warmed blastocyst transfer (SVBT) were compared among the groups.

Participants/materials, setting, methods:

Maturation status of oocytes was defined by confirming spindles using a Polscope. A small droplet of PVP was added to an ICSI dish and the injection pipette was washed there for coating. PVP was not used for sperm suspension. ICSI were performed by senior embryologists, using a pneumatically-driven injector. The survival, fertilization and good-quality blastocyst formation rates, clinical pregnancy (gestational sac observation), live birth at >22 weeks of pregnancy, and miscarriage rates were analysed.

Main results and the role of chance:

The survival rates of oocytes after ICSI in PVP-ICSI and non-PVP-ICSI groups were 96.8% (579/598) and 96.7% (759/785), respectively, there was no significant difference between the groups. There were no significant differences in normal fertilization and multiple nucleation (3PN<) rates between PVP-ICSI and non-PVP-ICSI groups [normal fertilization rates: 79.9% (478/598) vs 80.8% (634/785) and multiple nucleation rates: 5.2% (31/598) vs 3.7% (29/785), respectively]. Nonetheless, good-quality blastocyst formation rates (Gardner criteria: grade >3) were significantly higher in non-PVP-ICSI than those in the PVP-ICSI group [non-PVP-ICSI: 36.7% (288/785), PVP-ICSI: 31.4% (188/598), P<0.05]. A total of 161 and 237 cycles of SVBT were performed in PVP-ICSI and non-PVP-ICSI groups. The clinical pregnancy and live birth rates in PVP-ICSI and non-PVP-ICSI were 39.1% (63/161), 42.6% (101/237), 31.1% (50/161), and 29.1% (69/237), respectively. No significant differences were observed between the groups. The miscarriage rate did not significantly differ either [PVP-ICSI: 44.4% (28/63) and non-PVP-ICSI: 41.6% (42/101)].

Limitations, reasons for caution:

The main limitation of the present study is related to its retrospective design and a single-centre study. In addition, no comparisons with sibling oocytes were made. A further prospective sibling-split trial is required to confirm the potential adverse impact of PVP on embryonic outcomes.

Wider implications of the findings:

Our results demonstrate that good-quality blastocyst formation rates were significantly lower when ICSI was performed using a PVP-coated injection pipette, suggesting the potential adverse impact of PVP application on embryonic development. Moreover, this adverse effect may be expected even when a small amount of PVP is used.

None

O-231 Does the difficulty of blastocyst biopsy increased embryo mosaicism? A prospective cohort study

L. Guzman Masias[1], M. Jazmin[1], R. Lopez[2], J. Portella[3], P. Villanueva[1], L. Noriega-Portella[1], L. Noreiga-Hoces[1], N.P. Polyzos[4]

[1]Pranor - Laboratorio de Reproducción Asistida, Embryology and Genetics Deparment, Lima, Peru

[2]ADN Diagnostico, Embryology and Genetics Deparment, Lima, Peru

[3]Instituto de Medicina Reproductiva-Clinica Ricardo Palma, Laboratorio de Embriologia, Lima, Peru

[4]Dexeus University Hospital, Embryologia, Barcelona, Spain

Study question:

Is the technical difficulty of blastocyst biopsy associated with increased the embryo mosaicism rate?

Summary answer:

Loss of cellular integrity (CI) of more than 50% of biopsied cells almost doubles blastocyst mosaicism rate.

What is known already:

Biological mechanism and prevalence of mosaicism at blastocyst-stage remains difficult to be established. The technical limitations to determine an embryo as a mosaic are diverse, the fluctuation of copy number profiles can be explained by preferential DNA amplification, resulting in a DNA profile similar to the presence of mosaicism.

Additional biological sources of errors should be considered when evaluating mosaicism from thophectoderm biopsies. Reciprocal aneuploidies and trisomies at the same proportion might produce an euploid profile, leading to a false negative diagnosis. Another source of error could be the presence of cells in S-phase may appear as a mosaic aneuploidy.

Study design, size, duration:

This prospective study was performed in 242 IVF/ICSI cycles. From January 2017 to June 2018, 949 blastocysts were biopsied on day 5 or 6. NGS analysis was performed using Illumina platform following manufacturer's instructions.

Participants/materials, setting, methods:

Embryo biopsy was performed with the aid of laser with a power of 100% and a potency ranging from 350 to 400 µs. Biopsied cells were analyzed under microscope and classified by the number of cells biopsy and CI. The CI classification was decided prior to study initiation as follows: Grade I= more than 90% of CI; Grade II= 90-70% of CI; Grade III= 69-50% of CI and Grade IV= less than 50% of CI.

Main results and the role of chance:

The mean maternal age was 39.1±6.6. The overall euploidy rate was 43% (409/941), while mosaicism rate was 25% (239/941) and aneuploidy rate was 31% (293/941). mosaicism rate remains similar among the three first groups (25% (52/210); 26% (144/547); 21% (33/160) respectively) but significantly increased in group IV (42% (10/24)(p=0.024). On the contrary, eupliod rates was similar in group I, II and III ((45% (95/210); 43% (235/547) and 46% (74/160) respectively), but decreased significantly in group IV (21% (5/24), p=0.020). Finally, aneuploidy rate was similar for all groups.

To avoid cofounder factors, the maternal age, ICM and trophectoderm quality was classified by CI and any differences were found.

Limitations, reasons for caution:

Further work is needed to find other biological and technical variables which can explained the origen of mosacism in blastocyst.

Wider implications of the findings:

Our data suggest that mosaicism incidence may be overestimated when the CI of TE cells after embryo biopsy is extensively compromised. Embryo biopsy is an invasive technique that might impact genetics results.

Trial registration number:

None

O-232 IVF vs ICSI in non-male factor infertility: time to change course?

K. Lattes Altamirano[1], O. Cairo[2], S. Serra[2], M. Garí[2], C. Molins[2], J. Bello[2], A. Pujol[2], M. Castro[1], D. García[3], R. Vassena[3], D. Mataró[1]

[1]Center for Infertility and Human Reproduction CIRH, Assisted Reproduction, Barcelona, Spain

[2]Center for Infertility and Human Reproduction CIRH, IVF Laboratory, Barcelona, Spain

[3]Clínica Eugin, Assisted Reproduction, Barcelona, Spain

Study question:

What are the reproductive outcomes of Intracytoplasmic Sperm Injection (ICSI) without indication of male factor, compared to conventional In-vitro fertilization (IVF)?

Summary answer:

ICSI performed without indication of male factor is associated with lower cumulative live birth rates (CLBR) compared to conventional IVF.

What is known already:

The widespread use of ICSI in patients with normal semen parameters is driven by an increase of both fertilization rates and number of available embryos. Nevertheless, little good-quality evidence supports ICSI effectiveness in this population. Published randomized-controlled trials do not take into account the results of subsequent frozen embryo transfers from the cycles studied and, therefore, do not report CLBR. We perform a comprehensive comparison of reproductive results between ICSI and conventional IVF cycles in a non-male factor infertility, combined with sub-analyses in women of advanced maternal age (≥40 years) and poor responders (≤ 4 retrieved oocytes).

Study design, size, duration:

Retrospective cohort of 956 autologous IVF or ICSI cycles, performed in 2008-2016. Only first cycles of patients were included, with men of normal semen parameters (WHO 2010 guidelines). Patients with abnormal karyotype in either man or women; history of recurrent pregnancy loss, chronic infections; need for PGT, BMI over 30 kg/m2 in the woman, presence of endocrine or uterine abnormalities and evidence of chronic, autoimmune or metabolic diseases were excluded.

Participants/materials, setting, methods:

Laboratory and reproductive outcomes of cycles with at least one oocyte at retrieval, following insemination by standard IVF (n=479) or ICSI (n=477) were compared using Chi-square tests and multivariate logistic regression analyses, adjusted for maternal age, number of retrieved oocytes, number of available embryos and number of transferred embryos. Sub-analyses were performed for poor responders and women of 40 years of age or more. Differences were considered significant if $p<0.05$.

Main results and the role of chance:

Per transfer live birth rate was significantly higher in the IVF group, both in the univariate (24.7% vs 18.9%; p=0.038) and multivariate analysis (OR 1.55; 95% CI 1.09-2.19). We found no difference in biochemical pregnancy (40.6% vs 35.5%; p=0.12), clinical pregnancy (34.3% vs 28.5%; p=0.06) or pregnancy loss (39.2% vs 46.8%; p=0.16). Fertilisation failure and cycle cancellation (no embryo transfer) were expectedly lower in the ICSI group (4.2% vs 7.1%; p=0.06 and 6.7% vs 9.8%; p=0.12, respectively). More importantly, the cumulative LBR was significantly higher in the conventional IVF group (36.2% vs 23.4%; p<0.001), and this was further confirmed in the multivariate analysis (OR 2.92; 95% CI 2.07-4.12). In poor responders, performing IVF significantly improved cumulative LBR (23% vs 13.8%; p=0.02 and OR 3.08; 95% CI 1.61-5.88), while this improvement, although present, did not reach statistical significance in women ≥ 40 years (17.8% vs 12.5%; p=0.201 and OR 1.87; 95% CI 0.95-3.69).

Limitations, reasons for caution:

The main limitation of our study is its retrospective nature. Although we adjusted our statistical analysis for known and suspected confounders, we cannot exclude the possibility of residual confounding factors.

Wider implications of the findings:

ICSI has been advocated in non-male factor infertility to increase fertilization rates and to prevent fertilization failure. Our data shows that adopting a systematical ICSI policy yields significantly worse reproductive results, both after the first ET and cumulatively, and call for a critical review of current practices.

O-233 Time interval between ovulation triggering and oocyte injection: does it affect the clinical outcome?

L. Vandenberghe[1], S. Santos-Ribeiro[2], N. De Munck[3], B. Desmet[1], W. Meul[1], H. Van de Velde[1], G. Verheyen[1]

[1]Vrije Universiteit Brussel- Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium

[2]IVI-RMA, Lisboa, Lisbon, Portugal

[3]IVI-RMA, Middle East Fertility Clinic, Abu Dhabi, United Arab Emirates

Study question:

Does the time interval between ovulation triggering and oocyte injection affect clinical pregnancy and live birth rates?

Summary answer:

The timing of oocyte injection after ovulation triggering had no impact on clinical pregnancy and live birth rates.

What is known already:

In assisted reproduction, ovarian stimulation (OS) is used to induce the simultaneous growth of multiple follicles, followed by final maturation and ovulation triggering with exogenous hCG. Generally, oocyte retrieval (OR) is performed 35-36h later. In addition, 1-3 hours in culture of the cumulus-oocyte complexes prior to oocyte injection is believed beneficial for fertilization and embryo quality, probably due to improved oocyte cytoplasmic maturity. However, in large ART centers with heavy workloads, respecting these exact time intervals is frequently challenging.

Study design, size, duration:

A single-center retrospective cohort analysis was performed including 8889 ICSI cycles from 2010 until 2015. Regarding the time interval between ovulation triggering and oocyte injection, seven categories were considered: <36h, 36h, 37h, 38h, 39h, 40h and ≥41h. The interval of <36h and 36h occurred only if OR was carried out before the planned 36h trigger interval and followed by immediate injection. As primary outcome measures, clinical pregnancy (CPR) and live birth rates (LBR) were considered.

Participants/materials, setting, methods:

During the study period, OR was routinely performed 36h post-triggering except in the <36h and 36h groups. Only cycles with fresh autologous gametes were included. Exclusion criteria were: injection with testicular/epididymal sperm, managed natural cycles, conventional IVF, combined conventional IVF/ICSI, PGT and IVM cycles. Statistical analysis was performed by multivariable multilevel mixed modeling regression analysis. Female age, number of oocytes, day of transfer, number of embryos transferred and embryo quality were considered as potential confounders.

Main results and the role of chance:

No effect of the time interval was observed on clinical pregnancy rates (range 21.9%-36.5%; p=0.286) and live birth rates (range 15.6%-27.9%; p=0.263), after adjusting for potential confounders. The adjusted analysis showed that the chance of having a live birth tends to be lower (OR 0.522, 95%CI: 0.247-1.104; P=0.075) when oocyte injection was performed before 36h compared to 38h after ovulation triggering, however, no significant difference was reached. Injection ≥41h post-triggering did not affect live birth rate (OR 1.038, 95%CI: 0.864-1.247; P=0.691) compared to injection at 38h post-ovulation.

Limitations, reasons for caution:

As this is a large retrospective study, the influence of uncontrolled variables cannot be excluded. These results should not be extrapolated to other ART procedures such as IVM, conventional IVF or injection with testicular/epididymal sperm.

Wider implications of the findings:

Our results indicate that the optimal insemination time window is less stringent than previously thought. This is reassuring, as busy centers might not always be able to follow strict time intervals. We observed a tendency to lower pregnancy and live birth rates when ICSI is performed <36h after ovulation triggering.

O-234 Is ICSI ethically supported by evidence as the method of fertilisation in donor oocyte cycles, in the absence of a medical indication?

P.R. Supramaniam[1], I. Granne[1], C. Becker[1], L.N. Lim[1], R. Venkatakrishnan[2], M. Mittal[3]

[1]Oxford University Hospitals NHS Foundation Trust, Womens and Childrens, Oxford, United Kingdom

[2]IVI Midlands, Reproductive Medicine, Birmingham, United Kingdom

[3]Imperial College Healthcare NHS Trust, Womens and Childrens, London, United Kingdom

Study question:

Does ICSI improve success in donor oocyte cycles in the absence of a medically indicated reason?

Summary answer:

IVF results in a higher clinical pregnancy and live birth rate whilst ICSI has a lower failed fertilisation rate.

What is known already:

Donor oocytes have expanded the scope of assisted reproductive technology (ART) for women unable to conceive with autologous oocytes, and resulting in higher live birth rates. However, the degree of anxiety surrounding donor cycle outcomes is increased, with some advocating ICSI for all donor oocyte cycles to reduce the likelihood of failed fertilisation. ICSI has a clear role in the management of male factor subfertility, but its use for other indications has yet to be proven. A recent RCT performed in autologous oocyte cycles demonstrated no additional benefit with ICSI in cases of non-male factor subfertility.

Study design, size, duration:

Retrospective cohort analysis of all cycles conducted between 2002-2016, from the Human Fertilisation and Embryology Authority database. 23,589 fresh donor cycles (12,989 IVF cycles; 12,400 ICSI cycles), excluding male factor subfertility were undertaken. Assuming that the live birth rate for IVF is 30% and 40% for ICSI cycles, a power calculation demonstrated that 712 cycles would need to be analysed for 80% power and a 5% significance level to detect 10% difference.

Participants/materials, setting, methods:

The database was analysed for singleton live birth rate (SLBR), stratified by recipient age, donor age, number of previous IVF treatments and type of cycle (fresh IVF versus fresh ICSI). Cycles complicated by male factor subfertility were excluded from the final analysis as this is known to influence the method of fertilisation. Statistical analysis was performed using Logistic Regression and Chi-square; $p<0.05$ was considered statistically significant.

Main results and the role of chance:

The overall IVF to ICSI ratio for donor oocyte treatment cycles in the absence of male factor subfertility favoured IVF (68:32) in 2002, with a yearly rise seen in ICSI cycles reaching 42:58 in 2016.

The clinical pregnancy rate is statistically higher with donor IVF (n=4721;40.5%) versus donor ICSI cycles (n=4280;38.3%) (odds ratio [OR] 1.10, 95% confidence intervals [CI] 1.04-1.16, p=0.0009).

The overall live birth rate per embryo transferred was higher in the IVF group (n=5,230;26.6%) compared with ICSI (n=4,593;24.1%). The OR was calculated using binary logistic regression and adjusted for recipient age, donor age, number of previous IVF cycles and cause of subfertility, giving IVF an OR 1.13 (95% CI 1.04-1.23, p=0.004).

The failed fertilisation rate was higher for IVF (n=270;2.08%) compared with ICSI (n=196;1.58%) (relative risk [RR] 1.32, 95% CI 1.09-1.58, $p<0.0001$). Furthermore, the data from this study suggests that the number needed to treat to prevent one failed fertilisation through IVF is 200 cycles of ICSI.

Limitations, reasons for caution:

The accuracy of the database is dependent on the information submitted to the HFEA. Until 2007, this data was manually captured adding the risk of data entry error. Furthermore, information on embryo quality is not available including the inability to account for cumulative pregnancy rates in women with previous attempts.

Wider implications of the findings:

The reduction in the failed fertilisation rate does not translate to an improvement in the live birth rate and therefore, ICSI does not confer any additional benefit compared to IVF. This provides patients with the ability to make an informed choice of IVF over ICSI, with an overall cost saving.

[7]The Fertility Clinic at Skive Regional Hospital- Aarhus University- Denmark, Reproductive Gynaecology Specialist, Skive, Denmark

Study question:

Could the use of a novel long acting, single dose GnRH antagonist, Degarelix, cause efficient pituitary downregulation during ovarian stimulation in oocyte donors?

Summary answer:

Single administration of a novel long-acting GnRH antagonist can efficiently downregulate LH, produce mature oocytes and achieve comparable pregnancy outcome to the classical short-antagonist protocol.

What is known already:

GnRH antagonists have started to be widely used in the last decade. Their immediate action, successful LH surge suppression and complete eradication of OHSS, especially when combined with GnRH agonist triggering and a freeze all strategy create a favorable-luring profile. Their action, though immediate is however short lived, requiring multiple doses to be administered in the mid follicular phase leading to increased cost and patient discomfort**.** Women faced with infertility undergoing IVF treatment experience repeated drug injections as traumatic and bothersome and the special population of oocyte donors could benefit from an even more convenient and patient friendly protocol.

Study design, size, duration:

This RCT recruited healthy women, under 35yrs undergoing oocyte donation and studied the efficacy of a single Day6 follicular dose of degarelix (Firmagon, Ferring Pharmaceuticals) compared to the classical daily dose protocol from January 2017-December 2018. Two groups of patients were compared: Group-A (Classical antagonist group) consisted of 89 women, who followed a fixed Day6 GnRH-antagonist protocol with daily injections of 0,25mg ganirelix, whereas, Group-B (Degarelix Group) involved 76 women undergoing the new antagonist protocol.

Participants/materials, setting, methods:

Ovarian stimulation was initiated on cycle Day2 with gonadotropins 175-300IU, daily, in both groups. In Group-A 0,25mg of antagonist (ganirelix or cetrorelix) was administered daily from stimulation Day6 in a fixed manner. On the same day a single bolus injection of 0,1 ml Degarelix was administrated subcutaneously in Group-B. Agonist triggering (Triptorelin 0,3ml) was employed for all and OPU performed at 36h. Fresh /frozen blastocyst-only transfer was performed following recipient endometrial oestrogen and progesterone priming.

Main results and the role of chance:

The mean age (27.0 vs 28.1 years), AMH (4.15 vs. 3.65ng/ml) and total gonadotropin dose (2400 vs 2508 IU) of participants were not different among group-A and group-B respectively. No LH rise or any OHSS was noticed in any groups. Although, statistically significant more oocytes retrieved (18.8 vs.16.6, $p<0.05$) with degarelix short antagonist group, not statistically different mean number of blastocysts produced among groups (6.6 in group-A vs. 7.5 in group-B). All recipients underwent 2 blastocysts transfer. Pregnancy is expressed per donor. Initial positive HCG per donor was significantly higher ($p<0.05$) in the Degarelix Short Antagonist (Group B) 80.3% (61/76) as compared with 65.9% (n=60/91) in classic short antagonist (Group A). Similarly, Cumulative delivery rate was 60.5% (46/76) in the new single shot Degarelix short antagonist group as compared to 49.5% (n=45/91) in classic antagonist group, however not statistically significant ($p>0.05$)

Limitations, reasons for caution:

Limitation is that, this is a proof of concept study, and the trial is still ongoing. Additionally, the titration of the degarelix dose was made for the first time by our group and maybe other doses can be tested in future studies.

Wider implications of the findings:

This is a new concept, with a fixed bolus follicular administration of a new long acting GnRH antagonist, which offers convenience and simplifies the IVF protocol. This single dose of degarelix, makes the antagonist protocol even more patient friendly.

Trial registration number:

NCT03240159

O-236 Mild vs. Conventional stimulation for in vitro fertilization: a stratified meta-analysis according to the level of ovarian response

P. Montoya[1], I. González-Foruria[2], I. Rodríguez[2], B. Coroleu[2], P.N. Barri[2], N.P. Polyzos[2]

[1]Conceptum, Reproductive Medicine and Infertility, Bogota, Colombia

[2]Dexeus University Hospital, Reproductive Medicine Department, Barcelona, Spain

Study question:

Is conventional stimulation (CS) superior to mild stimulation (MS) (i.e., oral compounds, lower doses or shorter treatments) in poor, normal or high responders undergoing IVF?

Summary answer:

CS results in higher live birth rates (LBR) compared to MS in normal responder women. No difference is observed in either poor or high-responders.

What is known already:

Previous randomized trials and meta-analyses have shown that mild ovarian stimulation may result in equivalent pregnancy rates compared with conventional stimulation, with a potentially higher safety profile, patient satisfaction, and lower costs, suggesting that the higher cycle cancellation rate and fewer oocytes retrieved following mild stimulation, does not affect the final reproductive outcome. Still, none of the previous meta-analyses evaluated whether this is the case in all ovarian response categories and different mild-stimulation protocols, given that the possible benefit of a higher oocyte yield might be more evident in specific ovarian response categories.

Study design, size, duration:

We conducted a systematic search of relevant randomized controlled trials (RCTs). We searched electronic databases including MEDLINE, EMBASE, LILACS-BIREME, CINAHL, The Cochrane Library, CENTRAL (Cochrane Register), Web of Science, Scopus, Trip Database, and Open Grey, to identify all relevant studies published up to January 2019. We searched trial registries for ongoing trials. No publication-year or language restrictions were adopted. We examined the reference list of all included studies, reviews, and, abstracts of major scientific meetings.

Participants/materials, setting, methods:

We included subfertile women undergoing IVF/ICSI characterized as poor, normal or high responders and compared primary and secondary outcomes between the different protocols of mild stimulation IVF (i.e., oral compounds, lower doses or shorter treatments) and conventional IVF. We used the PICO (Patients, Intervention, Comparison, and Outcomes) model to select our study population. The primary effectiveness outcome is LBR.

Main results and the role of chance:

Overall, 48 randomized controlled trials were included in the meta-analysis: 18 trials for poor, 27 trials for normal and three trials for high ovarian responders. In women characterized as poor ovarian responders, LBRs were comparable between mild vs. conventional stimulation RR(95%CI) 0.90 (0.66-1.24), heterogeneity: I2=0%,(n = 958 patients, 5 studies). No difference was observed either when using utilizing oral compounds (OC) (i.e., letrozole and clomiphene), three RCTs, lower doses (LD), or with shorter treatment duration (ST).

In women with normal ovarian response LBRs were significantly higher in the conventional stimulation (MS vs. CS) RR(95%CI) 0.78 (0.69-0.89), I2=0%, (n = 1673 patients, 5 studies). Conventional stimulation was superior to mild either when using OC, LD or ST.

Finally, in high ovarian responders, LBRs were comparable between MS vs. CS RR(95%CI) 1.09 (0.86-1.38), I2=78%, (n =1282 patients, 3 studies). No difference was observed either when using LD, ST, whereas no studies with OC have been published.

Limitations, reasons for caution:

This meta-analysis reports data for ongoing and live-birth rates. Given the higher oocyteyield in the majority of the patients' categories, no guidance can be given on whether MS is comparable to CS with regards to CLBR. Results for high-responders need to be interpreted with caution owing to high statistical heterogeneity.

Wider implications of the findings:

This is the first systematic review, and meta-analysis comparing the three general protocols of mild stimulation (i.e., oral compounds, lower doses or shorter treatments) to the conventional ovarian stimulation, and the first to evaluate them regarding the profile of the patient (i.e., high-, normal-, and poor-responders).

O-237 Long-Antagonist protocol versus Classical-day-6 Antagonist. Single luteal use of long-acting GnRH-antagonist Degarelix can efficiently downregulate LH during ovarian stimulation for IVF achieving comparable pregnancy outcome

E. Papanikolaou, MD- PhD[1], E. Timotheou[2], P. Tatsi[2], T. Chartomatsidou[2], I. Asouchidou[3], M. Grynberg[4], C. Vlachou[5], E. Katsoula[5], R. Najdecki[1]

[1]Assisting Nature- Centre of Human Reproduction and Genetics, Medical Department, Thessaloniki, Greece

[2]Assisting Nature- Centre of Human Reproduction and Genetics, Embryology Lab, Thessaloniki, Greece

[3]Aristotle University of Thessaloniki, Medical Department, Thessaloniki, Greece

[4]Hôpital Antoine Béclère, Department of Reproductive Medicine & Fertility Preservation, Paris, France

[5]Assisting Nature- Centre of Human Reproduction and Genetics, Coordination Department, Thessaloniki, Greece

Study question:

Is the new protocol with only a single luteal dose of long-acting GnRH-antagonist comparable to the short follicular antagonist protocol in terms of pregnancy achievement?

Summary answer:

A single dose of long-acting antagonist Degarelix, during luteal phase, down-regulates LH, produces mature oocytes, implantable embryos and results comparable to classical short antagonist protocol.

What is known already:

GnRH-antagonists in daily doses from stimulation day-5 or 6 gradually becomes the protocol of first choice, as it is more patient friendly and reduces dramatically the risk for Ovarian Hyperstimulation Syndrome risk (OHSS). Nevertheless, due to the limited flexibility in cycle programming long-agonist protocol is still the preferred treatment in the majority of IVF clinics. We hypothesized whether a single luteal dose of long-acting antagonist causes prolonged suppression of LH rise allowing thus flexibility in the starting day of gonadotropins later in the follicular phase.

Study design, size, duration:

This proof of concept randomized control trial studied the efficacy of a single dose of long-acting antagonist, Degarelix. The study was performed during January-December 2018. Two groups of patients were compared: Group A (Short-Antagonist group) involved 59 women, following a classic fixed day-6 GnRH-antagonist protocol whereas, Group B (study group-New Long-Antagonist Group) involved 54 women undergoing the new long-antagonist protocol. Both groups included infertile women <40 years, prepared for IVF treatment in Assisting Nature Centre.

Participants/materials, setting, methods:

In the new protocol, a single bolus injection of 0.5ml Degarelix was administrated subcutaneously in late luteal phase (day-24). Ovarian stimulation with gonadotropins 200-300IU started from cycle-day-2 to 10. In the classical short-antagonist-group gonadotropins 200-300IU started on cycle day-2 or 3, while 0.25mg of antagonist (ganirelix) from stimulation-day-6. RecHCG or agonist triggering was used when three 18mm follicles were present, followed by oocyte-pick-up 36h later. Fresh/frozen day-5 only embryotransfer was decided upon response/ progesterone rise.

Main results and the role of chance:

The mean age and AMH of participants were not different (33,8 vs. 33,2) and (2,42 vs. 2,58) among groups respectively. Stimulation ranged from 9-10 days in control group A, whether in the Long Antagonist group ranged from 10-11 days and patients, even triggered with HCG up to cycle-day-22. Similar number of oocytes retrieved (10.8 vs. 11.9) and not statistically different mean number of blastocysts were produced in both groups (4.8 vs. 5.8). No LH rise or any OHSS was noticed in any groups. All patients underwent blastocyst transfer. Fresh embryotransfer was performed in 26 out of 59 patients in group-A achieving a 23.1% ongoing/delivery rate (n=6/26) and the rest 33 patients underwent frozen embryotransfer in a Freeze-All strategy achieving a 60.6% ongoing/delivery rate (n=20/33). Similarly, fresh embryotransfer was performed in 12 out of 54 patients in group B achieving a 25% ongoing/delivery rate (n=3/12) and the rest 42 patients underwent frozen embryotransfer in a Freeze-All strategy achieving a 64.3% ongoing/delivery rate (n=27/42). Cumulative ongoing/delivery rate was 44,1% (n=26/59) in classic

antagonist (group A) and 55,5% (30/54) in the new Long Antagonist (group B), p<0.05.

Limitations, reasons for caution:

Limitation is the small size of the groups; however, this is a proof of concept still ongoing trial.

Wider implications of the findings:

This pure novel concept for IVF couples combines security, flexibility and eventually pregnancy efficacy. This new Long-Antagonist protocol addresses cycle programming that was missing with antagonist protocols in the top of eradicating OHSS. However, larger studies are required to confirm the success of this protocol.

NCT03684421

O-238 A systematic review and meta-analysis comparing Biosimilar versus Originator Recombinant Follitropin Alfa in women undergoing IVF/ICSI

S. Longobardi[1], B. Mol[2], S.J. Chua[3], R. Wang[3], C. Venetis[4], R. Papsch[1], G. Trew, H[5], R. Orvieto[6], T. D'Hooghe[1]

[1]*Merck KGaA, Global Medical Affairs Fertility, Darmstadt, Germany*

[3]*University of Adelaide, Robinson Research Institute and Adelaide Medical School, Adelaide, Australia*
[4]*UNSW Australia, Centre for Big Data Research in Health, Sydney, Australia*
[5]*The Fertility Partnership, Reproductive Medicine and Surgery, London, United Kingdom*
[6]*Sheba Academic Medical Centre, Department of Obstetrics and Gynecology, Ramat Gan, Italy*

Study question:

What is the efficacy and ovarian hyperstimulation syndrome (OHSS) risk with biosimilar compared with originator recombinant follitropin alfa for ovarian stimulation in women undergoing IVF/ICSI?

Summary answer:

Biosimilar follitropin alfa preparations result in significantly lower live birth and clinical pregnancy rates compared with the originator preparation; there is insufficient evidence on OHSS.

What is known already:

IVF is one of the cornerstones of the modern management of infertility. Ovarian stimulation with gonadotropins is an important part of IVF treatment, but these are expensive. Biosimilars have been introduced as they are presumed to be equally effective and safe, but cheaper than the originator preparation.

Study design, size, duration:

We performed a systematic review and meta-analysis comparing efficacy outcomes and OHSS (moderate to severe) with biosimilars compared with originator follitropin alfa. We searched Medline, Embase, Cochrane and Web of Science from origin to January 2019. We also searched clinical trial registries including ClinicalTrials.gov and the WHO international clinical trial registry platform for additional studies.

Participants/materials, setting, methods:

We searched for randomised controlled trials (RCTs) comparing biosimilars and originator follitropin alfa. The primary endpoint was live birth. Secondary endpoints included clinical pregnancy and OHSS (moderate to severe). Fixed effect meta-analysis was used to pool the data, and relative risks (RRs) with 95% confidence intervals (CIs) were calculated for each outcome. The I-squared statistic was used to evaluate heterogeneity.

Main results and the role of chance:

Our search identified 370 references, of which 12 were potentially eligible. After screening the full texts, three RCTs (Retenbacher 2015, Strowitzki 2016, NCT01687712; 1761 women) were found to be eligible. The biosimilar preparations were Bemfola in two studies and Ovaleap in one study.

Compared with the originator preparation, the live birth rate was significantly lower after the use of biosimilars (RR 0.82, 95% CI: 0.70 to 0.97; 3 RCTs) and the clinical pregnancy rate was also significantly lower (RR 0.83, 95% CI: 0.71 to 0.96; 3 RCTs). The overall RR for OHSS (moderate to severe) was non-significantly higher (RR 1.30; 95% CI: 0.83 to 2.70; 3 RCTs) when comparing biosimilars with the originator preparation. The heterogeneity was negligible for all outcomes (I-squared=0%).

Limitations, reasons for caution:

This meta-analysis was limited to the first treatment cycle. Two studies reported the second cycle separately but it was not possible to identify the participants with the same event in both cycles in the aggregated data. In addition, women with history of severe OHSS were excluded from the trials.

Wider implications of the findings:

In published RCTs in women undergoing IVF, ovarian stimulation with biosimilar follitropin alfa reduced the chances of live birth by 18% compared with the originator preparation.

O-239 Follicular steroidogenesis in GnRH antagonist ovarian stimulation cycles with r-FSH vs. hp-HMG. A randomized controlled trial

E. Bosch Aparicio[1], P. Alamá[1], J.L. Romero[1], M. Mari[1], E. Labarta[1]

[1]*IVI-RMA, Human Reproduction, Valencia, Spain*

Study question:

Does ovarian stimulation with hp-HMG protect from elevated Progesterone in the follicular phase compared to r-FSH cycles through a different follicular steroidogenesis?

Summary answer:

Hp-HMG enhanced the Δ_4 pathway from Pregnenolone to Androgens, while r-FSH promoted the conversion of Pregnenolone to Progesterone leading to higher follicular phase serum Progesterone

What is known already:

Elevated Progesterone in the follicular phase has been related to lower clinical outcome in fresh IVF cycles. Progesterone levels are positively correlated to ovarian response, and some studies have shown that when r-FSH alone is used for ovarian stimulation, serum P levels the day of triggering are higher than when hp-HMG is given. Whether this is due to a lower ovarian response in hp-HMG cycles or to a different follicular steroidogenesis between both ovarian stimulation regimens has not been well characterized

Study design, size, duration:

Randomized controlled trial including 110 oocyte donors undergoing ovarian stimulation with GnRH antagonists and 225 IU/day of rFSH (n=56) or hp-HMG (n=54) in a University affiliated private infertility clinic. Subjects were recruited between October 2016 and June 2018

Participants/materials, setting, methods:

Women aged 18 to 35, with a regular menstrual cycle (25-35 days) and normal ovarian reserve (AMH=10-30 pMol/L) undergoing ovarian stimulation for oocyte donation. Serum FSH, LH, Estradiol, Estrone, Progesterone, Pregnenolone, 17-OH-Progesterone, Androstenodione, Dehidroepiandrostenodione, and Testosterone, were determined on stimulation days 1, 4, 6, 8 and triggering and in follicular fluid. Samples were frozen at -20°C until determination. Total exposures across the follicular phase were compared by polynomic extrapolation

Main results and the role of chance:

Subjects of both groups were comparable for age, body mass index and AMH levels. Ovarian response was also similar: 17.5±7.9 vs. 16.5±7.5 oocytes with r-FSH and hp-HMG respectively (p=0.49)Serum P (ng/mL) the day of trigger was 0.46±0.27 in the hp-HMG group vs. 0.68±0.50 in the r-FSH group (p=0.010).Differences were also significant on stimulation days 6 and 8. The Pregnenolone:Progesterone ratio was significantly increased in the r-FSH group from stimulation day 8 to the day of trigger (p=0.019).

Serum Androstenodione (ng/mL) the day of trigger was 3.0±1.4 in the hp-HMG group vs. 2.4±1.1 in the r-FSH group (p=0.015). Differences were also significant on stimulation day 8. The Pregnenolone:Androstenodione ratio was significantly higher in the hp-HMG group (p=0.012). There were no other significant differences between both groups for any other hormones in any stimulation day. Follicular fluid E2, FSH, LH, Dehidroepioandrostenodione, Androstenodione and Testosterone were significantly higher in the hp-HMG

group.No differences were observed for Progesterone, Estrone, 17-OH Progesterone and Pregnenolone. The multivariable regression analysis showed that ovarian stimulation with r-FSH remained as a significant factor for elevated serum P on stimulation day 8 and triggering after adjusting for age, ovarian response and body mass index

Limitations, reasons for caution:

All women included in the study were young, non infertile, had a normal body mass index and a good ovarian reserve. Findings might be different in other patients' subpopulations

Wider implications of the findings:

The findings of the present study suggest that stimulation with hp-HMG may prevent for Progesterone elevation at the end of the follicular phase because of a different follicular steroidogenesis, regardless of ovarian response. This should be considered particularly in high responders if a fresh embryo transfer is planned

Trial registration number:

NCT02738580

O-240 The dydrogesterone and FSH protocol in patients with polycystic ovarian syndrome undergoing controlled ovarian hyperstimulation in IVF/ICSI cycle

A.S. Gurbuz[1], F. Gode[2]

[1]*Novafertil IVF Center, Obstetrics and Gynecology, Konya, Turkey*
[2]*Bahcesehir University, Obstetrics and Gynecology, Istanbul, Turkey*

Study question:

Can dydrogesterone be used as an alternative suppressor of LH surge in controlled ovarian stimulation in PCO patients.

Summary answer:

Dydrogesterone can be used as an alternative suppressor of LH surge in controlled ovarian stimulation in PCO patients.

What is known already:

Progesterone-primed ovarian stimulation (PPOS) is a new ovarian stimulation regimen based on a freeze-all strategy that uses progestin as an alternative to a GnRH analog for suppressing a premature LH surge during the follicular phase. Dydrogesterone (DYD), medroxyprogesterone acetate (MPA) and natürel micronized progesterone (NMP) has been successfully used as adjuvant to gonadotrophin in the PPOS protocol in normoresponders and poor responders . However, the use of freeze-all strategy is suitable for hyperresponders. DYD has less side effect than the other progestin.

Study design, size, duration:

A retrospective trial including 488 patients was performed between April 2017 and November 2018. The patients results were collected to at a 1:1 ratio into two treatment groups: an rec FSH +DYG group (242 patients) or an rec FSH + GnRH antagonist (Cetrorelix) group (246 patients) followed by IVF or ICSI with the freeze-all strategy. The primary outcome of the trial was the number of oocytes retrieved.

Participants/materials, setting, methods:

Patients under 35 years of age with PCO patients who were undergoing IVF/ICSI procedure, based on the oral progestin or antagonist protocol used: rec FSH+DYG or GnRH Antagonist protocol: rec FSH+cetrorelix . The DYD was simultaneously administered at the beginning of menstrual cycle 3. The cetrorelix was administered on 6th day of controlled ovarian stimulation. Oocyte maturation was triggered by GnRH agonist (0,2mg triptorelin). All viable embryos from both protocols were cryopreserved for later transfer.

Main results and the role of chance:

Basic characteristics in both groups were similar. There was no significant difference in the number (mean±SD) of oocytes retrieved (14,2±5.3 for the rec FSH + DYG group versus 15.1±5.8 for the rec FSH+Cet group, (P=0.31) or the oocyte retrieval rate (76.2±15.3% for the rec FSH + DYG group versus 76.7 ±17.5% for the rec FSH + Cet group, P=0.71) between the groups. The viable embryo rate per oocyte retrieved did not differ between the two groups (odds ratio (OR): 1.06, 95% CI: 0.96–1.19, P=0.17): 36% (1314/3642) for the rec FSH + DYG group versus 35.8% (1331/3718) for the rec FSH +Cet group. During the whole process of ovarian stimulation, the mean LH level in the rec FSH + DYG group was always higher than that in the rec FSH+ Cet group ($P < 0.001$); however, no patient from either group experienced a premature LH surge. No patients experienced ovarian hyperstimulation syndrome . No significant difference was found in the clinical pregnancy rate of the FET cycle between the two groups (OR: 0.81, 95% CI: 0.55–1.24, P = 0.33): 56.7% for the rec FSH + DYG group (118/208) versus 52.0% for the rec FSH + Cet group (101/194).

Limitations, reasons for caution:

Main limitation of this study is that is retrospective study. This study has only clinical pregnancy rates because of live birth rates were not observed in the follow up period.

Wider implications of the findings:

DYG, which exhibits no or only weak inhibition of ovulation in normal dosage, can serve as an rec FSH adjuvant during ovarian stimulation. This finding suggests the possibility of a new application of DYG: as an appropriate alternative LH surge suppressor for hyperresponder patient in IVF.

O-241 Luteinizing hormone receptor deficiency in granulosa cells explains the retrieval of immature (germinal vesicle) oocytes after controlled ovarian stimulation

M. Casalechi[1], M.T. Pereira[1], I.K. Cavallo[1], C. Dela Cruz[1], F. Marcos dos Reis[1]

[1]*Hospital das Clinicas da Universidade Federal de Minas Gerais, Dept. of Obstetrics and Gynecology, Belo Horizonte, Brazil*

Study question:

Why are immature (germinal vesicle, GV) oocytes retrieved after controlled ovarian stimulation (COS) for in vitro fertilization (IVF)?

Summary answer:

Follicles containing GV oocytes at the time of oocyte retrieval for IVF have almost undetectable luteinizing hormone receptor (LHR) mRNA levels

What is known already:

Following the LH surge, paracrine messages from granulosa cells induce the oocyte to resume meiosis and acquire full competence. However, some oocytes retrieved for IVF do not respond to this stimulus and remain at GV stage. Case reports have documented patients whose repeated IVF attempts yielded only GV oocytes despite of the correct use of gonadotropins for COS and ovulation triggering. Moreover, in typical IVF cycles about 8% of the retrieved oocytes are arrested in GV stage. Until now, there is no reasonable explanation to this failed meiotic resumption of some oocytes after COS.

Study design, size, duration:

This was a prospective cohort study including 39 women (26 to 42 years old) who underwent COS in a single IVF center. The participants were enrolled in the study from February to September 2018. The study was approved by the local IRB and all participants provided written informed consent.

Participants/materials, setting, methods:

Luteinized granulosa cells (GC) and cumulus cells (CC) were collected from 96 preovulatory follicles and the maturation stage of the oocytes was immediately evaluated. LHR gene expression levels were measured by quantitative reverse-transcription real-time PCR in GC and in CC surrounding each oocyte. The relative mRNA expression of LHR was compared between cells from follicles containing GV, metaphase I (MI) and metaphase II (MII) oocytes using Kruskal-Wallis analysis of variance.

Main results and the role of chance:

The qPCR results were homogeneous for amplification of the S26 reference gene. The duplicates of the samples were concordant and the melting curves (Tm) showed a single peak for LHR and S26 genes, demonstrating the reliability of the results.

LHR mRNA expression was detected in both CC and GC of follicles containing MII or MI oocytes, being four-fold more abundant in CC than in GC. LHR mRNA was nearly undetectable in both CC (fold change 0.25, $p<0.01$) and GC (fold change 0.24, $p<0.01$) from follicles containing GV oocytes.

Limitations, reasons for caution:

Samples were obtained from patients who underwent COS for IVF, hence we cannot extrapolate these findings to natural ovarian cycles. We did not measure proteins or perform functional studies, but the severe deficiency of LHR mRNA in GC and CC is likely to explain the oocyte unresponsiveness to LH.

Wider implications of the findings:

Until now, there was no reasonable explanation for the lack of oocyte maturation in response to COS. Our finding reveals a potential mechanism

for this condition and suggests that novel drugs acting beyond LHR should be developed to treat IVF patients with a high proportion of GV oocytes.

O-242 Are human embryos able to modulate mitochondrial DNA (mtDNA) content before implantation?

M. Pérez[1], A. Díez-Juan[2], C. Vidal[3], D. Castelló[4], M.J. De los Santos[4]

[1]*IVI-RMA Global, Research, Valencia, Spain*
[2]*Igenomix, Product Innovation, Valencia, Spain*
[3]*IVI-RMA Global, Gynecology, Valencia, Spain*
[4]*IVI-RMA Global, IVF lab, Valencia, Spain*

Study question:

To determine if the human embryo is able to modulate his mitochondrial DNA (mtDNA) content in response to an external stress before implantation.

Summary answer:

There is a high increase in mtDNA copy number in arrested cleavage stage embryos which are arrested and in blastocyst after vitrification and warm.

What is known already:

Mitochondrial dynamics are essential for stress responses. Mitochondria are able to respond to an acute cellular stress by different mechanisms: motility; fusion and fission processes; inter-organellar contacts; cristae remodeling; rebuilding, recycling, permeabilization and biogenesis; (Eisner V. et al., 2018). However, no evidences have been reported so far concerning the ability of human embryo to modulate mtDNA content before implantation occurs. The study of the mtDNA content in embryos that have suffered some kind of stress will shed light on this topic.

Study design, size, duration:

A prospective cohort study was performed with 35 fresh arrested cleavage stage embryos, 21 vitrified embryos on day 3 of development, 32 aneuploid blastocysts cultured 0 hours post-warm, 5 aneuploid blastocysts that were warmed and cultured 2 hours post-warm and 9 aneuploid blastocysts warmed and cultured 5 hours post-warm. All embryo stages were tubed in PCR tubes separately with 2,5 µl of PBS.

Participants/materials, setting, methods:

Q-PCR was performed with SurePlex DNA Amplification System (Illumina) using specific primers for the ATP8 and β-Actin genes to assess the total and per cell mtDNA copy number. Data was analysed by ANOVA test with Scheffé multiple comparison for categorical variables and linear regression for numerical variables.

Main results and the role of chance:

Arrested cleavage stage embryos had a significantly ($P<0.05$) higher total and per cell mtDNA copy number (Log_2 ATP8=34.20, Log_2 ATP8/β-Actin=23.10) compared to not arrested day 3 embryos (Log_2 ATP8=18.26, Log_2 ATP8/ β-Actin=5.46) and blastocyst stage embryos cultured 0 hours post-warm (Log_2 ATP8=16.39, Log_2 ATP8/ β-Actin= 3.15). The earlier the arrest occurred the lower mtDNA levels were found ($P<0.05$). Vitrification had a significant impact over the final quantities of mtDNA, reaching the higher levels 5 hours post-warm (Log_2 ATP8=17.81, Log_2 ATP8/ β-Actin= 5.17) compared to 2 hours (Log_2 ATP8=16.19, Log_2 ATP8/ β-Actin= 3.03) and 0 hours (Log_2 ATP8=16.39, Log_2 ATP8/ β-Actin= 3.15) post-warm ($P<0.05$). Then, the increase in mtDNA copy number observed in arrested embryos and after vitrification/warm process could indicate that human embryos are not only able to modulate the mtDNA content before implantation but also that embryos modify its mtDNA content to face a stress situation.

Limitations, reasons for caution:

All the analyzed blastocyst were aneuploid, so we need to check whether euploid human blastocysts will have similar behavior. Additionally, an increase in sample size is required to confirm these preliminary findings.

Wider implications of the findings:

As far as we know this is the first study evidencing how embryos are able to respond to stress situation modulating its mtDNA content, and that this can happen during its preimplantation period. This would be useful to do further studies to know how its implantation capacity would be affected.

O-243 Gene Expression Profiling of Cumulus Cells Derived from Oocytes at Different Maturational Stages Reveals Marked Differences, Potentially Shedding Light on Pathologies of Maturation

N. Fuchs Weizman[1,2], B. Wyse[3], S. Kadish[3], M. Sangaralingam[3], H. Balakier[4], I. Gat[1,2], S. Kenigsberg[3], C. Librach[5]

[1]*University of Toronto, Obstetrics and Gynecology, Toronto, Canada*
[2]*CReATe Fertility Center, Clinic, Toronto, Canada*
[3]*CreAte Fertility Center, Research, Toronto, Canada*
[4]*CReATe Fertility Center, Embryology Lab, Toronto, Canada*
[5]*CreATe Fertility Center, Director, Toronto, Canada*

Study question:

Can transcriptomic profiling of cumulus cells (CCs) encapsulating germinal vesicle (GV) and metaphase-two (MII) oocytes, improve our understanding of pathologies of maturation and have implications on treatment decisions?

Summary answer:

Differences between transcriptomic profiles of CCs from GV and MII oocytes explain the functional gap between them, and have the potential to improve treatment outcomes.

What is known already:

CCs support growing oocytes and can be collected without compromising their integrity. Their transcriptomes mirror those of corresponding oocytes, and are considered as potential non-invasive biomarkers for oocyte quality. Trying to mature GVs that have been previously exposed to gonadotropins in the lab, is an inefficient process and often yields oocytes with lower developmental potential. Transcriptomes of CCs encapsulating oocytes of different maturity could better elucidate the functional gaps between them. Addressing these gaps could potentially be the first step in improving maturation rate in vitro, and the quality of the resulting oocytes.

Study design, size, duration:

Twelve consented patients undergoing IVF-ICSI at the CReATe Fertility Centre (Toronto, CA) were enrolled in the study. Cumulus cells were collected, and the corresponding oocyte maturation was assessed and recorded by an embryologist. RNA sequencing and differential gene expression and pathway analysis between CCs from mature MII and immature GV oocytes were performed.

Participants/materials, setting, methods:

cDNA libraries (Clonetech SMARTer-v4 and Nextera-XT) were sequenced using the NextSeq 550. Sequences were aligned to hg19, and differential expression was conducted. We then performed pathway analysis to elucidate differences in hallmark ovarian and cellular processes, and leading edge analysis to determine which genes were driving these differences. A comprehensive literature search revealed potential roles of each leading edge gene in the pathophysiology of defective oocyte maturation.

Main results and the role of chance:

Principal component analysis revealed that samples clustered primarily according to the maturation stage of the oocyte. Following differential expression, 795 genes were significantly up-regulated and 1034 were down-regulated between MIIs and GVs.

Mature oocytes expressed enhanced steroid metabolism, with up-regulation of *AREG* (which induces meiotic resumption, and progesterone production), enhanced *MAPK/ERK* signaling pathway, with up-regulation of *AREG*, *EREG* and *PTGS2* (which together mediate cumulus expansion and oocyte maturation, as well as corpus luteum formation and maintenance and reduce spindle abnormalities), and enhanced regulation of cell size with up-regulation of

BDNF, (which promotes oocyte maturity and follicular growth). Mature oocytes also expressed attenuated pathways including cell cycle regulation, with down-regulation of the pro-apoptotic and anti-angiogenic gene *SFRP4*, decreased assembly of pre-replication complex marked by down-regulation of *CDC6*, decreased mitotic spindle formation and chromosome segregation with down-regulation of *CDK1* (required for spindle migration and membrane protrusion leading to polar body extrusion) and attenuated extra-cellular matrix remodeling.

Limitations, reasons for caution:

Our findings are limited by the relatively small sample size and the inherent biological variability of human samples. To adjust for this, "significant differentially expressed genes" between MIIs and GVs were defined with stringent criteria, increasing the confidence in the validity of the findings.

Wider implications of the findings:

Data is slowly accumulating regarding the potential of modified incubation media for immature oocytes, mostly from non-human models. Our findings could further promote modifications for existing media, with the hope of improving maturation rates in the lab, as well as yielding MIIs with enhanced developmental potential in humans.

O-244 Pronuclear score significantly correlates with clinical pregnancy rates in top quality embryos

S. Stigliani[1], C. Massarotti[2], I. Casciano[1], F. Sozzi[1], V. Remorgida[2], P. Anserini[1], P. Scaruffi[1]

[1]*IRCCS Ospedale Policlinico San Martino, UOS Physiopathology of Human Reproduction, Genova, Italy*

[2]*University of Genova, Department of Neurosciences- Rehabilitation- Ophthalmology- Genetics- Maternal and Child Health DINOGMI- Academic Unit of Obstetrics and Gynecology, Genova, Italy*

Study question:

Is the pronuclear (PN) morphology an useful additional criterion to improve prediction of blastocyst development and clinical pregnancy?

Summary answer:

The PN score based on the recently standardized ESHRE system improves prediction of clinical pregnancy in cleavage-stage embryos with good morphology.

What is known already:

In assisted reproduction technology embryo competence is routinely evaluated on morphological criteria but their efficacy remains relatively low. Additional information could be obtained by evaluation of PN morphology. Up to now controversial results have been reported about correlation between the zygote morphology and the embryo competence. One of the main limitation of literature data is the use of different methods of PN classification. To this regard, in 2011 the ESHRE and Alpha Scientists in Reproductive Medicine defined three PN categories to standardize the zygote assessment. To date, no studies verified the efficacy and the reproducibility of such a recent classification.

Study design, size, duration:

We included 2799 zygotes from 731 women who underwent ICSI at our Center between 2014 and 2018. Zygotes were assessed 16-18 hrs after injection according to the Alpha consensus PN scoring system (1: symmetrical, 2: non-symmetrical, 3: abnormal). They were individually cultured. On day 2-3 1091 embryos were transferred into uterus, 1380 were cultured up to day 5-7, 213 arrested on day 2-3, 10 were cryoconserved on day 2-3; 105 zygotes did not cleaved.

Participants/materials, setting, methods:

Chi-square test was used to evaluate the relationship between the PN score and cleavage rate, quality of embryos, blastocyst development, clinical pregnancy rates. Clinical pregnancy was defined as viable pregnancy at 12 weeks. A multivariable logistic regression model was applied including the following characteristics: age of patient, PN score, embryo day 2-3 morphology grade. A P value <0.05 was considered significant. All analyses were carried out by R software, v. 3.4.1.

Main results and the role of chance:

A total of 2130 (76%) score 1, 594 (21%) score 2, and 75 (3%) score 3 zygotes were obtained. There was not a significant difference in day 2-3 morphology among the three PN score groups. Moreover, the zygote score did not always correlate with the embryo grade: only 58% top quality zygotes formed grade 1 embryos, and 51% poor quality zygotes (score 3) also became high quality embryos. A total of 1032 PN score 1-, 314 score 2-, and 34 score 3-derived embryos were placed in extended culture. We did not found any reduction of blastulation rates in score 2 (32%) and score 3 (50%) groups respect to score 1 (35%). A better clinical pregnancy rate for PN score 1- was found respect to score 2-3-derived embryos (14% and 7%, respectively, P=0.0101). Cycles with transfer of good quality cleavage-stage embryos from top quality zygotes had a significant higher clinical pregnancy rates than those with transfer of PN score 2-3-embryos (OR 0.42; 95% CI 0.21-0.77, P=0.008), even if the morphology of the embryos was good. Consistently, the PN score remained predictive of clinical pregnancy in the subgroup of embryos with top quality morphology grade (OR 0.43; 95% CI 0.21-0.68, P= 0.009).

Limitations, reasons for caution:

Although our findings could be interesting for the majority of laboratories conventionally performing discrete morphological assessment once a day by microscopic analysis, the main limitation of this study is its own not-morphokinetics nature. In fact, we did not evaluated the dynamics of pronuclear morphology and additional kinetic parameters.

Wider implications of the findings:

This is the first study applying the PN score system proposed by ESHRE. Although validation in randomized perspective studies is needed, our findings suggest that the PN score may be routinely included among criteria for embryo evaluation to provide patients with an increased chance of becoming pregnant.

Trial registration number:

O-245 Assessment of the oxidative stress levels in culture media as a biomarker of embryo cohort quality.

A. Mercader[1], L. Bori[2], L. Alegre[1], J.M. Zapata[2], M. Meseguer[1]

[1]*IVIRMA Valencia, IVF laboratory, Valencia, Spain*

[2]*IVIRMA Valencia, Research laboratory, Valencia, Spain*

Study question:

Are the oxidative stress levels measured in grouped cultured embryos spent culture media a biomarker of culture conditions, media quality or embryo quality?

Summary answer:

Optimum culture conditions linked with better pregnancy outcomes were related to oxidative stress levels.

What is known already:

Embryo's *in vitro* environment is known to affect their development and subsequent clinical outcome. The establishment of optimum culture conditions is therefore crucial aiming at the standardization of *in vitro* fertilization (IVF) protocols. The Thermochemiluminescence (TCL) Analyzer™ (Carmel Diagnostics, Israel) determines the oxidative status of the embryo's spent culture media assessing the adequacy of the embryo culture conditions, in terms of media, humidity, gas concentration, temperature, etc. The aim of the present study is to assess the use of a novel quality control device in IVF laboratories.

Study design, size, duration:

A prospective cohort study on 471 spent embryo culture media collected from 312 IVF cycles that were analysed from May 2017 to December 2018. Embryos were group cultured and monitored with time-lapse incubators: Embryoscope+® (Vitrolife) and Geri® (Genea). 15 µl/dish of embryo culture media were analysed through TCL Analyzer (Carmel Diagnosis).

Participants/materials, setting, methods:

The TCL Analyzer™ working mechanism consists on the heat-induced oxidation of biological fluids, leading to the production of light energy counted as photons emitted per second (cps). Cps amplitude is assessed in a 300-second period, where TCL parameters are obtained from: cps after 55 seconds (**H1**), 155 seconds (**H2**) and 255 seconds (**H3**). A smoothing algorithm (sm) was used to normalize data. Our results were statistically analysed by a multifactor Anova test.

Main results and the role of chance:

Even though both incubators allow cultivating 16 embryos in group, significantly higher oxidative stress was found in samples collected from Geri dishes than from ESD+ ones ($p<.05$). This might be due to the amount of culture medium in each dish (80µl and 180µl, respectively) and the impact over the concentration of free radicals. Samples from embryo cohorts cultured since blastocyst stage in single-step culture media (s-s) showed higher TCL parameters than those from embryos cultured in sequential culture media: **H1sm** (cps)= 93.24 for two-step vs. 98.75 for s-s, **H2sm** (cps)= 96.51 for two-step vs. 102.57 for s-s and **H3sm** (cps)= 104.89 for two-step vs 111.09 for s-s. In addition, samples provided from egg donor programs had higher oxidative stress values than those provided from cycles with autologous eggs. The mean and standard deviation of the TCL parameters were as follows (cps): 96.82 ± 39.34 for autologous eggs vs. 103.62±41.58 for donated eggs. Additionally, culture media from embryo cohorts that lead at least one ongoing pregnancy had significantly higher TCL parameters ($p<.05$). Culture media of embryo cohorts with no pregnancy showed an average of 92.08 ± 42.08 cps and 108.02 ± 39.88 cps for those with one or more pregnancy.

Limitations, reasons for caution:

There is a need to further assess the wide number of different independent variables in culture conditions that may be affecting the oxidative stress levels. Number of embryos cultured in each dish can vary depending on patient and may potentially affect the oxidation.

Wider implications of the findings:

TCL Analyzer™'s assessment has proven relationship with culture conditions (type of inclubator and type of media) embryo quality and reproductive outcome. Those values with higher oxidation were related with superior embryo quality and higher chances of a successful pregnancy.

O-246 Analysis of spindle morphology in MII oocytes matured in vitro from denuded GV and MI oocytes

P. Karamtzioti[1], A. Ferrer-Vaquer[1], G. Tiscornia[1], D. García[1], I. Vernos[2], R. Vassena[1]

[1]Clinica Eugin, Assisted reproduction, Barcelona, Spain

[2]Centre for Genomic Regulation CRG & Institució Catalana de Recerca I Estudis Avançats ICREA, Research, Barcelona, Spain

Study question:

How does the meiotic spindle morphology of MII oocytes from GVs and MI matured *in vitro* compare to that of MII oocytes matured *in vivo*?

Summary answer:

Spindles of MII from denuded GVs cultured *in vitro* show higher proportion of unfocused poles compared to those matured from MI or in vivo MII.

What is known already:

A functional spindle is required for chromosomal segregation during meiosis. GVs matured *in vitro* within the cumulus oophorous assemble spindles similar to *in vivo* matured MII oocytes. Maturation of GVs without cumulus cells (GV-MII) result in spindle abnormalities, chromosome misalignment and compromised developmental potential. Although aneuploidy rates in GV-MII are not higher than MII, disorganized chromosomes may contribute to compromised developmental potential. However, spindle morphology has not been quantitatively examined and no comparison with *in vitro* culture of MI oocytes matured to MII (MI-MII) has been reported

Study design, size, duration:

GV (n=109), MI (n=49), and MII oocytes (n=19) were retrieved from 30, 17 and 18 stimulated women, respectively, 20 to 35 years old. GVs and MI were denuded and cultured *in vitro* in G-2 PLUS medium until MII stage (approximately 30h and 8h, respectively). In vivo matured MII oocytes were stored vitrified, and warmed before processing.

Participants/materials, setting, methods:

All women were stimulated using a GnRH antagonist protocol, with a GnRH agonist trigger. Trigger criterion was 2 or more follicles ≥18mm; oocytes were harvested 36h later. Spindle microtubules were incubated with antibodies against alpha tubulin (T6199 Sigma-Aldrich at 1/100 dilution), chromosomes stained with Hoechst 33342 and samples subjected to confocal immunofluorescence microscopy (ZEISS LSM780). Images were collected and analyzed with ImageJ software; the Kruskal Wallis and Fisher's exact test were used for statistical analysis.

Main results and the role of chance:

Evaluation of spindle quality was based on measurements of the length of major, minor, proximal and distal axes, proximal/distal axis ratio, major to minor axis angle, spindle to cortex distance, spindle pole shape and spindle volume estimation as established in Cottichio et al 2013 (*Hum Reprod*). Of all matured oocytes, only properly oriented spindles (orthogonal orientation to the objective) were analyzed. All parameters were similar between groups, except for a) the proximal/distal axis ratio which was higher in MII oocytes and GV-MII as compared to MI-MII (Kruskal Wallis 3 way comparison, $p = 0.017$), and b) double flattened spindle poles (poles displaying a flat cross-segment >2µm with a barrel-like appearance), which were observed in 12/15 of the GV-MII (80%) compared to 6/20 of MI-MII (30%) and 5/19 of MII (26.3%) (Fisher´s exact test, $p = 0.0035$). We hypothesize that the loss of microtubule focus points at spindle poles may contribute to chromosome misalignment, delayed chromosome separation and compromised developmental potential.

Limitations, reasons for caution:

Oocytes retrieved from hyperstimulation cycles could be intrinsically impaired since they failed to mature in vivo. Our conclusions should not be extrapolated to IVM in non-stimulated cycles, as the cumulus oophorus is a major factor in oocyte maturation and correlation with spindle dynamics has been inferred.

Wider implications of the findings:

The inability to organize focused poles could be an underlying cause of impaired quality of GV-MII. Microtubule motors (dynein-dynactin), pole components (NuMA) and minus-end binders may be imbalanced; investigating the localization of these factors in GV-MII in comparison to MII oocytes would offer a molecular understanding of the flat-pole phenotype.

O-247 A novel mutation in the TUBB8 gene is associated with a complete oocyte maturation arrest: a case report about an infertile woman

A. Chargui[1], T. Bienvenu[2], L. Ferreux[1], C. Jean[1], K. Pocate-Cheriet[1], E. Girondon-Boulandet[2], M. Bourdon[3], C. Maignien[3], P. Santulli[3], J.P. Wolf[1], D. Vidaud[2], C. Patrat[1]

[1]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service d'Histologie-Embryologie et Biologie de la Reproduction, Paris, France

[2]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service de Génétique et Biologie moléculaires, Paris, France

[3]Hôpital Cochin- Assistance Publique des Hôpitaux de Paris, Service de Gynécologie-Obstétrique II et de Médecine de la Reproduction, Paris, France

Study question:

Is there a new mutation in the tubulin beta eight class VIII *(TUBB8)* responsible of female infertility with an oocyte maturation arrest phenotype?

Summary answer:

We identified a new mutationsin *TUBB8 gene* associated with a total oocyte maturation arrest. This mutation was confirmed by a family analysis.

What is known already:

A genetic defect in the *TUBB8* gene has been shown to be responsible for oocyte maturation, fertilization and early embryonic developmental arrest. This gene encodes a special β-tubulin isotype that is the major component of the oocyte and early embryo spindle. Heterozygous or de novo mutations in the TUBB8 gene are associated mainly to human metaphase I (MI) arrest and some early embryonic development failure. Other homozygous or compound heterozygous mutations seem to be responsible of fertilization failure and early embryonic development arrest.

Study design, size, duration:

We have characterized a patient with 5-year history of primary unexplained infertility belonging to a consanguineous family from Tunisia and with infertile relatives. During 3 assisted reproduction attempts (conventional IVF, ICSI and IVM), the woman presented a total MI oocyte arrest for each oocyte retrieval after controlled ovarian hyperstimulation. We performed Sanger sequencing of the *TUBB8* gene in the patient and her family members. A spindle immunostaining was performed on some blocked MI oocytes.

Participants/materials, setting, methods:

The oocytes morphology was evaluated by light inverted microscope. Oocyte spindles were stained with anti β-tubulin antibody after fixation and membrane permeabilizing, then examined by confocal microscopy. Genomic DNA samples of the patient and her family's members were extracted from peripheral blood using Chemagic technique. The 4 exons composing *TUBB8* were amplified and sequenced using an Illumina NextSeq500. TUBB8 sequences was aligned by Human GRCh37/hg19 UCSC Genome Browser and analyzed by SIFT and Polyphen-2.

Main results and the role of chance:

In total, after 3 oocytes retrievals, 42 oocytes were collected for our 32 years-old patient. All (13, 10 and 19 oocytes) were arrested at MI. Six oocytes from the second oocyte cohort were immunostained to analyze the spindle structure. The spindles were very weakly visible and unstructured comparing to control.

The genomic analysis of the fourth exon found a missense homozygous variant c.935 C>T (**p.Thr312Met**) in the patient, her father and her two sisters. The same mutation was detected for the mother and the brother but with a heterozygous expression. According to biostatistics browsers SIFT and Polyphen-2, this variant is considered as deleterious and probably damaging. In ExAC browser, this variant is rarely described, only 3 times among 243004 alleles, and always as heterozygous.

According to the genomic analysis, the missense homozygous variant **p.Thr312Met** (unknown signification, Class III) located on the C-terminal domain of β-tubulin with a recessive autosomic father inheritance, can explain the patient infertility and her sisters infertilities (2 and 3 years respectively, but not attending an ART center yet). The detection of this variant may confirm the phenotypic arrest of oocyte maturation at MI stage, that has been verified by a molecular proof (the spindle immunostaining) too.

Limitations, reasons for caution:

The genomic analysis (DNA extraction DNA, TUBB8 sequencing) of blocked oocytes is not performed yet to detect the local expression of this variant.

A causal relationship between t mutation and the spindle assembly need to be established by microinjection of wild-type and mutant TUBB8 encoding RNAs on K.O. mouse oocytes.

Wider implications of the findings:

Yet, this case report brings a new insight about the role of *TUBB8* on meiosis and the possibility that a TUBB8 homozygous mutation can lead to a MI maturation arrest and not only heterozygous mutations are responsible of it.

O-248 Does the trophectoderm biopsy technique affect the result of the genetic analysis in PGT-A cycles?

L. Herrero Grassa[1], L. Cascales Romero[1], J.A. Ortiz Salcedo[2], M. Aparicio Gonzalez[1], J. Ten Morro[3], R. Bernabéu Peréz[4]

[1]*Instituto Bernabéu Madrid, IVF Laboratory, Madrid, Spain*

[2]*Instituto Bernabeu Alicante, Molecular biology and Genetic Department, Alicante, Spain*

[3]*Instituto Bernabeu Alicante, IVF Laboratory, Alicante, Spain*

[4]*Instituto Bernabeu, Director, Alicante, Spain*

Study question:

Does the trophectoderm biopsy technique, pulling or flicking, affects the diagnostic rate, mosaicism rate or transferability rate displayed by the genetic analysis in PGT-A cycles?

Summary answer:

Pulling required more laser shots to obtain the same number of cells from the trophectoderm, and higher mosaicism rate was observed when pulling was performed.

What is known already:

Preimplantation genetic testing for aneuploidy (PGT-A) aims to find the best euploid embryo, improving live birth rate per transfer. The analysis of single day 3 cells has gradually led to trophectoderm (TE) biopsy, increasing the number of cells available, allowing the detection of mosaicism and being less harmful for the embryo.

Two techniques have been proposed: "pulling" or "flicking". Among 4-8 cells must be biopsied and the inner cell mass must be place far from the TE cells biopsied.

Although it has been demonstrated that TE biopsy does not harm the embryo, the biopsy technique may affect the genetic test.

Study design, size, duration:

144 PGT-A cycles were included in this retrospective analysis involving 421 blastocysts biopsied between January 2018-December 2018 by two expert embryologists[RB1] .

Assisted hatching on day 3 were performed; 212 blastocysts were biopsied using pulling and 209 using flicking; 244 were biopsied on day 5 and 177 on day 6; 273 blastocysts came from egg donation cycles (64.8%).

Each blastocyst was biopsied using pulling or flicking depending on the embryologist available to perform the procedure.

Participants/materials, setting, methods:

In the "flicking method", cells were aspirated and removed by a quick movement of the biopsy pipette against the holding.

In the "pulling" method, cells were suctioned and pulled away while laser pulses were applied.

Same embryologist performed biopsy and tubing, and registration of sample quality assessment, number of cells retrieved and number of laser shots (NLS).

Blastocysts were classified as miss-diagnosed or informative (euploid, aneuploid, transferable-mosaic, non-transferable-mosaic).

T-test, Chi-square and logistic regressions were performed.

Main results and the role of chance:

No significant differences were found between groups in: number of oocytes, oocyte age, sperm concentration, embryo quality (day 3) or blastocyst expansion and quality.

Regarding the biopsy technique, flicking and pulling reveals no differences in number of cells biopsied (5.58±1.5 vs 5.34±1.3, p=0.103), fragment visualization during tubing (97.1% vs 95.3%, p=0.322), amplification failure rate (4.3% vs 6.1% p=0.400) and transferability rate (55% vs 48%, p=0.177), respectively.

However, we found statistically differences in favor of the flicking method: mosaicism rate was higher in the pulling group (17.1% vs 9.5%; p=0.026). Moreover, the pulling method needed more shots than the flicking method (6.18±2.4 vs 3.51±1.9, p <0.0001) and also sample quality was better in flicking group (86.1% vs 78.3%, p=0.018).

A regression analysis was carried out to check which variables could affect the possibility that an embryo was transferable. The biopsy technique was the only influencing factor (p=0.019, OR=1.868, CI95% 1.109-3.146). Moreover, the biopsy technique turned out to be the most influencing factor in the possibility of being mosaic (p=0.026, OR=2.375, CI95% 1.11-5.076). Notwithstanding, when NLS appeared in the equation, biopsy technique disappeared as influencing factor, and NLS was the only one close to be statistically significant (p=0.051, OR=1.180, CI95% 0.999-1.394).

Limitations, reasons for caution:

These results came from an IVF laboratory with two embryologists, using the same micromanipulation and laser equipment. Further studies are needed to make consistent conclusions about the impact of biopsy technique, the influence of the NLS on the genetic analysis, and the correlation between NLS and mosaicism.

Wider implications of the findings:

In our study, both biopsy techniques resulted in similar euploidy rate, but flicking technique was proved to need less laser shots to obtain the same number of cells from the TE, resulting in better fragment quality. Biopsy by flicking also was associated to less mosaicism rate.

O-249 Men with fertilization failure linked to PLCZ1 mutations exhibit abnormal phospholipase C zeta pattern and overcome by ICSI with assisted oocyte activation

J. Dai[1,2], C. Dai[2], Y. Li[1,2], F. Gong[1,2], C. Lu[1,2], G. Lin[1,2]

[1]*Central South University, Institute of Reproductive and Stem Cell Engineering- School of Basic Medical Science, ChangSha, China*

[2]Reproductive and Genetic Hospital of CITIC-XIANGYA, Reproductive Center, ChangSha, China

Study question:

Does different *PLCZ1* mutations affect levels and localization patterns of the oocyte activation factor phospholipase C zeta (PLCz) and how to overcome fertilization failure?

Summary answer:

Three men with *PLCZ1* mutations exhibited abnormal localization in PLCz and no dynamic changes during capacitation and acrosome reaction, which overcame by ICSI with AOA.

What is known already:

PLCz is a sperm-related oocyte activate factor that is required to induce normal calcium oscillations after fertilization. Abnormal patterns of Ca^{2+} oscillations caused by infertile male sperm are associated with oocyte activation defects and fertilization failure. PLCz is localized to acrosomal and post-acrosomal regions and undergoes dynamic changes during capacitation and the acrosome reaction. Previous studies reported that two biallelic mutations of *PLCZ1* identified in two men were related to fertilization failure.

Study design, size, duration:

Twenty-eight couples with fertilization failure were collected from January 2014 to December 2018. Seven of twenty-eight infertile couples were tested by mouse oocyte activation test (MOAT) that ensure sperm-related activation deficiencies.

Participants/materials, setting, methods:

Four affected men and their parents from consanguineous families and three men from non-consanguineous families were subjected to whole-exome sequencing. After identifying possible causative genes, in silico and evolutionary conservation analysis was used to evaluate possible effects of candidate mutations on protein secondary structure. Immunofluorescence was used to analyze the protein levels of PLCz and acrosome status.

Main results and the role of chance:

In fertilization failure couples of China, about 25% (7/25) couples were caused by sperm factors. From seven men with definitive sperm factors, 3 patients were identified homozygous mutations in *PLCZ1* gene: c.T1048C (p.S350P), c.C736T (p.L246F) and c.C588A (p.C196X), which were highly conserved. These infertile men exhibited normal sperm counts, motility, and sperm morphological features. Though immunofluorescence of PLCz and Lectin, sperm from three *PLCZ1* mutations showed no dynamic changes during capacitation and the acrosome reaction. The sperm with p.S350P showed signal for PLCz in the post-acrosomal region, and sperm with p.L246F exhibited signal in opposite ends in equatorial region. The sperm with homozygous stop-gain mutation p.C196X exhibited no expression of PLCz. Among them, three patients were treated with ICSI with assisted oocyte activation (AOA) in the next cycle, and successful fertilization and embryo development was obtained (the rate of fertilization and good-quality embryo: 76.4% and 41.2%). Two of them got successfully pregnancy.

Limitations, reasons for caution:

Only a small number patient with *PLCZ1* mutations was available because of its rare incidence.

Wider implications of the findings:

This study expanded the mutation spectrum of *PLCZ1* gene and found the mutation frequency was 42.9% (3/7) in male-factors ICSI fertilization failure population in China. It uncovered the abnormal pattern of PLCz expression may effect the Ca^{2+} oscillations. It further provided a therapeutic and prognostic method for *PLCZ1* mutations patients.

[3]Soroka University Medical Center-Ben Gurion University of the Negev, Fertility clinic and IVF Unit-Division of Obstetrics and Gynecology, Beer Sheva, Israel
[4]Soroka University Medical Center- Ben Gurion University of the Negev, Faculty of Health Sciences, Beer Sheva, Israel
[5]Department of Software and Information Systems Engineering, Faculty of Engineering Sciences- Ben-Gurion University of the Negev, Beer Sheva, Israel
[6]The Shraga Segal Department of Microbiology- Immunology and Genetics., Faculty of Health Sciences- Ben-Gurion University of the Negev, Beer Sheva, Israel

Study question:

Can clinical and biological variables-based machine learning support the prediction of the presence or absence of sperm in testicular biopsy in NOA patients?

Summary answer:

Our machine learning model was able to predict (AUC of 0.8) presence or absence of spermatozoa in patients with NOA.

What is known already:

Patients with NOA can conceive with their own biological gamete using intra-cytoplasmic sperm injection (ICSI) in combination with testicular sperm extraction. Testicular sperm retrieval is successful in up to 50% of men with NOA; however, to the best of our knowledge there is no existing model that can accurately predict the success of sperm retrieval in testicular sperm extraction (TESE). Moreover, machine learning was never used for this purpose.

Study design, size, duration:

A retrospective cohort study consisting of 118 patients who underwent TESE in a single IVF unit between the years 1995-2017 was conducted. All patients with NOA who underwent TESE procedure during their fertility treatments were included. To develop a random forest model(RFM) to predict presence or absence of spermatozoa in patients with NOA in comparison to a multivariable logistic regression mode(MvLRM).

Participants/materials, setting, methods:

We used univariable and multivariable binary logistic regression to try and predict the probability of successful TESE using a dataset from a retrospective cohort. In addition, we used the ensemble machine learning model (Gradient Boosting Trees) and evaluated its predictive performance using the leave one-out cross validation procedure. A cut–off value for successful/unsuccessful TESE was calculated with receiver operating characteristic (ROC) curve analysis.

Main results and the role of chance:

ROC analysis resulted in an AUC of 0.807± 0.064 (95%CI, 0.682-0.927) for the proposed RFM and 0.75 ±0.052 (95%CI 0.65-0.85) for the MvLRM to predict presence or absence of spermatozoa in patients with NOA. This RFM approach and the MvLRM yielded, respectively sensitivities of 78% and 97% and specificities of 75% and 25% A total of 77 (65.3%) men with NOA experienced successful TESE. FSH, LH, testosterone, semen volume, age, BMI, ethnicity, and testicular size on ultrasound were included in those models.

Limitations, reasons for caution:

This study is a retrospective cohort study with all associated inherent biases. This model was used only for TESE, since micro-TESE is not performed in our center

Wider implications of the findings:

This machine learning model can support the clinicians together with their patients when making decision concerning TESE in patients with NOA. The findings of this study should be confirmed with further largerand prospective studies

O-251 The FSHB -211 G>T polymorphism as predictor for testicular sperm extraction success (TESE) in patients with unexplained azoospermia

M. Schubert[1], A.S. Busch[2], F. Tüttelmann[3], J.F. Cremers[1], V. Nordhoff[1], A.N. Schüring[4], M. Zitzmann[1], S. Kliesch[1], J. Gromoll[5]

[2]Department of Growth and Reproduction & International Center for Research and Research Training in Endocrine Disruption of Male Reproduction and Child Health EDMaRC, University Hospital, Copenhagen, Denmark
[3]Institute of Human Genetics, University Hospital, Münster, Germany
[4]Department of Gynecology and Obstetrics, Fertility Centre- University Hospital, Münster, Germany
[5]Department of Endocrinology and Epigenetics, Centre of Reproductive Medicine and Andrology- University Hospital, Münster, Germany

Study question:
The FSHB -211G>T single-nucleotide polymorphism (SNP) is known to impact spermatogenesis, however to which extent it also serves as predictor for sperm retrieval rates in TESE is unknown.

Summary answer:
In patients with unexplained azoospermia the FSHB -211 G>T polymorphism is significantly associated with positive sperm retrieval rate in surgical testicular sperm extraction.

What is known already:
In azoospermia, characterized by the lack of sperm in semen, the etiology for the phenotype remains most often unexplained. Patients are often referred to TESE followed by assisted reproductive techniques. The known non-invasive predictive parameters for sperm retrieval rate (SRR) like FSH level and testicular volume are inadequate to counsel azoospermic patients prior to surgery. Therefore, powerful non-invasive predictive markers are warranted.FSH plays a key role in initiation and maintenance of spermatogenesis. One well-studied single nucleotide polymorphism (SNP) within the FSHB gene (c.-211G>T) impacts endocrine feedback, testicular size and spermatogenesis. However, its impact on SRR is so far unknown.

Study design, size, duration:
In a monocentric, retrospective analysis we studied 1075 patients with azoospermia who had undergone TESE procedure at our centre. In 248 couples subsequent TESE-ICSI was performed. We evaluated the association of the FSHB -211G>T SNP (rs10835638), as well as two SNPs in the FSH receptor FSHR -29G>A (rs1394205) and FSHR c.2039A>G (rs6166) with reproductive hormones, testicular histopathology, sperm retrieval rate and pregnancy rate.

Participants/materials, setting, methods:
Patients were grouped upon the etiology of azoospermia: i) unexplained ii) genetic cause iii) obstruction. Histological evaluation was classified according to the highest achieved grade of spermatogenesis (complete vs. arrest vs. Sertoli cell only). TESE was considered positive if at least one spermatozoon was detected. Biochemical and clinical pregnancy were defined by serum hCG >30IU/L or fetal heartbeat. Logistic regression models were used to analyze the association of continuous and categorical variables with binary outcomes.

Main results and the role of chance:
We observed a significant association of FSHB -211G>T with reduced FSH levels in patients with unexplained azoospermia. For the histopathological analysis we found in the same cohort that T allele homozygosity was 8 times higher in patients with Sertoli cells only, than in patients having complete spermatogenesis ($p<0.05$). The FSHB -211G>T T allele count was significantly associated with reduced chances of positive sperm retrieval in TESE. For minor allele homozygosity (TT) Odds ratio was 0.20 (0.06 to 0.70, p=0.01). Interestingly, the association of the SNP with SSR could not be solely attributed to decreased FSH levels. Our results indicate an improvement of the predictive power (proportional reduction in error) by 7% for FSHB -211G>T in the group of unexplained azoospermia. In patients with azoospermia due to genetic (Klinefelter Syndrome, Y-Microdeletions) or obstructive disease the FSHB -211 G>T did not have an impact on testicular histopathology nor SRR. FSHR -29G>A and FSHR c.2039A>G were not associated with testicular histopathology or SRR in any etiology.61 out of 248 female partners obtained pregnancy after TESE-ICSI. FSHB -211G>T minor allele count was not associated with pregnancy rates ($p = 0.62$), and fertilization potential seems not to be reduced by this genetic variant.

Limitations, reasons for caution:
This analysis delineates FSHB -211G>T as a new, remarkably informative and non-invasive predictor for SRR. This effect could be mediated by an inadequately low FSH stimulus in T allele carriers, which might affect Sertoli cell proliferation and numbers earlier in life, however this remains to be elucidated in subsequent studies.

Wider implications of the findings:
In perspective, a calculator/score including the non-invasive parameters FSH, testicular volume and the FSHB haplotype can be considered to estimate the chances for sperm retrieval in azoospermic men.

O-252 Heterozygous mutations in PLCZ1 are associated with fertilization failure after ICSI

R.R. Guggilla[1], A. Boel[1], M. Ferrer-Buitrago[2], D. Bonte[1], P. De Sutter[2], P. Coucke[3], B. Heindryckx[1]

[1]Ghent University Hospital, Ghent-Fertility And Stem cell Team G-FaST- Department for Reproductive Medicine, Ghent, Belgium
[2]Ghent University Hospital, Ghent-Fertility And Stem cell Team G-FaST- Department for Reproductive Medicine, Ghent, Belgium
[3]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium

Study question:
Are heterozygous mutations in the phospholipase C zeta (PLCZ1) gene associated with fertilization failure after ICSI?

Summary answer:
PLCZ1 mutation screening in 35 patients with failed or low fertilization after ICSI resulted in the identification of six different mutations in twelve patients.

What is known already:
The oocyte activation process is initiated by sperm-oocyte fusion and is characterized by a series of calcium oscillations in the oocyte cytoplasm.Phospholipase C zeta (PLCZ1) is responsible for this series of calcium oscillations, which hallmarks the start of oocyte activation.Mutations in *PLCZ1* gene are described in some case reports to cause oocyte activation failure(OAF) and subsequent fertilization failure after ICSI. To obtain more insight in to the role of PLCZ1 in fertilization and to know the frequency of *PLCZ1* gene mutations in patients experiencing failed or low fertilization after ICSI, *PLCZ1* gene screening in larger cohort of patients is required.

Study design, size, duration:
Patients (n=35) with previously low or total failed fertilization after routine ICSI were enrolled in the study after obtaining written consent from 2014-present. Genetic screening for *PLCZ1* mutations was performed, next to evaluation of the activation potential of the sperm

Participants/materials, setting, methods:
Genomic DNA was extracted from the saliva samples. PCR was performed using primers designed to amplify all the 15 coding exons and the exon-intron boundaries. The amplified PCR products were sequenced using illumine MiSeq. A diagnostic test Mouse oocyte activation test (MOAT) was performed on the mouse oocytes by injecting patient sperm in to mouse oocytes and determine the number of activated oocytes, in comparison to a positive control

Main results and the role of chance:
PCR amplification and Illumina Sequencing of *PLCZ1* gene revealed six different mutations in twelve patients, which include four missense mutations D46N, H233L, S500L and R141H, one invariant splice site mutation c.136-1G>C and one protein truncating mutation K322∗. Three of the patients had experienced partial hydatidiform moles (PHMs) with their partners *in vivo*. Of the twelve patients, eight patients carried mutations in a heterozygous state which include four patients with S500L mutation, two with H233L mutation, one with R141H mutation and one patient with c.136-1G>C mutation. Two patients carried S500L mutation in a homozygous state. Two patients carried two mutations in each, one patient had D46N and S500L and the other patient had H233L and K322∗ in a compound heterozygous state.The activation potential of the sperm was classified in three groups according to the MOAT result; based on the percentage of mouse oocytes activated by patient sperm: MOAT1 group(0-20%), MOAT2 group(21-84%) and MOAT3 group(>85%).The patient with H233L and K322∗ mutations in a compound heterozygous state was classified in MOAT1 group and the patient with H233L mutation and R141H mutation showed normal activation potential (MOAT3 group). All the other patients were classified as MOAT2 group.

Limitations, reasons for caution:
We are now verifying further the functional effect of these mutations by making recombinant protein of these mutations and injecting them into oocytes

to evaluate its effect on activation rate, calcium pattern and embryonic developmental potential.

Wider implications of the findings:

From our study we show that most of the patient's sperm with heterozygous mutations cannot initiate oocyte activation and the frequency of PLCZ1 mutations in our patient cohort with OAF is as high as 34% and it is therefore recommended to do PLCZ1 screening for better management of OAF.

O-253 Clinical results of couples with AZFc microdeletion using testicular sperm

K. Kobayashi[1], S. Mizuta[1,2], K. Yamaguchi[2], H. Matsubayashi[1,2], K. Kotaro[2], T. Takeuchi[1], T. Ishikawa[1,2]

[1]reproduction clinic tokyo, reproductive medicine, 3F- Shiodome City center- 1-5-2-higashi shinbasi- minato- Tokyo, Japan

[2]reproduction clinic Osaka, reproductive medicine, 4-20-A15F- Ohuka-Cho- Kita-Ku-osaka, Japan

Study question:

To clarify the results of intracytoplasmic sperm injection (ICSI) using sperm of azoospermia factor (AZF) c microdeletion patients.

Summary answer:

Sperm was retrieved from 88.2% patients with AZFc microdeletion, however, fertilization rate was fairly low in ICSI using sperm from those patients.

What is known already:

Microdeletions of Y chromosome, especially in the AZF, are the most common known genetic cause involving spermatogenesis and three spermatogenesis loci in the Y chromosome long arm have been classified as AZFa, AZFb, and AZFc. Especially, AZFc microdeletion is the most commonly encountered Y microdeletion, comprising 60% of all AZF deletions type that range from oligozoospermia to complete azoospermia and patients with AZFc microdeletions have a chance to father babies through sperm extraction techniques in vitro fertilization with ICSI and there were few reports regarding ICSI outcome in the couples of AZFc microdeletion.

Study design, size, duration:

This study was retrospectively examined a total of 1222 patients underwent microdissection testicular sperm extraction (micro TESE), including 51 with AZFc microdeletion (36.1±5.1 years of age) and 649 with unexplained NOA (unexplained NOA; not including after orchidopexy, Klinefelter's syndrome, cryptozoospermia, mumps orchitis, etc) (38.4±6.1 years of age) a reproductive center from September 2013 to December 2018.

Participants/materials, setting, methods:

A total of 1077 azoospermic patients were examined genetic testing for AZF deletions by Promega Y Chromosome AZF Analysis System (version 2.0). A total of 45 patients with AZFc microdeletion who attempted ICSI cycles were studied. Outcomes were compared sperm retrieval rate (SRR), two pronuclei (2PN) oocytes, blastocysts development, good-quality blastocysts (Grade 3BB and above on day 5 by the Gardner scoring), and clinical pregnancy rate between AZFc microdeleted group and control group (unexplained NOA).

Main results and the role of chance:

We identified 111 Y chromosome microdeletions out of 1077 azoospermic patients (10.3%). Forty-five (4.2%) had AZFc deletion, and 65 of microdeletions were AZFa, AZFb, AZFb+c, or complete Yq deletions in azoospermia.

Sperm were retrieved 45 of 51 in AZFc deleted patients (88.2%) and 121 of 649 in unexplained NOA (18.6%). In first TESE cases, 87.1% were retrieved (27/31) in AZFc deleted patient similar to those of patients who previously underwent micro TESE were retrieved to 90.0% (18/20). Whilst in unexplained NOA, SRR in first TESE cases was significantly higher than patients who previously underwent micro TESE (21.2% vs. 11.4%). AZFc deleted group was significantly higher SRR than unexplained NOA ($P<0.001$) by micro TESE. As for the number of motile sperm that we injected for oocytes in ICSI, in AZFc microdeletion was 343/929 (34.9%) and unexplained NOA was 1796/2066 (86.9%) ($P<0.001$). There were significant differences for 2PN oocytes rates (41.3% vs. 53.9%), blastocyst development rates (14.8% vs. 45.1%) and good-quality blastocyst rates (9.4% vs. 18.7%) ($P<0.001$). Clinical pregnancy rates per embryo transfer cycles for AZFc deleted group (27.5%) were similar to those for unexplained NOA (29.7%). The number of healthy babies of the AZFc deleted couples was 15 so far.

Limitations, reasons for caution:

In this study we included both of cryptozoospermia and azoospermia. We did not show the data using ejaculated sperm with AZFc microdeletion. We need long-term follow-up of babies of the AZFc deleted couples.

Wider implications of the findings:

Sperm retrieval rates for the AZFc microdeleted patients were significantly higher than those of unexplained NOA patients with. However, couples with AZFc microdeletion seem to have lower ICSI outcomes than unexplained NOA.

Trial registration number:

None.

O-254 Effect of sperm processing time on reproductive outcomes after ICSI

A. Quintana-Vehi[1], M. Torra-massana[1], M. Barragan[1], D. Garcia[1], R. Vassena[1], A. Rodriguez[1]

[1]Clinica Eugin, Assisted reproduction, Barcelona, Spain

Study question:

Do sperm processing times, from obtaining the sample to fertilization, affect reproductive outcomes in ICSI cycles?

Summary answer:

Sperm processing times do not seem to affect fertilization rates (FR), pregnancy or live birth rates.

What is known already:

Sperm sample processing is necessary in IVF, but processing times differ both between and within facilities. While longer processing times are associated to increased sperm DNA fragmentation, intermediate processing times seem to be beneficial for capacitation, chromatin condensation and FR after ICSI; nevertheless, controversy on the appropriate processing time to maximize outcomes still exists. Most studies make use of manual annotation to record times, and do not report live birth rates as outcomes. We use an operator-independent radiofrequency-based time recording system and extensive statistical analysis to assess the effect of processing times on reproductive outcomes up to live birth.

Study design, size, duration:

Retrospective cohort study of 560 ICSI cycles carried out between 2012 and 2016. All cycles included patient's own fresh semen and oocytes either from partner or donor, followed by fresh embryo transfer (ET). A radiofrequency-based system was used to record sperm processing times: T1: from sample collection to swim-up; T2: swim-up to ICSI; T3: total time (T1+T2). We analyzed the effect of these times on FR, biochemical, clinical, ongoing pregnancy, and live birth (LB) rates.

Participants/materials, setting, methods:

Differences in processing times (T1, T2, and T3) between positive and negative pregnancy rates (biochemical, clinical, ongoing) and LB rates were tested by Student's t-test. The likelihood of pregnancy and LB was modeled by LOWESS regression and logistic regression, adjusting for man's and woman's age and BMI, semen parameters, number of oocytes, number and morphological score of transferred embryos, and day of ET. The effect of times on FR was modelled by generalized linear modelling.

Main results and the role of chance:

Mean male age was 42.5±7.1 years, while women were 33.15±9.65 years on average. Mean sperm concentration and motility were 45.2±72.5 million/ml and 34.1±19.7 %a+b, respectively, and semen processing times in hours were T1: 0.36±0.24 [range: 0.09-1.63], T2: 3.28±2.2 [0.23-10.7] and T3: 3.64±2.2 [0.42-11.2]. Biochemical, clinical, ongoing pregnancy and live birth rates overall were 42.1%, 32.5%, 29.5% and 29.5%, respectively. Neither T1, nor T2 or T3 were significantly different for patients who did achieved pregnancy (biochemical, clinical and ongoing) and LB compared to those who did not. LOWESS regression did not return relevant correlations between T1 and FR or reproductive outcomes, while T2 and T3 showed a slight positive tendency to higher ongoing pregnancy and LB upon time. However, multivariate analyses did not reveal a significant effect for any of the time intervals on LB rate: OR 1.003 (95%CI: 0.72-1.40) for T1, and OR 1.091 (95%CI: 0.85-1.41) for T2. The same results were found for biochemical, clinical and ongoing pregnancy. Similarly, generalized linear modelling analysis did not show a significant effect of sperm processing time on FR after ICSI ($p=0.27$ for T1, $p=0.54$ for T2).

Limitations, reasons for caution:

These results should not be extended to ICSI cycles using testicular spermatozoa or samples with severe semen parameters, such as motility <1% a+b or cryptozoospermia, which were excluded from the study.

Wider implications of the findings:

This is the first study evaluating the effect of sperm processing time on ICSI using an exact, radiofrequency-based, operator-independent system on a large cohort. Our results suggest that processing time, especially after swim-up, have undetectable effect on pregnancy and live birth rates after ICSI, within the time interval analyzed.

Trial registration number:

O-255 Evidence that testicular sperm in infertile men has improved DNA integrity compared to ejaculated sperm

J. Ramsay[1], L. Vyas[1], E. Foster[1], A. Taylor[3], J. Nicopoullos[3], R. Faris[3], S. Minhas[1], S. Lewis[2]

[1]*Imperial Healthcare Trust, Andrology, London, United Kingdom*
[2]*Examen, Examen, Belfast, United Kingdom*
[3]*Lister Hospital, Fertility clinic, London, United Kingdom*

Study question:

Is there any difference in DNA integrity between testicular sperm and epididymal sperm, compared with fertile donors

Summary answer:

This data provides novel and compelling evidence that testicular sperm from infertile men has no significant difference in comet score compared to fertile donors.

What is known already:

The prevalence of high DNA fragmentation occurs in male partners of unexplained infertile couples. DNA fragmentation in sperm can increase the risk of miscarriage and IVF/ICSI outcomes. There are multi-factorial causes of DNA damage and Comet is a gel electrophoresis test used to measure DNA fragmentation. It can be conducted in an alkaline or neutral solution and gives a percentage for DNA fragmentation.

Study design, size, duration:

Sperm DNA fragmentation was measured by alkaline Comet assay to assess double plus single stranded breaks and neutral Comet assay to determine double stranded breaks only. Main outcome measures included comparison of single stranded break (SSB) and both double stranded breaks (DSB) and SSB, in ejaculates and with testicular sperm. Average Comet scores, Low Comet scores and High Comet scores were determined. Comparisons made for ejaculated and testicular sperm from infertile men and fertile donors.

Participants/materials, setting, methods:

59 men with persistently raised DNA fragmentation from couples who had failed cycles of intracytoplasmic sperm injection (ICSI) with ejaculated sperm underwent testicular sperm extraction. Results were also compared with 76 fertile donors. In 10 infertile men ejaculate comparison was made between single stranded DNA abnormalities compared to single and double stranded abnormalities

Main results and the role of chance:

For total DNA damage ejaculate Average Comet scores (ACS) (%) from infertile men was 39.9+/- 1.3 versus 17.9+/-1.3 in testicular sperm and 14.8+/- 0.6 from ejaculates from fertile donors[sm1] .

Ejaculate Low Comet scores (LCS) (%) from infertile men was 34.7+/- 2.7 versus 77.3+/-2.4 from testicular sperm and 90.2+/- 1.0 from ejaculates from fertile donors.

Ejaculate High Comet scores (HCS) (%) from infertile men was 29.1+/-2.9 v 8.8+/-1.8 from testicular sperm and 1.9+/-0.4 from ejaculates of fertile (P<0.01) donors.

Comparison of infertile ejaculate with fertile ejaculate was significant for all 3 groups of scores (P<0.001).

The comparison of SSB only v SSB plus DSB in testicular sperm sdemonstrated ACS (%) 10.6+/-1.2 v 14.7+/-0.9; LSC (%) 91.3+/- 2.0 v 92.2+/-1.4; HSC (%) 4.4+/-1.2 v 1.89+/-0.5 (P>0.05).

The total sperm DNA damage in testicular sperm from infertile men is not significantly different from ejaculated sperm from fertile donors (P=0.08). However, DSB made up most DNA damage in testicular sperm and only half of the damage observed in ejaculated sperm.

Limitations, reasons for caution:

To understand the clinical utility of the test.

Wider implications of the findings:

This data provides novel and compelling evidence that testicular sperm from infertile men have the same high DNA quality as ejaculated sperm from fertile donors. DNA damage in testicular sperm is all double stranded compared to only half of DNA damage in ejaculated sperm in a subgroup.

[3]*University of Zagreb, Department of Obstetrics and Gynaecology, Zagreb, Croatia*
[4]*Clínica Alemana, Centre for Reproductive Medicine Santiago, Santiago, Chile*
[5]*IVI - Lisboa, Instituto valenciano de infertilidad, Lisboa, Portugal*

Study question:

Does reproductive outcome differ among the various types of women with poor ovarian response (POR) meeting the Bologna criteria?

Summary answer:

Live birth rates (LBR) and cumulative LBR differ significantly among Bologna POR patients

What is known already:

In 2011, the European Society of Human Reproduction and Embryology (ESHRE) elaborated on the definition of women with inadequate response to ovarian stimulation. This consensus definition—known as the Bologna criteria—was initially introduced with the primary objective of standardising the definition of POR. However, the Bologna criteria may have merged various patient categories with potentially different prognosis. Evidence regarding the reproductive outcome of different categories of patients is sparse.

Study design, size, duration:

This was a retrospective cohort analysis carried out at a university based tertiary centre aiming to evaluate cumulative LBR in different categories of Bologna POR. All Bologna POR patients who underwent ovarian stimulation for ART using a GnRH-antagonist protocol from 1st January 2011 until 31th December 2017 were included in the study.

Participants/materials, setting, methods:

Women were divided in four categories according to their Bologna criteria pattern: group A women ≥ 40 years with an abnormal ovarian reserve test; group B women ≥ 40 years with an abnormal ovarian reserve markers and one previous cycle with poor response; women in group C were ≥ 40 years and had one previous cycle with poor response; group D patients with an abnormal ovarian reserve test and one previous cycle with poor response.

Main results and the role of chance:

In total 846 cycles in 706 Bologna POR patients were included in the analysis: 310 cycles in group A, 169 in group B, 52 in group C and 315 in group D. There were significant differences in female age, antral follicle count, antimüllerian hormone, cycle cancellation rates and number of retrieved oocytes between the four groups. LBR and cumulative LBR differed significantly between groups and were highest in Group D (LBR: 7.4% (A) vs. 4.1% (B) vs. 5.8% (C) vs. 13.4% (D),

p =0.001 and CLBR: 8.3% (A) vs. 4.1 % (B) vs. 9.6% (C) vs. 16.8% (D) p<0.001). In particular, the p values for the unadjusted cumulative LBR between groups were as followed: Group B vs A (p=0.15), Group C vs A (p=0.9), Group D vs A (p<0.001), Group C vs B (p=0.2), Group D vs B (< 0.001), Group D vs C (p=0.08). A multivariate regression model accounting for relevant confounders demonstrated that the Bologna criteria pattern was an independent predictor of cumulative LBR (coefficients Group (A): reference group, Group (B): -0.6, Group(C): 0.05, Group (D): 0.8, p value <0.001). The number of oocytes retrieved was also significantly associated with cumulative LBR.

Limitations, reasons for caution:

The retrospective study design should be taken into consideration when interpreting these results.

Wider implications of the findings:

POR represent a heterogeneous population with distinct clinical prognosis. This is the first study evaluating cumulative LBR in the different Bologna criteria patterns.

Trial registration number:

O-257 The differences on the cumulative live-birth rates in poor ovarian responders using mild and controlled ovarian stimulation protocols:a randomized controlled study

X.P. Liu[1], B. Wang[1], T.T. Li[1], R. Huang[1]

[1]*Reproductive Medicine Center, 6th Affiliated Hospital-Sun Yat-sen University, Guangzhou, China*

Study question:

What is the difference on the cumulative live birth rate between mild ovarian stimulation and conventional controlled ovarian stimulation for poor ovarian responders?

Summary answer:

There were similar cumulative live birth rates between mild ovarian stimulation and conventional controlled ovarian stimulation for poor ovarian responders.

What is known already:

In in vitro fertilization (IVF) treatment a considerable proportion of women responsed poorly during conventional ovarian stimulation, facing with a low number of retrieved oocytes and available embryos for transfer. These poor responders have reduced pregnancy rates compared with normal responders. Poor ovarian response (POR) to controlled ovarian stimulation (COS) occurs in 9%–24% of women undergoing IVF. Treatment of this common condition remains a major challenge in assisted reproduction technology (ART). A number of studies have sought to determine the ideal protocol for women identified as poor responders, but most have failed to reach definitive conclusions.

Study design, size, duration:

A randomized, controlled, prospective study,conducted from September 2013 to September 2015 at the Reproductive Medicine Research Center, The Sixth Affiliated Hospital of Sun Yat-Sen University, Guangzhou, China.

Participants/materials, setting, methods:

One hundred and ninety-one patients who met the Bologna criteria of poor ovarian response were recruited in this study.

All women were prospectively randomized into two groups according to random number table. The patients in LA group were stimulated according to the letrozole/antagonist protocol (n=97), while the patients in HGS group were stimulated according to a high dose of Gn combined with GnRH agonist stop protocol (n=94).

Main results and the role of chance:

Demographic parameters including mean age, duration of infertility, body mass index (BMI), serum AMH, AFC and basal FSH level were similar between two groups before the initiation of stimulation protocols.Comparing with HGS group, both the stimulation duration and the total gonadotropin dose was significantly lower in the LA group (6.33±1.80 vs. 10.81±2.38 day, 939.43±264.52 vs. 3117.82±749.56 U, respectively; *P*<0.001). Likewise, the serum E_2 level at trigger was statistically different between two groups (563.69±465.06 vs. 1195.10±701.45 pg/mL, respectively; *P*<0.001). No significant difference was found between the two groups in the serum LH and P levels on the trigger day.A higher number of retrieved oocytes (2.77±1.89 vs. 4.01±2.81; *P*<0.001), number of 2 pronuclei (2PN) oocytes (1.74±1.52 vs. 2.53±2.01; *P*<0.001) and transferred embryos (1.50±1.41 vs. 1.97±1.61; *P*=0.038) was observed in the HGS group. While no statistically significant differences were noted with respect to the percentage of fertilized oocytes or the number of good-quality embryos.The cumulative live birth rate after one complete ART cycle including fresh and subsequent frozen-thawed cycles per allocated woman were similar in the LA and HGS group 19/97 (19.59%) and 17/94 (18.09%), respectively (*P*=0.791).

Limitations, reasons for caution:

The study has a smaller simple size.It was not powerful enough to detect the significant differences.

Wider implications of the findings:

Mild stimulation treatment can be a valid alternative to PORs instead of conventional controlled ovarian stimulation by using high dose of gonadotropins.

Trial registration number:

ChiCTR-TRC-13003454

O-258 The use of autologous platelet-rich plasma (PRP) versus antioxidants in women with low ovarian reserve undergoing assisted reproductive technology (ART): a comparative controlled pilot study.

P. Melo[1], C. Navarro[2], C. Jones[1], K. Coward[1], L. Coleman[2]

[1]*Nuffield Department of Women's & Reproductive Health, University of Oxford, Oxford, United Kingdom*

[2]*Assisted Reproduction, Fertiaguerrevere Fertility Clinic, Caracas, Venezuela*

Study question:

Is PRP an effective treatment for low ovarian reserve in infertile women prior to undergoing ART?

Summary answer:

A 3-month course of intracortical ovarian injections of PRP significantly improves ovarian reserve and subsequent reproductive outcomes in infertile women.

What is known already:

Female age remains the principal limiting factor of reproductive success due to an inevitable loss of ovarian reserve as women become older. Antioxidant supplements are thought to delay ovarian senescence, although meta-analyses have not confirmed their effectiveness. PRP, a blood derivative containing platelets in much higher concentrations than circulating serum, is effective in treating nerve and muscle injuries, however there is a paucity of data regarding the regenerative properties of PRP in reproductive medicine. While encouraging results have been reported from *in vitro* and animal experiments, there are no controlled studies evaluating the impact of PRP on human ovarian reserve.

Study design, size, duration:

Prospective three-arm comparative study conducted in a private clinic between February 2015 and February 2018. Strict inclusion criteria (age≥38; FSH>12 mIU; estradiol<100 pg/mL; AMH<0.8 ng/mL; normal hysteroscopy) and exclusion criteria (previous pelvic inflammatory disease; known hyperandrogenism; tubal or male-factor infertility) were applied. A total of 115 women were allocated to one of the following groups for 3 months according to patient choice: monthly ovarian PRP injections (n=46); daily oral antioxidants (n=32); or no intervention (n=37).

Participants/materials, setting, methods:

Written consent was obtained from all participants. In all three arms of the study, day-3 baseline ovarian reserve was quantified with FSH, AMH, estradiol and antral follicle count (AFC) in cycle 1. Repeat day-3 ovarian reserve measurements were recorded 3 months later as primary outcomes. Details of subsequent ART treatment (timed intercourse, IUI or IVF/ICSI) were documented. Secondary outcomes included number of oocytes collected and fertilised; biochemical/clinical/ongoing pregnancy rates; and miscarriage and live birth rates.

Main results and the role of chance:

Mean age was 41.2±2.6 (*P*=0.88). Demographic characteristics and baseline ovarian reserve markers were similar between the 3 arms. At the 3-month follow-up, women treated with PRP had the largest improvement in ovarian reserve: AMH rose by 86% (versus a 15% increase in the antioxidant group and no change in the controls,*P*<0.001); FSH dropped by 39% (versus a 9% reduction in the antioxidant group and no change in the control arm,*P*<0.001);

circulating estradiol increased by 67% (versus no change in the antioxidant and control groups,$P<0.001$); and there were on average 86% more antral follicles on ultrasound, compared to an 18% increase in the antioxidant group and a 7% reduction in the controls ($P<0.001$). Among women who underwent IVF/ICSI following participation in the study (n=55), those previously treated with PRP yielded more than double the oocyte number of controls (5.2±1.9 versus 2.2±1.9 respectively, mean±SD,$P<0.001$), although fertilisation rates were similar between groups ($P=0.46$). Women conceiving with timed intercourse/IUI were more likely to achieve biochemical and clinical pregnancy following PRP (OR 1.26, 95% confidence interval [CI] 1.03-1.55), but not those who conceived with IVF/ICSI (OR 3.73, 95% CI 0.67-20.9) Rates of miscarriage ($P=0.16$) and live birth ($P=0.64$) were similar across the 3 study arms.

Limitations, reasons for caution:

The main limitation of this study was the lack of randomisation. However, in the absence of previous data attesting the safety of PRP injection into human ovaries, voluntary enrolment into one of the 3 groups was deemed appropriate. Randomised controlled studies would be required to corroborate our results.

Wider implications of the findings:

This is the first controlled study attesting the efficacy of PRP injections in inducing a resurgence of ovarian activity. Further research is required to investigate whether the increase in estradiol following PRP is sustained, and the potential cardiovascular and bone health benefits of PRP in women with premature ovarian insufficiency.

Trial registration number:

Ethical approval was granted by a local Institutional Review Board (IRB) and the Venezuelan Health Ministry (IRB reference number #0940).

O-259 Effectiveness of recombinant-LH supplementation (LHS) on reducing pregnancy loss (PL) for poor ovarian responders (POR) in IVF/ICSI cycles.

P. Arvis[1], N. Massin[2], P. Lehert[3]

[1]*Clinique La Sagesse, AMP, RENNES, France*
[2]*Centre Hospitalier Inter-communal Créteil, Amp, Creteil, France*
[3]*Faculty of Medicine, - the University of Melbourne, Melbourne, Australia*

Study question:

Our objective was to assess the effectiveness of LHS on pregnancy loss for POR, based on a large controlled study in a real world context.

Summary answer:

r-LH supplementation to rFSH (LHS) has a highly significant beneficial effect in reducing pregnancy loss among POR, positively correlated with the severity of POR.

What is known already:

PL is known to generate emotional burden for women, especially when pregnancy is attempted through ART. The detrimental effects of miscarriage are reported to endure a complex course of resolution. Moderate-quality evidence suggests little or no LHS benefit in rates of pregnancy loss (PL) during controlled ovarian stimulation (COS) for normo-responders. As to whether this benefit is limited to POR remains controversial. PL may be affected by the type (fresh/frozen) of the embryo transfer, baseline conditions and PL incidence during previous cycles undertaken by the patient. On the other hand, PL is suspected as varying among centers.

Study design, size, duration:

This non-interventional retrospective national multicentre controlled study compared rFSH+rLH to rFSH alone administered during COS, in POR patients defined by ESHRE Bologna criteria. We[P1] used an exhaustive registry collected from 12 IVF French centres during 2007–2016 period. Out of a total of 113,253 cycles, 11571 were found in POR associated with r-FSH or LHS treatment. Out of them a gestational[P2] sac was found for 2120 cycles (1112 r-FSH,1008 LHS).

Participants/materials, setting, methods:

The primary endpoint was the PL from all fresh/thawed embryos. The statistical model was a full factorial design of treatment by baseline severity, random factors being patient nested into site, and matched-subclass constructed from a ranked propensity score. Baseline severity was defined following the PROSPER score (mild, moderate and severe POR groups predicting PL). A non linear mixed model featuring logistic regression was used for PL

Main results and the role of chance:

The overall PL rate was 26.9%. the population of reference were cycles with fresh embryos, without previous PL observed in previous cycles, mild Prosper baseline score and treated with r=FSH Alone for which a PL rate of 24.2% ([19.5%,32.1%]) was found. However, this value was strongly varying among centres with a credibility interval of [21%,28.2%]. The PL rate was impacted by several baseline covariates: Higher PL for frozen embryos compared with fresh (OR=1.52 [1.15,2.03],p=.003), PL occurrence during previous cycle (OR=1.91, [1.53, 2.37, p<.001), and Prosper Score (OR=1.29/point [1.09,1.52],p=.002). Moreover, an important center effect was observed In adjusting for these covariates, a highly significant benefit was found for LHS compared with r-FSH alone (OR=66, [.52,.84],>p=.001)

Limitations, reasons for caution:

Potential biases might still exist due to non randomized treatment attribution selection, in spite of correction through propensity score and statistical adjustment.

Wider implications of the findings:

Whereas LHS appears to improve cumulative live-birth rate only for the most severe POR, LHS has a beneficial effect on reducing PL in the whole range of POR. As LHS has no effect on the oocytes yield, these findings suggest a beneficial effect of LHS on oocyte quality for POR.

Trial registration number:

None

O-260 Subcutaneous progesterone (25mg twice daily) for endometrial preparation in substituted cycles for oocyte donation: an International, multicenter, pilot study to correct a probable dose mistake

G. Zito[1], R. Viñoles[2], A. Forgiarini[2], G. Lammens[2], G. Ricci[3], E. Giolo[1], M. Martinelli[1], F. Naranjo[2], L.A. Quintero Espinel[2]

[1]*Institute for Maternal and Child Health- IRCCS Burlo Garofolo, SC Fisiopatologia della Riproduzione e PMA, Trieste, Italy*
[2]*Instituto de Medicina Reproductiva IMER-NextClinics, Assisted Reproductrion, Valencia, Spain*
[3]*Institute for Maternal and Child Health- IRCCS Burlo Garofolo, Department of Medical- Surgical- and Health Sciences- University of Trieste, Trieste, Italy*

Study question:

Are there outcomes differences, between subcutaneous progesterone (SP), using twice the recommended dose and micronized vaginal progesterone (MVP) in embryo transfer cycles to oocyte recipients?

Summary answer:

In the subcutaneous progesterone group, significant differences were observed in terms of higher ongoing pregnancy rate at 12 weeks of gestation and lower miscarriage rate.

What is known already:

The dose recommended by the manufacturer / official supplier of the aqueous subcutaneous progesterone is 25 mg per day.

A previous randomized, controlled trial, found no significant difference in ongoing pregnancy rate between the use of SP at the usual recommended dose (25 mg daily) and MVP (200 mg tid daily). However, a higher percentage of biochemical abortion was observed in the group of patients in whom 25 mg per day of SP was used.

To date, clinical outcomes using SP at double the recommended dose (25 mg x 2 daily) has not been assessed.

Study design, size, duration:

International, multicenter, prospective, pilot study. During one year, 149 oocyte recipients were included in the study to receive 25 mg twice daily SP (n=67) or 200 mg three times daily MVP (n=82).

Participants/materials, setting, methods:

The patients had medical and legal criteria to be included in an oocyte donation program. All followed standard treatment of endometrial preparation with oral estradiol valerate.

The oocytes used were frozen / thawed and in all cases fresh blastocysts were transferred.

Progesterone administration, in both groups, started on the day of thawing / ICSI of the oocytes.

The quantitative variables were assessed by t-test and anova test; Fisher test were used for qualitative variables.

Main results and the role of chance:

The mean age and BMI of the patients included in both groups was similar (SP group: 41.5 years & 24.1 Kg/m2; MVP group: 41,02 years & 23.6 Kg/m2). The treatment days of the endometrial preparation were also similar in both groups (15.9 and 16.2 days, respectively).

The mean of blastocysts transferred in both groups was similar (SP: 1.4 & MVP: 1.5). However, the implantation rate was significantly higher in the SP group (55.2%) than in the MVP group (35.2%).

We found a significantly higher ongoing pregnancy rate in the SP group (67,2%) than the MVP group (46,3%). The miscarriage rate in the SP group was 5,9% and in the MVP group it was 18,4% (p<0,005).

Limitations, reasons for caution:

As this is a pilot study, the limitations of this format should be taken into account ie. sample size, RCT design, etc. . .

Wider implications of the findings:

Despite our data show that the administration of 25 mg twice daily of subcutaneous progesterone results in higher implantation and pregnancy rates and lower rate of miscarriage, caution must be exercised in interpreting these promising results. Additional studies are needed to demonstrate its utility in substituted cycles.

Trial registration number:

not applicable

O-261 Is more always better? Female age modifies the oocyte number where maximal cumulative live birth rate per aspiration is observed: an analysis of 221,221 cycles

Y.J. Law[1], N. Zhang[1], C. Venetis[1], G. Chambers[1], K. Harris[1]

[1]University of New South Wales, Centre for Big Data Research in Health, Sydney, Australia

Study question:

Is the oocyte number where maximal cumulative live birth rate per aspiration (CLBA) is observed during assisted reproductive technology (ART) different based on female age?

Summary answer:

Maximal CLBAs were observed at ~25 oocytes in women aged 18-35, >30 oocytes in women aged 36-44, and ~9 oocytes in women aged ≥45.

What is known already:

Live birth rate per fresh or frozen/thaw embryo transfer (FET) has traditionally been the primary measure of ART success. However, with the introduction of highly efficient embryo cryopreservation methods, CLBA encompassing live delivery outcomes from the fresh and all subsequent FET following a single ovarian stimulation and oocyte collection is increasingly viewed as a more meaningful measure of treatment success. There is growing evidence suggesting that larger oocyte yields are associated with higher CLBA. Whether this association is uniform across female ages has not yet been properly explored and warrants further investigation.

Study design, size, duration:

This is a large retrospective population-based cohort study using data from the Australian and New Zealand Assisted Reproduction Database (ANZARD). Overall, 116,677 women undergoing 221,221 autologous oocyte aspiration cycles between January 2009 to December 2015 were included in the analysis. All fresh and FET resulting from the associated aspiration cycle were included in the analysis until one live birth occurred or all embryos were used. Cycles where no oocytes were retrieved were excluded from analysis.

Participants/materials, setting, methods:

CLBA was defined as at least one liveborn baby at ≥20 weeks gestation resulting from an ART aspiration cycle. Generalised estimating equations were used to account for the clustered nature of data. Univariate and multivariable regression analysis was performed to identify and adjust for factors known to independently affect CLBA. An interaction term between female age and the number of oocytes retrieved was introduced to assess the effect-modifying role of female age.

Main results and the role of chance:

The number of oocytes retrieved remained a significant predictor (P<0.001) of CLBA after adjusting for female age, parity and cycle count. Compared to the reference group of 10-14 oocytes retrieved, the adjusted odds of achieving a live birth (i.e. CLBA) increased with the number of oocytes retrieved:

With 1-3, 4-9, 15-19, 20-24 and ≥25 oocytes, the adjusted odds are 0.21 (95% CI: 0.20-0.22), 0.56 (95% CI: 0.55-0.58), 1.38 (95% CI: 1.34-1.43), 1.75 (95% CI: 1.67-1.84) and 2.10 (95% CI: 1.96-2.25) respectively.

The CLBA for women aged <30 and 30-34 years appeared to reach a plateau at 73% after retrieval of 25 oocytes. The CLBA of women aged 35-39 and 40-44 years continued to increase with higher oocyte yields, reaching 68% and 40% respectively when 30 or more oocytes were retrieved. The CLBA of women aged >45 peaked at around 9 oocytes, remaining consistently below 5%. Trends in CLBAs and oocyte numbers differ by age, with the rate of increase in CLBA per additional oocyte retrieved being lower in older age groups.

Limitations, reasons for caution:

Despite this study being in complete ascertainment of ART cycles across two countries, ovarian stimulation protocols and oocyte quality parameters were not collected by ANZARD and could not be adjusted for. It cannot be excluded that the observed association may be due to the inherent characteristics of the population examined.

Wider implications of the findings:

This study demonstrates that female age modifies the number of oocytes retrieved where maximal CLBAs are observed. Younger women require fewer oocytes to achieve maximal CLBA. Furthermore, there is limited benefit in stronger ovarian stimulation protocols to retrieve more oocytes in older women as maximal CLBA decreases with advancing age.

Trial registration number:

O-262 the cycle scheduling impacts the cytokine profile in cervical mucus: oral contraceptive pills (OCP) for 14 days vs. pretreatment with estrogen in luteal phase

B. Martazanova[1], N. Mishieva[2], M. Martynova[2], V. Vtorushina[2], L. Krechetova[2], A. Abubakirov[2]

[1]Kulakov-s National Medical Research Centre of Obstetrics- Gynaecology and Perinatology of the Russian Ministry of Healthcare, Department Of Preservation And Restoration Of Reproductive Function, Moscow, Russia C.I.S.

[2]Kulakovs National Medical Research Centre of Obstetrics- Gynecology and Perinatology, Department of Preservation and Restoration of Reproductive Function, Moscow, Russia C.I.S.

Study question:

Does the cycle scheduling affect the cytokine profile in cervical mucus and impact pregnancy rate in fresh GnRH antagonist cycles?

Summary answer:

OCP is associated with depression of VEGF, FGF basic, IL-6, LIF, IL-17A, IL-12p70, GM-CSF levels in cervical mucus and lower pregnancy rates in fresh cycle.

What is known already:

According to Cochran database the OCP pretreatment is associated with a lower ongoing pregnancy rate than no pretreatment; however the pathogenesis of this is still unknown. Also controversy exists around estrogen pretreatment: some studies show that estrogen priming improves the implantation rate. According to other data, estrogen does not impact cycle outcome. Uterine secretomics was used for a non-invasive analysis of the in-vivo milieu encountered by the embryo; previous studies showed that soluble regulators of implantation could be detected in cervical mucus. However, there is limited data about cervical mucus cytokine profile and IVF treatment success after cycle priming.

Study design, size, duration:

This prospective randomized study included 94 normal responder patients. Group 1 (n=31) received OCP (2 mg cyproterone + 0.035 mg ethinylestradiol/day) for 14 days, and stimulation was started on day 5 after discontinuing the OCP. Group 2 (n=30) received 4 mg/day oral estradiol valerate from day 25 for 5-10 days, stimulation was started next day after estrogen stopping. Group 3 (n=33) did not receive pretreatment, stimulation was started on day 2-3 of the cycle.

Participants/materials, setting, methods:

Inclusion criteria: age <35 years; basal FSH<12 IU/ml; regular cycle, AMH 1.0-3.5 ng/ml. Exclusion criteria: uterine fibroids, deep endometriosis, severe male infertility, PCOS; reduce ovarian reserve, bacterial vaginosis.

Concentrations of 29 key regulatory cytokines, chemokines and growth factors were measured with immunofermental assay. Cervical mucus samples were collected via velvet endocervical flocked swab («Copan», Italy) after cervix was cleansed on oocyte pick up day (OPU), on OPU+3 and ET days.

Main results and the role of chance:

Concentrations of 2 an angiogenic factors (VEGF, FGF basic), 4 proinflammatory cytokins (IL-6, LIF, IL-17A, IL-12p70) and 1 growth factor (GM-CSF) showed significant changes after cycle scheduling: *VEGF* (223.15±188.34 vs. 1032.39±245.23 pg/ml, *p*=0.019), *IL-12p70* (32.1±25.5 vs. 143.98±37.0 pg/ml, *p*=0.024), *FGF basic* (6.3±0.7 vs. 34.7±12.5 pg/ml, *p*=0.046), GM-CSF (146.28±139.14 vs.653.13±156.30, *p*=0.027), and *IL-17A* (25.9±11.7 vs. 63.9±25.2, *p*=0.044) levels were significantly lower in group I compared to group III on OPU day. Concentrations of *VEGF* (383.09±212.97 vs. 1839.71±271.49, *p*=0.031), *IL-12p70* (55.7±25.9 vs. 250.94±74.0, *p*=0.028), *LIF* (13.6±3.3 vs. 41.8±4.6, *p*=0.023), and *IL-6* (740.11±229.97 vs.1271.66±29, *p*=0.048) were significantly lower on ET day in group I compared to group III. *FGF basic* (6.3±0.7 vs. 33.5±14.7, *p*=0.017) *and IL-17A* (25.9±11.7 vs. 87.6±33.6, *p=0.045*) on OPU day, plus *IL-6* (740.11±229.97 vs. 1605.75±225, *p*=0.012) levels on ET day were lower in group I compared to group II. Embryological characteristics were similar in all groups. Pregnancy rate per ET were comparable between groups (35.5% (11/31) vs. 50.0% (15/30) vs. 51.5% (17/33) in group I, II and III, respectively). However, ongoing pregnancy rate were significantly lower in group I compared to other groups (19.4% (6/31) vs. 46.7% (14/30) vs. 48.5% (16/33) in group I, II and III, respectively, *p***=0.04, *p****=0.036).

Limitations, reasons for caution:

Our study was carried out in a relatively small subset of patients; therefore, obtained results cannot be extrapolated on other groups of patients and need to be confirmed in larger trials.

Wider implications of the findings:

The study was funded by an internal grant from the Kulakovs National Medical Research Centre of Obstetrics, Gynaecology and Perinatology of the Russian Ministry of Healthcare.

Wednesday 26 June 2019 Strauss 1+2 10:00 - 11:45

O-263 To analyze the incidence of ectopic pregnancy in fresh embryo transfer compared with frozen-thawed embryo cycles in a tertiary infertility centre in India.

K.D. Nayar[1], S. Gupta[1], M. Singh[1], M. Gupta[1], R. Gahlot[1], G. Kant[1], A.J.S. Gulati[1], D. Nayar[1]

[1]Akanksha IVF Centre - Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question:

Is there is a difference in rate of ectopic pregnancy in assisted reproductive technology(ART) cycles in fresh or frozen-thawed embryo transfer?

Summary answer:

The incidence of ectopic pregnancy is greatly reduced in frozen thawed embryo transfer when compared to fresh embryo transfer cycles.

What is known already:

In vitro fertilization–embryo transfer (IVF-ET) is one of the major risk factors for an ectopic pregnancy (EP). Some authors believe that it might be due to increased incidence of tubal disease in such patients or stimulation of uterine contractions at the time of transfer or dysfunction of uterine musculature due to disturbed hormonal status. Recent research has suggested that frozen-thawed ET (FET) is associated with a greatly reduced incidence of EP compared with fresh transfers. This study was undertaken to evaluate the incidence of ectopic pregnancies in fresh and frozen embryo transfer at a tertiary fertility centre in India.

Study design, size, duration:

A prospective cohort study was carried out between 1st January 2016 to 31st December 2018.

Participants/materials, setting, methods:

A total of 671 fresh cycles and 767 frozen thawed ET cycles occurred during the duration of the study. Main outcomes measured were incidence of Ectopic pregnancy with fresh IVF-ET compared with frozen-thawed ET cycles, clinical pregnancy rate, and rate of ectopic pregnancy per embryo transfer.

Main results and the role of chance:

For the 671 fresh IVF-ET cycles, 286 patients had clinical pregnancies and 20 patients had ectopic pregnancy and out of 767 FET cycles, 375 patients had clinical pregnancy and 10 patients had ectopic pregnancy. The clinical pregnancy rate in fresh IVF –ET cycles was 42.62% and in FET cycles was 48.89%, which was statistically significant(p= 0.02). The incidence of an ectopic pregnancy per embryo transfer was 2.23% (20/671) for the fresh group and 1.04% (10/767) for the FET group ; the difference was statistically significant (p=0.042). Majority of patients with ectopic pregnancies had tubal factor as a cause of infertility, Fresh ET group 55% and frozen ET group 60%. There was a statistical significant difference in ectopic pregnancy rate in fresh vs. FET cycle when day 3 embryos were transferred (13 vs. 5; p= 0.05) but the difference was not significant when day 5 embryos were transferred in the fresh and FET groups (7 vs. 5; p=0.60).

Limitations, reasons for caution:

The study was a prospective cohort study at a single centre, larger prospective trials with an increased number of patients are needed to confirm our findings.

Wider implications of the findings:

Frozen thawed ET is associated with significantly lower rates of ectopic pregnancy compared with fresh cycles. These findings suggest that increased chance of ectopic pregnancy is due to disturbed hormonal milieu of ovarian stimulation. Freeze all strategy followed by FET would decrease the incidence of ectopic pregnancies in ART.

[2]Osaka Electro-Communication University, Graduate School of Biomedical Engineering, Shijyo-nawate, Japan

[3]Taniguchi Hospital, Department of Obstetrics and Gynecology, Izumisano, Japan

[4]University of Manchester, Maternal and Fetal Health Research Centre- Division of Developmental Biology and Medicine- School of Medical Sciences- Faculty of Biology-Medicine and Health, Manchester, United Kingdom

[5]Manchester Academic Health Sciences Centre, Maternal and Fetal Health Research Centre- St. Mary's Hospital- Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom

Study question:

Can the measurement of in-vivo intrauterine pH and/or oxidation-reduction potential (ORP) determine the alterations of uterine endometrium for implantation and evaluate prospective uterine receptivity?

Summary answer:

In-vivo intrauterine ORP, but not pH, can detect the alteration of uterine endometrium for implantation and evaluate prospective uterine receptivity electrophysiologically in mouse and human.

What is known already:

Uterine receptivity is associated with various glycosylation changes that affect negative charge density at the luminal epithelial cell surface.

Study design, size, duration:

To prove our basic concept, we assessed in-vivo intrauterine pH and ORP during the early stages of pregnancy in naïve mice, as well as in an implantation failure model mice (n = 21). Then, to investigate whether in-vivo intrauterine ORP could be used to predict pregnancy in women, a prospective cohort study was conducted for patients, undergoing ART treatment (n = 52).

Participants/materials, setting, methods:

The implantation failure model mice were prepared by local and transient suppression of Stat3 in the uterus. The patients who had received a frozen-thawed single embryo transfer in a programmed, hormonally controlled cycle were enrolled in this study. The in-vivo intrauterine ORP was measured 3 times during the treatment cycle, at cycle days 9-10 (time [T] 1), 1 day before progesterone administration (T2) and immediately before the embryo transfer (T3).

Main results and the role of chance:

Sulfation and sialylation changes were observed in the luminal epithelial glycocalyx. There was no change in the in-vivo intrauterine pH between post-coitus Days 2 and 6, while ORP was significantly higher compared to the day before (during early stage of pregnancy in the naïve mouse). One day before implantation began, intrauterine ORP was significantly decreased in the implantation failure model mice compared with the naïve ($P < 0.001$, Student's t-test) and control ($P < 0.001$, Student's t-test) mice. In women there was no significant difference in age and BMI between the pregnant and non-pregnant groups. The intrauterine ORP values at T1 were significantly lower in the pregnant group than in the non-pregnant group ($P < 0.001$, Student's t-test). Receiver operator characteristic (ROC) curve analysis of intrauterine ORP as a predictor of non-conception showed an area under the ROC curve of 0.96 (95% confidence interval 0.92–1.00) in the mouse study and 0.80 (95% CI: 0.61-1.00) in the human clinical study.

Limitations, reasons for caution:

Embryo biopsy for preimplantation genetic testing for aneuploidies could not be performed in this study due to the policies of the Institutional Ethics Committee.

Wider implications of the findings:

The measurement of intrauterine ORP may help to prospectively evaluate uterine receptivity in women. This includes the measurement of intrauterine ORP as part of a frozen–thawed embryo transfer strategy may improve the efficiency of ART.

O-265 Endometrial microbiota and pregnancy outcome of IVF patients in Japan: an analysis using species level resolution 16S rRNA gene amplicon sequencing

K. Kyono[1], T. Hashimoto [1], N. Okuyama[1] , Y. Nagai[2] , Y. Sakuraba[2]

[1]*Kyono ART Clinic Takanawa, Dept. of Ob/Gyn, Tokyo, Japan*

[2]*Varinos Inc.-, Provide services of next-generation genomic testings, Tokyo, Japan*

Study question:

What kind of species comprised of the endometrial communities detected in the endometrium of IVF patients who achieved successful ongoing-pregnancy or miscarriage?

Summary answer:

Lactobacillus iners-dominated and L. *crispatus*-dominated groups accounted for one-third of the delivered/ongoing-pregnant cases. Nearly half of the miscarried cases showed L. *crispatus*-dominated endometrium.

What is known already:

Recent reports have suggested that human uterine microbiota are related to implantation success, and that non-*Lactobacillus*-dominated microbiota was associated with adverse pregnancy rates [Moreno et al. 2016]. Also, in our previous study, pregnancy rate of IVF was higher in patients with ≧80% *Lactobacillus*-dominated endometrial microbiota compared to that with < 80% *Lactobacillus* [Kyono et al. 2018]. Although specific species in vaginal microbiota are reported to be related to infertility [Campiscinano et al. 2017] and preterm birth [DiGiulio et al. 2015], there are no studies relating the composition of endometrial microbiomes at the species level to miscarriage.

Study design, size, duration:

This is a retrospective, non-comparative single-center study carried out from August 2017 to June 2018. 117 IVF patients had their endometrial bacterial status (genus level) examined from August 2017 to March 2018. 56 patients achieved pregnancy (53 by single frozen-thawed blastocyst transfer, 3 by natural conception) by the end of June 2018, and for those 56 cases, bacterial status at the species level was analyzed by remnant samples. Last follow-up was January 2019.

Participants/materials, setting, methods:

Endometrial fluid samples were collected using an IUI catheter. The species-level bacterial profiles were analyzed using next-generation sequencing technologies. The V1-V2 region of 16s rRNA gene was amplified and sequenced by MiSeq platform, and data was analyzed by inhouse QIIME using SILVA and V1-V3 16S rRNA reference database for vaginal microbiome. Clinical pregnancy was defined as confirmed gestational sac in the uterine cavity. Ongoing pregnancy was defined as the pregnancy having completed ≥20 weeks gestation.

Main results and the role of chance:

Of the 56 patients who achieved pregnancy by the end of June 2018, the sample quality was sufficient for endometrial species composition analysis in 49 patients (47 by single frozen-thawed blastocyst transfer, 2 by natural conception). Of the 49 pregnancies, 28 delivered, 10 were ongoing, and 11 miscarried, as of January 2019. 48 cases were Japanese.

7 cases received prebiotic/probiotic therapy before bacterial analysis. The average age of delivered/ongoing cases was significantly lower than that of miscarried cases (35.2 ± 4.2 vs 38.4 ± 3.0 years old, $P<0.05$).

12 cases (10 delivered/ongoing, 2 miscarried) showed non-*Lactobacillus*-dominated (NLD) (<80%) endometrium prior to embryo transfer. All 7 cases with NLD endometrium delivered at term. Among the 21 delivered cases with *Lactobacillus*-dominated (LD) (≥80%) endometrium, only one case delivered preterm, due to pregnancy-induced hypertension at 35 weeks pregnant.

The bacterial communities were clustered into six main groups, dominated by I: *Lactobacillus crispatus*, II: L. *iners,* III: L. *gasseri*, V: L. *jensenii*, IV and VI: non-*Lactobacillus* dominated. Groups I and II accounted for 28.9% and 31.6% of the delivered/ongoing cases, while group I accounted for 45.5% of the miscarried cases. There was no correlation between the percentage of dominant species and pregnancy outcome.

Limitations, reasons for caution:

The limitations of this study are short follow-up period, limited study numbers, not analyzing other aspects of gynecological histories, such as bacterial vaginosis or endometriosis. The endometrial species composition should have been compared with patients with LD endometrium who did not achieve pregnancy but was not analyzed in this study.

Wider implications of the findings:

This may be the first report analyzing endometrial microbiota at the species level regarding pregnancy outcome of IVF patients in Japan. Although this study has limitations, a specific *Lactobacillus* spp. in the endometrium detected prior to implantation may not be a strong biomarker of miscarriage.

Trial registration number:

Not applicable.

O-266 Regulation of PI3K/Akt pathway in idiopathic recurrent spontaneous miscarriage during window of implantation

B. Chakravarty[1], T. Das[1], D. Sherpa[2], K. Chaudhury[3], R. Chattopadhyay[4], S. Ghosh[1], S.K. Goswami[1]

[1]*Institute of Reproductive Medicine, Department of Assisted Reproduction, Kolkata, India*

[2]*Indian Institute of Technology Kharagpur, School of Medical and Science and Technology, Kharagpur, India*

[3]*Indian Institute of Technology- Kharagpur, School of Medical Science and Technology, Kharagpur, India*

[4]*Institute of Reproductive Medicine, Assisted Reproduction, Kolkata, India*

Study question:

Is PI3K/Akt pathway associated with idiopathic recurrent spontaneous miscarriage(IRSM) during window of implantation?

Summary answer:

PI3K/Akt pathway dysregulation with down-regulation of glucose receptors and enhanced inflammation mediated by PI3K via IKK/NFκB pathway were observed in endometrial tissue of IRSM women.

What is known already:

Akt signaling promotes proliferation and remodeling of the endometrium with an increased expression during embryo implantation in mice model. It is also reported that phospho Akt (p-Akt) is essential for endometrial decidualization and implantation of fertilized eggs in rats. PI3K/AKT signaling pathway is associated with follicular implantation during cellular proliferation induced by

estrogen and *progesterone*. PI3K/Akt pathway also regulates glucose metabolism for preparation of the epithelium and stroma in embryo implantation during successful pregnancy. PI3K/Akt pathway has a pivotal role in implantation, placentation and maintenance of normal pregnancy by enhancing trophoblast proliferation and invasiveness.

Study design, size, duration:

This study, approved by the internal review board, was conducted at the Institute of Reproductive Medicine, Kolkata in collaboration with the School of Medical Science & Technology,IIT Kharagpur, India between October 2017 and June 2018. Twenty infertile women with history of 3 or more previous IRSM and 20 women with azoospermic male partners (controls) were enrolled. Histology with immunoblotting techniques were used to study endometrial tissues collected from these subjects during window of implantation.

Participants/materials, setting, methods:

Eligible IRSM patients and controls were recruited and treated with estradiol valerate &vaginal progesterone for 10 days following which endometrial thickness (ET) was determined by serial USG. Endometrial tissue was collected when ET $\geq$ 6.5mm during window of implantation. Histological studies by hematoxylin and eosin staining and immunohistochemistry and quantitative estimation of p-PI3K (p85, p110), p-Akt (Ser473, Thr308), GLUT3, GLUT4, IKK and NF$\kappa\beta$ proteins was done using immunoprecipitation and immunoblotting techniques.

Main results and the role of chance:

We found the expression of p-PI3K (p85)(2.73-fold, $p<0.001$), p-PI3K (p110)(2.86-fold, $p<0.001$),p-Akt (Ser473)(1.98-fold, $p<0.001$) and p-Akt (Thr308) (1.68-fold, $p<0.01$) to be significantly reduced in the endometrial tissue of women with IRSM. Levels of both the glucose receptors, GLUT3 (2.46-fold, $p<0.001$) and GLUT4 (4.49-fold, $p<0.001$) were also down-regulated in these patients, possibly mediated by the PI3K-dependent pathway. IKK (3.43-fold, $p<0.001$) and NF$\kappa\beta$ (2.75-fold, $p<0.001$), two key proteins associated with inflammation, were also significantly increased in IRSM cases. IKK aggravated inflammatory response via NFκB seems likely. Immunohistochemistry was used to localize the insulin signaling proteins, including p-PI3K (p85), p-PI3K (p110),p-Akt (Ser473), p-Akt (Thr308), GLUT3 and GLUT4 in tissues of both the groups. While a reduced number of immunostained cells was observed for p-PI3K (p85),p-PI3K(p110), p- Akt (Ser473), p-Akt(Thr308) and GLUT4, the expression of IKK and NfkB were found to be significantly higher in women with IRSM. This study strongly suggests that PI3K/Akt pathway is dysregulated in the endometrium of women with IRSM during window of implantation.

Limitations, reasons for caution:

Glucose and insulin level estimation in the endometrial tissue to be performed. Correlation between the altered proteins and IVF outcome parameters, such as miscarriage rate and pregnancy rate could provide useful insight to the clinicians.

Wider implications of the findings:

Targeted intervention of PI3K/Akt signaling pathway specifically in the endometrium could be a promising treatment for the effective management of IRSM.

Study question:

Is the frequency of mutations in MAD1L1 and MAD2L1 genes in products of conception (POC) with aneuploidy higher than the highest reported frequency of these mutations?

Summary answer:

We found two novel deleterious mutations in these genes of POC with aneuploidy. Some of known mutations had higher frequency than the highest reported frequencies.

What is known already:

Chromosomal abnormality certainly aneuploidy is a main cause of spontaneous abortion. Although aneuploidy is associated with advanced maternal age it is frequent in young women. Spindle assembly checkpoint (SAC) complex has a critical role in correct chromosome segregation. Several genes are involved in SAC, such as *MAD1L1*, *MAD2L1* and BUB1. A study has reported decrease in the level of BUB1 MAD2 proteins in clinical samples of spontaneous miscarriages. The probable role of deletion of the last part of MAD2L1 gene in fibroblasts of the patients with a history of trisomic abortion has also been reported.

Study design, size, duration:

An ongoing descriptive study of 100 POC samples with aneuploidy was started in February 2018. At the time of submission, study of 40 cases has been completed.

Participants/materials, setting, methods:

To detect aneuploidy, POC of mothers younger than 36 years were analyzed using quantitative fluorescence polymerase chain reaction (QF-PCR) and/or array comparative genomic hybridization (aCGH). Those with aneuploidy were enrolled in genotyping. Areas of interest of *MAD1L1* and *MAD2L1* were genotyped using PCR and Sanger sequencing. Frequency of the observed SNVs were compared with the highest population minor allele frequency (MAF) using Chi Square. Pathogenicity of already unreported SNVs was predicted using seven predictor tools.

Main results and the role of chance:

We found some unreported SNVs that their deleterious/neutral confidence according to predictSNP is mentioned below: Q34H of MAD2L1 is deleterious (87%), F629I of MAD1L1 is deleterious (51%) and V621A of MAD1L1 is neutral (60%). We observed rs10260386, rs1481591257, rs10257349, rs372373978, rs752408355, rs1639921, rs376061507, rs62442486, rs74431414 SNVs with following allele frequencies and P values of comparison with the highest population MAF in *MAD1L1* gene: A:0.7/G:0.3 ($P<0.0001$), G:0.9875/A:0.0125 ($P=0.8222$), T:0.4/C:0.6 ($P=0.2816$), G:0.9875/0.0125 ($P=0.8222$), A:0.9875/G:0.0125 ($P= 0.1775$), T:0.89/C:0.11 ($P<0.0001$), T:0.71/C:0.29 ($P<0.0001$), A:0.71/G:0.29 ($P<0.0001$) and G:0.9625/T:0.0375 ($P=0.9092$), respectively. In exons 4 and 2 of *MAD2L1* gene, we observed rs758373815, rs752146697, rs78047690 and rs1168908864 SNVs with following allele frequencies and P values of comparison with the highest population MAF: T:0.97/G:0.03 ($P=0.7402$), G:0.92/A:0.08 ($P=0.0069$), G:0.94/A:0.06 ($P=0.1295$) and T:0.975/C:0.025 ($p=0.822$), respectively.

Limitations, reasons for caution:

This is an ongoing project. Completion of experiments and analyses might change some SNVs frequencies.

Wider implications of the findings:

Finding of deleterious SNVs in POCs, certainly, those with high confidence in genes contributed in chromosome segregation could lead to the selection of healthier embryos for transfer through preimplantation genetic testing.

Trial registration number:

Study question:
Is the POC analysis with NGS (Next Generation Sequencing) +STRs (Short Tandem Repeats) providing relevant information for the cause of clinical miscarriage?

Summary answer:
POC analysis with NGS+STRs and multi-dissection allows to rule out maternal cell contamination (MCC) providing the chromosomal constitution in 99% of the cases

What is known already:
Spontaneous miscarriages are one of the main complications in first trimester pregnancies occurring in 20-25% of clinically recognized pregnancies. Aneuploidies are the cause in more than 50% of the cases, mostly due to autosomal trisomies and monosomy X (1). This percentage can be higher than 60% in assisted reproduction treatments (ART) (2). Classic cytogenetic techniques require tissue culture, and growth failure can occur from 10 up to 60% of the cases (3). Also, MCC frequently mask the results and could give a false negative normal female result

1. Hassold et al., 1980.
2. Campos-Galindo et al., 2015.
3. Fritz et al., 2001.

Study design, size, duration:
Prospective observational study that includes 2,531 POC analyzed from January 2014 to December 2017. Results were performed using either array Comparative Genomic Hybridization (aCGH) (n = 675) or NGS (n = 1,856) after STR analyzed to rule out MCC and/or polyploidy. Maternal age, gestational age and origin of oocytes were investigated

Participants/materials, setting, methods:
POC samples were received on saline sterile solution and dissected in three portions. Then, maternal DNA (provided in a blood sample in EDTA tubes) was compared versus fetal DNA from the dissected samples performing SRTs to rule out MCC and/or polyploidy. When MCC was ruled out, aCGH was performed using array 24sure BAC (Bacterial Artificial Chromosome) (Illumina Inc., San Diego, CA, USA) or NGS with Ion ReproSeq PGS Kit (ThermoFisher Scientific, Waltham, MA, USA)

Main results and the role of chance:

1. Informativity rates and the percentage/distribution of abnormal results was similar with aCGH and NGS. Informative results were obtained in 99% of POC, being 12.8% of them MCC identified by STRs analysis. From the informative cases, 53.5% were abnormal (39.7% trisomies, 5% monosomy X, 4.1% complex abnormal, 2.5% polyploidies, 1.2% deletions/duplications (del/dup), and 1% autosomal monosomies). It is important to point out that 21 autosomal monosomies were identified for chromosomes 4, 13, 15, 21 and 22. As expected, the percentage of abnormal POC increases significantly ($p<0.05$) with female age: 50% in women $\leq$35 years; 65% in women 36-40 years, and 70% in women >40 years. Regarding gestational age, between 9-12 weeks the percentage of abnormal results was 65%, but after 12 weeks decreased to 34% ($p<0.0001$). When the patients miscarried with own oocytes (either with spontaneous pregnancy or after ART) the percentage of abnormal results was 54.5% versus 29.7% with donated oocytes ($p=0.001$). Interestingly, the percentage of sex chromosome monosomy was 9.1% in miscarriages with own oocytes versus 36.8% with egg donation ($p=0.001$), highlighting the potential higher contribution of aneuploidies of paternal origin in egg donation from young donors

Limitations, reasons for caution:
The resolution of the genetic platform allowed to detect del/dup $\geq$6Mb. Mosaicism was not considered

Wider implications of the findings:
This is the largest number of POC analyzed by NGS technology. Together with STRs analysis, we can provide results in 99% of the cases. With the use of more accurate technology we have been able to detect for the first-time monosomies for chromosomes 4 and 15 in POC

Trial registration number:

O-269 The implications of unsuccessful IVF/ICSI cycles for future placental development

C. Sacha[1], K. James[2], A. Harris, L[1], J. Yeh[1], I. Souter[1], D. Roberts, J[3]
[1]Massachusetts General Hospital and Harvard Medical School, Division of Reproductive Endocrinology and Infertility, Boston, U.S.A.
[2]Massachusetts General Hospital and Harvard Medical School, Deborah Kelly Center for Outcomes Research- Department of OB/GYN, Boston, U.S.A.
[3]Massachusetts General Hospital and Harvard Medical School, Department of Pathology, Boston, U.S.A.

Study question:
Is a history of multiple failed IVF/ICSI cycles associated with abnormal placentation in nulliparous women?

Summary answer:
Nulliparous women with multiple prior failed IVF/ICSI cycles may have an increased risk of marginal placental cord insertion and chronic decidual inflammation when pregnancy occurs.

What is known already:
IVF/ICSI pregnancies are at increased risk of abnormal placentation compared to spontaneous pregnancies. However, the mechanisms leading to that increased risk—whether it is the hormonal environment, the assisted reproduction procedures themselves, or an unidentified endometrial or uterine factor—remain unclear.

Study design, size, duration:
A cohort of 1147 live births with placental pathology arising from autologous IVF/ICSI cycles between 2004 and 2017 was retrospectively reviewed.

Participants/materials, setting, methods:
We compared placental pathology between nulliparous women who underwent their first, second, or third or greater IVF/ICSI cycle with fresh transfer at a large academic fertility center. An experienced placental pathologist categorized placental pathology from electronic reports as anatomic, infectious, inflammatory, and/or vascular. We used Pearson's chi-squared test and multivariate logistic regression models for analysis, controlling for maternal age, IVF diagnosis, gestational age at delivery, and number of fetuses.

Main results and the role of chance:
There were 477 nulliparous women with pathology available who underwent a fresh embryo transfer, including 303 undergoing a first attempt, 117 undergoing a second attempt, and 57 undergoing their third or greater attempt. The median singleton placental weights based on standard reference values were 430g in the first attempt group, 459g in the second attempt group, and 430g in the third or greater attempt group (corresponding to 25%ile for each), but 34%, 29% and 39% of placentas, respectively, were at the 10%ile or lower ($p = 0.34$). In unadjusted models, there were no differences in infectious or vascular pathology between women who underwent a first, second, or third or greater cycle. However, an increasing number of prior failed IVF attempts seemed to be associated with a significantly greater incidence of anatomic placental pathology, specifically marginal cord insertion (8.6% vs. 13.7% vs. 19.3%, respectively, $p = 0.04$), and inflammatory pathology, specifically chronic plasma cell deciduitis (1.3% vs. 5.1% vs. 8.8%, respectively, $p = 0.005$). When adjusting for possible confounders, the trend towards a higher incidence of chronic deciduitis with increasing number of failed IVF attempts remained significant (attempt $\geq$ 3 vs. first attempt, OR=6.7, CI 1.7-26.9, $p = 0.007$).

Limitations, reasons for caution:
Our findings are limited the retrospective design of the study and by the relatively small number of nulliparous women with three or greater cycles, thus limiting the power to compare the incidence of some placental pathologies.

Wider implications of the findings:
This data indicate that nulliparous women with multiple prior failed IVF/ICSI attempts may have an altered implantation environment that leads to increased placental inflammation and altered cord insertion when pregnancy occurs. Our

findings highlight the need for a greater understanding of how infertility and assisted reproduction impact the placenta.

INVITED SESSION

SESSION 70: BURNING QUESTIONS IN POLYCYSTIC OVARY SYNDROME

Wednesday 26 June 2019 Mozart 12:00 - 13:00

O-270 Is AMH guilty of the dysregulation of the reproductive axis in women with Polycystic Ovary Syndrome?

D. Dewailly [1]

[1]*INSERM U1172 Jean-Pierre Aubert Research Centre, Laboratory of Development and Plasticity of the Neuroendocrine Brain, Lille, France*

Abstract text

Is AMH guilty of the dysregulation of the reproductive axis in women with Polycystic Ovary Syndrome?

Didier Dewailly, France

Until now considered as a pathology affecting only the ovaries, the PCOS would also modify the activity of neurons housed in the heart of the brain, in the hypothalamus by causing their overexcitation. The culprit would be the anti-Müllerian hormone (AMH). AMH is a hormone secreted by the ovaries, known to play a crucial role in sexual differentiation and gonadal function. Women with PCOS have 2 to 3 times higher AMH levels. In addition, the severity of the PCOS phenotype is correlated with the AMH level. On the other hand, in more than half of the cases of PCOS, abnormally high levels of LH are found without it being possible to say whether this increase is the cause or consequence of PCOS. In our group, we found that AMH had extra-gonadal effects and was notably able to increase the activity of GnRH neurons (1). It has been observed that around 50% of GnRH neurons (murine and adult human) have AMH type 2 (AMHR2) specific receptors. The combination of several in vitro and in vivo experiments has shown that AMH increases the pulsatile secretion of GnRH-dependent LH through central action. In the end, the increase in AMH concentration would cause a real chain reaction: the hypothalamic neurons would start to secrete more GnRH, which would then increase the production and pulsatility of LH by the anterior pituitary. These results raise the innovative hypothesis that the abnormally high levels of AMH found in patients with PCOS could either be at the origin or contribute to the hormonal and gonadal disorders encountered in this pathology. Indeed, the increase in pulsatility of LH is known to aggravate hyperandrogenism of ovarian origin. In addition, hyperandrogenism combined with the intra-gonadal action of AMH disrupts follicular growth at all stages, selection of the dominant follicle and therefore ovulation.

However, the exact pathophysiology of PCOS remains unknown at this time. Indeed, family studies have revealed the heritability of PCOS, but all the mutations identified do not explain the high prevalence of PCOS suggesting the intervention of environmental/epigenetic components at the origin of this syndrome. Recent results from our group suggest that high maternal AMH level may be the fetal trigger for neuroendocrine alterations that occur in PCOS later in life. While it was known that AMH levels decreased significantly in women during pregnancy, we demonstrated for the first time that in PCOS women, AMH levels remained significantly higher during pregnancy compared with controls. We also demonstrated that recombinant AMH administered intra-peritonaly in mice at a dose of 0.12 mg/kg/day between 16.5 and 18.5 gestation days was able to have a programming effect on female progeny, leading to the occurrence of perinatal hyperandrogenism and lean PCOS phenotype in adulthood (PAMH model) (2). Finally, we showed for the first time that the bioactive form of peripherally injected AMH could act directly on the brain via the windowed capillaries located at the median eminence of the hypothalamus. Androgenization and propensity to PCOS in PAMH model would be the consequence of a central action of AMH on GnRH neurons causing their hyperexcitation resulting in an increase in ovarian steroidogenesis via an increase in LH in mothers and/or of an inhibition of placental aromatase activity resulting in an increase in bioavailable testosterone both in mothers and fetuses. These results are consistent with data from the literature that showed a decrease in placental aromatase activity in PCOS women.

O-271 Should we go for prevention of long term health consequences?

J.S. Tapanainen [1]

[1]*University of Helsinki, Dept. of Ob/Gyn, Helsinki, Finland*

Abstract text

PCOS is a common condition in fertile-aged women, with a prevalence of 10-18%. Women with PCOS have an increased risk for adverse metabolic derangements. This presentation focuses on these metabolic alterations and their role in increasing the risk for cardiovascular diseases (CVD) in affected women. They commonly present with overweight/obesity (up to 70%), glucose intolerance, prediabetes, dyslipidemia, chronic inflammation, hypertension and metabolic syndrome (MetS). Although most of these are known to increase the prevalence of CVD it is still unknown whether this is also the case in PCOS. Why is that? The risk of CVD-related morbidity is greater in the presence of multiple risk factors, and PCOS can be considered often as a mild/moderate metabolic disorder. Furthermore, the studies have differed in study designs and PCOS phenotypes. More importantly, high-quality follow-up studies are lacking, and the oldest women with reliable diagnosis of PCOS are not more than 70-75 years old.

Prevention of weight gain and healthy lifestyle behaviors should be recommended as first-line intervention, as the weight gain often starts at childhood/adolescence. Individuals with overweight have an increased prevalence of T2DM, hypertension and dyslipidemia, and especially visceral fat increases CVD risk. Most quidelines identify diet and exercise as essential approaches for CVD risk reduction. Reducing the use of unsaturated fatty acids and use of fruits, vegetables, fish and lean meats are the key for controlling weight and dyslipidemia. Weight reduction diminishes PCOS symptoms and weight loss of 5-10% yields significant clinical improvements.

Insulin resistance and T2DM (3-5 fold risk) are increased in PCOS. Several studies and meta-analyses have concluded that PCOS is associated with an increased risk of these disorders, independently of BMI. Thus, the detection of glucose metabolism abnormalities is important as T2DM is a major risk factor for CVD, and approximately 65% of diabetes-related mortality is due to CVD. It is notable that elevated blood glucose is a late manifestation of insulin resistance. Also individuals with prediabetes are considered to have an increased risk for CVD. Up to 75% of women with PCOS fulfill the criteria for MetS. Metformin has been used in PCOS for ovulation induction and to improve metabolic disturbances, but duration of the studies has been weeks to months, and long-term data are lacking. Nevertheless, metformin seems to lower fasting glucose, helping in weight control and to some extent it also improves lipid profile. In nondiabetic population (mean age 51) with high metabolic risk, metformin therapy reduces the incidence of T2DM, but lifestyle intervention is even more effective.

Women with PCOS present atherogenic lipoprotein profile, which carry a significant risk for CVD. As in other adverse metabolic alterations in PCOS, the first-line approach to is the implementation of lifestyle changes. In PCOS statins have been shown to lower testosterone levels either alone or in combination with oral contraceptives but have not shown to improve clinical hyperandrogenic symptoms. Statins reduce total and LDL cholesterol levels, but seem to increase glucose intolerance in some women. Although long-term studies of statins on clinical CV outcomes are lacking in PCOS, there is strong evidence in general population that they are effective for both primary and secondary prevention of CVD.

In conclusion, although there are no long-term data on the morbidity for CVD in PCOS, it is advisable to perform metabolic and cardiovascular assessment in women with PCOS in order to prevent CVD and conditions leading to CVD. Especially individuals at increased risk (obese, family history) should be identified already at early adulthood. This means targeted screening, life style changes and medication on the basis of generally accepted criteria and individual risk assessment of glucose metabolism disorders and CVD.

INVITED SESSION

SESSION 71: CAN IVF INFLUENCE HUMAN EVOLUTION?

Wednesday 26 June 2019 Haydn 1 12:00 - 13:00

O-272 Yes, IVF can influence human evolution

H.I. Hanevik [1]

[1] *Sykehuset Telemark HF, Fertilitetsavdelingen Sor, Skien, Norway*

Abstract text

As all other animal species, humans are influenced by evolution. We change. In large, well-studied human populations, some recent changes in physiology and behavior were due to evolutionary effects [1]. The most common mechanism of evolution is natural selection, where selection pressures are applied on available phenotypes. All the necessary requirements for natural selection are present in IVF clinics, and in this talk I argue that IVF influences human evolution.

Natural selection also occurs in non-assisted human reproduction of course, but selection pressures in IVF are very different compared to the natural situation. Take for example the sprinter spermatozoon that wins the race in IVF. This spermatozoon swims very short distances compared to the long-distance specialist that fertilizes the oocyte in nature. ICSI is an extreme variant of this, where the spermatozoon barely has to move at all. The ICSI spermatozoon also avoids the hassle of finding its way to the oocyte by a probably chemotactic mechanism.

This and other examples concerning the systematically different selection pressures that are applied on oocytes, embryos and even couples wanting to conceive in IVF programs compared to the natural situation, suggest that IVF influences human evolution. If so, this is another case of cultural and technological advances inducing changes in the human genome. A previous, well-known example of such gene-culture co-evolution is the relationship between lactase expression and milk consumption in human populations. In comparison, the evolutionary implications of systematically different selection pressures in IVF could be even more influential, as evolutionary theory underlines that selection works through differential reproductive success and not through differential survival.

The purpose of this talk is not to judge or impose a set of norms on IVF, but rather to draw attention to the fact that IVF is not just a treatment for infertility, but also a technological intervention at the point in a human life cycle where natural selection operates at its strongest. Although IVF is a great medical achievement, it circumvents a range of pre- and post-zygotic reproductive barriers. It increases the reproductive fitness of subfertile couples by technologically removing several naturally occurring selective barriers and by altering other such barriers. In accordance with the basic principle of evolution, the subsequent generations will thus be genetically and epigenetically adapted to an environment in which reproduction is increasingly dependent on technological intervention.

O-274 Reaching ethnic minorities with a comic booklet to raise awareness of fertility

S. Gameiro[1], **E. El Refaie**[2], **B.B. De Guevara**[3], **A. Payson**[4]

[1] *School of Psychology, United Kingdom, Cardiff, United Kingdom*

[2] *Cardiff University, School of English- Communication and Philosophy, Cardiff, United Kingdom*

[3] *Aberystwyth University, Department of International Politics, Aberystwyth, United Kingdom*

[4] *Cardiff University, School of Journalism- Media and Cultural Studies, Cardiff, United Kingdom*

Abstract text

Infertility can affect any women or men in their reproductive years. The most recent statistics show that in the UK 8% of infertile people are non-white, with 51% of these being Asian or Asian British, 26% Black or Black British, 12% Chinese or other ethnic groups, and 11% Mixed (HFEA, 2006). Research suggests that some people from minority ethnic or religious groups perceive pressure to conceive from their communities, experience social costs when they are unable to have children, and stressful interactions with the fertility healthcare system while attempting to conceive. Nonetheless, there is a lack of available guidance about the support needs and preferences of ethnic and religious minority infertile patients.

This study was based on a one-day drawing workshop to collect visual (artwork produced by participants) and textual (all conversations and discussions during the workshop) data about the participants' views and experiences of infertility and their fertility care needs. Participants were nine adult women with a minority ethnic or religious status living in Wales, UK, who were experiencing or had experienced infertility in the past. The workshop comprised five activities: 1) small and large group discussion of infertility-related drawings, 2) powerpoint-based lecture consisting on an introduction to the basics of drawing objects and people and 3) thoughts and feelings, 4) free drawing session and 5) group sharing. Audio recordings of the workshop were transcribed verbatim. Textual data was analysed with thematic analysis. Risk for bias was addressed via individual coding by two authors followed by joint discussion and presentation and discussion of results with the research team and participants.

Forty-one themes were identified and grouped into 8 distinct higher order themes. These themes described the emotional, relational and social burden of infertility experienced by women, which they perceived to result from their communities' highly pronatalistic attitudes and stigmatization of infertility. Themes also captured women's coping strategies, their overall positive evaluation of their fertility health care, their desire for more infertility education (for themselves and their communities) and for socio-culturally and inter-personal sensitive care.

Results from this study support the view that women from ethnic and religious minority backgrounds perceive highly pronatalistic attitudes and stigmatization of childlessness and infertility from within their community, to which they attribute (most of) their infertility related stress. Women were critical of such attitudes, considered that fertility education was needed to overcome these, and put forward concrete proposals on how to implement it. Women's overall evaluation of their fertility health care was positive. Nonetheless, they desired more socio-culturally and interpersonally sensitive fertility care and recommended for fertility staff to be trained in these topics. Women also desired more infertility education (e.g., biological causes). Overall results suggest that these women present high levels of resilience and effective coping strategies (with religious coping being highly prevalent) in the face of infertility and the personal and social adversity it creates.

The sample was small and recruited in collaboration with a local charity, which may mean that all participants were well integrated in their communities. Analysis focused on capturing commonalities in participants' experiences and this may sometimes result in homogenizing diverse experiences.

In conclusion, more education about the infertility experiences of minority ethnic and religious groups at the community and healthcare deliver level can be beneficial for women. Together with our workshop participants we co-produced the comic booklet 'Thorns and Flowers - Infertility experiences of Black and Minority Women' (https://www.cardiff.ac.uk/psychology/about-us/engagement/thorns-and-flowers) that is available online and can be used by infertile people, fertility clinics and other stakeholders to introduce conversations and discussions on this topic.

O-275 Patient's information needs

M. Bulmanska-Wingett [1]

[1] *Stowrzyszenie na Rzecz Leczenia Nieplodnosci i Wspierania Adopcji Nasz Bocian- Association for the Infertility Treatment and Adoption Our Stork- Fertility Europe, Patient, Petaling Jaya, Malaysia*

Abstract text

The presentation reviews infertility patients' information needs and preferences as well as the actual situation and practice in the matter. As the internet is one of the main sources of patients' expertise on infertility and methods of its treatment, providing accurate and thorough information to patients is exceptionally important. In the era of easy access to all sorts of data, helpful as well as harmful, at times of massive information chaos delivering reliable data has became a true challenge. Not only does the availability of qualititative and verified information help to make the right choices in terms of existing medical procedures and reaching for professional help within a reasonable time but vastly helps to cope with burdens of treatment and infertility itself by increasing level of understanding of one's unique situation and suggested medical solutions. From both formal and legal points of view, access to proper information is an emanation of patients' fundamental rights and therefore indisputable.

A survey conducted among infertility patients throughout European countries delivers intelligence on their preferences in terms of content, the right form and manner of delivering and the right timing of providing information as well as proves quite common deficiencies in the field of quality and intelligibility of information offered to patients. It focuses on relation patient - health care provider although it also investigates briefly other sources of information available and their importance to patients. There are reported cases of biased medical advice based on personal beliefs of health care providers rather than on evidence-based medicine as well as cases of bias towards certain groups of patients present due to their specific features or life choices, i.e. age, gender, weight, education, sexual orientation etc. The presentation aims at delivering accurate and complete information on practice in terms of informing and including patients in the process of their own diagnosis and/or treatment in various European countries. It also aims at delivering the analysis of observed problems and seeking suggestions for desired solutions from the patients perspective. It will also indicate the areas for much-needed improvement in access to reliable information based on patients preferred sources of obtaining information and for common efforts of health care providers and patients' organizations towards providing knowledge and effective tools for critical verification of commonly and easily available information. The importance of providing easy access to reliable, qualitative and intelligible information is a factor vastly influencing not only patients well being during treatment but also the actual outcome of treatment when taking into account timing and limitations reflected by various factors, e.g. age or progressing severity of accompanying medical conditions.

INVITED SESSION

SESSION 73: ENDOMETRIOSIS, INFLAMMATION AND THE IMMUNE SYSTEM

Wednesday 26 June 2019 Haydn 2 12:00 - 13:00

O-276 Inflammatory changes in endometriosis

B. McKinnon [1]

[1] *University of Bern, Department of Clinical Research, Berne, Switzerland*

Abstract text

Endometriosis, characterised by the growth of endometrial tissue outside the uterine cavity, is often described as an inflammatory disease. Alterations in immune cells and inflammatory mediators have been reported in the eutopic endometrium of women with endometriosis and the inflammatory response to the growth of ectopic tissue alters the peritoneal environment. The inflammatory changes associated with endometriosis however are both varied and complex and their consequences are heavily reliant on both temporal and spatial context. An understanding of this context is required to fully appreciate the inflammatory changes associated with the disease.

To place inflammatory changes into context requires an understanding of both disease progression, and the contribution of various biological compartments and components. While the underlying aetiology of endometriosis remains unclear there is an increasing acknowledgement that the disease has a natural temporal progression starting with subtle changes in the eutopic endometrium that are transferred to the peritoneal cavity through the appearance of endometrial cells at various anatomic locations and eventually progresses towards large fibrotic lesions. Moreover, although characterised and ultimately diagnosed by the presence of endometrial epithelial and stromal cells there are significant roles for other cells including macrophages, natural killer cells, platelets and others. Inflammatory changes accompany all of these stages and are both mediated and influenced by all of these components.

Endometriosis therefore is a complex disease that involves multiple components all of which evolve over time. To better understand the role of inflammation in endometriosis context is paramount. In this presentation the inflammatory changes in endometriosis will be discussed through the paradigm of context, assessing its influence on the natural course of the disease and the components that contribute to its aetiology. A deeper understanding of inflammation within a temporal and spatial context may lead to better design and application of both current and novel treatments.

O-277 The association between endometriosis and other inflammatory diseases

SELECTED ORAL COMMUNICATIONS

SESSION 74: NEW ASPECTS IN REPRODUCTIVE ENDOCRINOLOGY

Wednesday 26 June 2019 Mozart 14:00 - 15:30

O-278 Measuring LH Pulsatility in Patients with Reproductive Disorders Using a Novel Robotic Aptamer-Enabled Electrochemical Reader (RAPTER)

W. Dhillo [1], **S. Liang** [2], **A. Kinghorn** [3], **M. Voliotis** [4], **J. Prague** [1], **J. Veldhuis** [5], **K. Tsaneva-Atanasova** [4], **C. McArdle** [6], **R. Li** [7], **A. Cass** [8], **J. Tanner** [2]

[6] *University of Bristol, Laboratories for Integrative Neuroscience and Endocrinology- Bristol Medical School, Bristol, United Kingdom*

[7] *LKS Faculty of Medicine- The University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, China*

[8] *Imperial College London, Department of Chemistry, London, United Kingdom*

Study question:

Could the emerging technology of electrochemical aptamer-based sensing offer a generalizable approach for LH pulsatility measurement in humans?

Summary answer:

The RAPTER system provides a new approach for LH pulsatility determination by reliably and immediately calculating varying LH concentrations within distinct patient cohorts.

What is known already:

Assessment of LH pulsatility is important for the clinical diagnosis of patients with reproductive disorders, but is not routinely available in the clinic because of the need for frequent blood sampling coupled with expensive serial immunochemical analysis.

The emerging technology of electrochemical aptamer-based (E-AB) sensing could potentially offer a generalizable approach for LH pulsatility measurement in humans.

E-AB sensors take advantage of the intrinsic properties of nucleic acid aptamers to specifically bind to a molecular target and undergo a reversible conformational change which can be measured through the electrochemical signal response.

However, there is currently no aptamer-based LH sensing technology.

Study design, size, duration:

Here, we report the development and application of a novel antibody-free DNA aptamer-mediated electrochemical analysis to accurately assess LH pulsatility in patients with reproductive disorders.

Through selective evolution of ligands by exponential enrichment, single-stranded DNA oligonucleotides (aptamers) were identified that bind specifically to LH (and that do not bind to FSH).

The aptamers were integrated into E-AB sensors on a robotic platform (which we term RAPTER) to enable sensitive, rapid and repeatable detection of LH.

Participants/materials, setting, methods:

We next determined if the RAPTER system could measure LH pulsatility in clinical samples from patients with reproductive disorders. We obtained 441 serum samples from 3 patient cohorts - young females with regular menstrual cycles, menopausal women, and women with hypothalamic amenorrhoea.

Blood sampling was performed every 10 minutes for 8 hours in these patients and samples were analysed using both the current gold standard LH immunochemical assay and RAPTER.

Main results and the role of chance:

We performed a Bland-Altman analysis and plotted the linear regression to compare the results obtained.

The RAPTER assay showed an almost perfect correlation with the clinical immunochemical assay (R2= 0.94).

Bayesian Spectrum Analysis was used to determine the effective LH pulse interval from both datasets (clinical assay and RAPTER assay).

We are able to distinguish 3 patient cohorts based on the time interval ranges.

Limitations, reasons for caution:

We have provided proof of principle that LH pulsatility measurement can be accurately carried out using aptamer based technology in patients with reproductive disorders. The next steps will be to convert this technology into a wearable device which can continuously sense LH in freely moving patients.

Wider implications of the findings:

The RAPTER system can determine LH pulsatility by reliably and immediately calculating varying LH concentrations within distinct patient cohorts. This has the potential to transform the clinical care of patients with reproductive disorders as LH pulsatility could be measured easily in clinical practice to aid correct diagnosis.

O-279 Melatonin ameliorates mitochondrial injury by enhancing SIRT1 expression and inhibiting PINK1/Parkin-mediated mitophagy in granulosa cells of classic polycystic ovary syndrome

S. Yi[1], M. Zhu[1], J. Meng[1], H. Sun[1], J. Zhou[1]

[1]The Affiliated Drum Tower Hospital of Nanjing University Medical School, Reproductive Medicine Center, Nanjing, China

Study question:

Does melatonin affect mitochondrial function by regulating the expression of Sirtuin1 (SIRT1) in granulosa cells (GCs) of classic polycystic ovary syndrome (PCOS)?

Summary answer:

Melatonin ameliorates mitochondrial injury by upregulating SIRT1 expression and inhibiting PINK1/Parkin-mediated mitophagy.

What is known already:

Recent researches suggest that chronic inflammation and oxidative stress caused by mitochondrial damage in granulosa cells of PCOS patients are closely related to pathophysiological changes of PCOS, and SIRT1 plays an important role in maintaining the normal function of mitochondria. Melatonin has been suggested to improve the pregnancy outcomes in PCOS patients, though the underlying mechanism remains largely undetermined.

Study design, size, duration:

Granulosa cells of classic PCOS patients diagnosed according to the 1990 NIH criteria and dihydrotestosterone (DHT)-treated KGN cells were used to investigate the molecular mechanisms in vitro. DHT-induced PCOS mouse model was performed to examine the roles of melatonin on granulosa cells. This is an experiment study lasted ten months.

Participants/materials, setting, methods:

GCs of classic PCOS patients, DHT-treated KGN cells and DHT-induced PCOS mouse were used as study models. Western blotting, quantitative RT-PCR, JC-1 dye, identification of mitochondrial DNA and transmission electron microscope (TEM) were used to determine the mechanism of mitochondria function changes induced by melatonin.

Main results and the role of chance:

The results of western blotting analysis showed that PINK1/Parkin-mediated mitophagy level was significantly increased in GCs in classic PCOS patients compared with control group. We found that mitochondrial membrane potential assessed was decreased ($p<0.05$) and the mtDNA content in GCs were significantly lower in classic PCOS than control group ($p<0.01$). The expression of SIRT1 mRNA and protein levels in GCs were significantly lower in classic PCOS group (both $p<0.01$). But supplementation of in-vitro culture medium with 100pM melatonin for 24h could enhance the expression of SIRT1 protein in GCs of PCOS ($p<0.05$). After 500nM DHT treatment for 24h in KGN cells, SIRT1 protein level was significantly decreased by ($p<0.001$), the PINK1/Parkin-mediated mitophagy level was significantly decreased, mitochondrial membrane potential and mtDNA content were significantly decreased (both $p<0.01$). At the same time, co-treatment with 100pM melatonin for 24h significantly increased SIRT1 protein level ($p<0.05$), inhibited PINK1/Parkin-mediated mitophagy, enhanced mitochondrial membrane potential ($p<0.05$) and increased mtDNA content ($p<0.05$). The results of western blotting assay and TEM showed that induction of PINK1/Parkin-mediated mitophagy was significantly enhanced in GCs collected from mice subjected to DHT administration. In contrast, reduced mitophagy level in GCs of PCOS mouse was observed following melatonin administration.

Limitations, reasons for caution:

The mechanism of melatonin ameliorates mitochondrial injury mediated by SIRT1 and the change in ovarian function of PCOS mouse should be further evaluated.

Wider implications of the findings:

Our results suggest that melatonin ameliorates mitochondrial function by enhancing SIRT1 expression and inhibiting PINK1/Parkin-mediated mitophagy. These finding may subsequently provide novel potential therapeutic regimens for patients with PCOS.

Trial registration number:

This work was supported by the National Natural Science Foundation of China (81771537).

O-280 Evaluation of the hormone Dehydro-epiandrosterone sulphate (DHEAS) as a potentially compelling 'oocyte-related factor' in mammalian oocyte activation: A paradigm shift?

B.N. Chimote [1], N.M. Chimote [1]

[1]Vaunshdhara Fertility Centre, Embryology- Endocrinology, Nagpur, India

Study question:

Is the lipid-soluble steroid hormone dehydro-epiandrosterone sulphate (DHEAS), the elusive oocyte-related factor that regulates mammalian oocyte activation by controlling Ca^{2+} release from inner mitochondrial stores?

Summary answer:

The **oestro-androgen** DHEAS is the 'oocyte-related factor' that influences fertilization, embryo development and pregnancy outcomes potentially by regulating oocyte activation via maintenance of calcium homeostasis.

What is known already:

Sperm-factor PLCζ is largely implicated in oocyte-activation (OA). However, fertilization-failure despite using PLCζ activated sperm; observation of OA-fertilization-live-birth using **PLCζ null sperm;** and obtaining oocyte calcium-signatures, suggests involvement of oocyte-factors. The androgen DHEAS, peculiarly also behaves as an oestrogen. Synthesized by ovarian cumulus/-granulosa cells, DHEAS acts via putative oocyte receptors/anion exchangers. In certain human cell-types, DHEAS regulates the same calcium-pumps which maintain calcium-oscillations and cause OA in mice. Altered DHEAS levels have been demonstrated in women with hampered fertilization/embryo development/pregnancy outcomes. DHEAS thus promises to be the hitherto elusive, potential oocyte-related factor that regulates oocyte-activation and affects fertilization/embryo development/pregnancy outcome.

Study design, size, duration:

Prospective Randomized study (July 2016-November 2018) of n=625 women (age:25-35years, BMI:18-28kg/m^2) undergoing antagonist stimulation protocol IVF-ICSI followed by day5 blastocyst-transfer for tubal-factor/unexplained infertility/previous 3-4 failed intra-uterine-insemination cycles or with previous 2-3 attempts of low/failed IVF/ICSI fertilizations. Patients with adrenal patho-physiology and/or male factor were excluded. Three DHEAS groups: Low (**A:**<95 µg/dL), Average (**B**:95-270 µg/dL), High (**C**:>270 µg/dL), were classified as per previously established thresholds of baseline D3serum-DHEAS, measured by radioimmunoassay. Follicular-fluid DHEAS was also measured.

Participants/materials, setting, methods:

Three groups, divided randomly into sub-groups, received following interventions: **A1** (lower control/no supplementation), **A2** (3 months oral micronized DHEAS 75mg/day); **B** (normal controls/no intervention); **C1** (higher control/no treatment), **C2** (3 months metformin treatment 1500mg/day). Anticipating 20-25% cycle-cancellations/dropouts/no response, a pre-treatment sample size n=125 per sub-group, assured 80-85% power to study. Intra-group, Intergroup differences in fertilization-cleavage-blastocyst formation, clinical pregnancy, live-birth, early miscarriage rates were calculated by Student's t-test/ANOVA, odds-ratio, correlation-coefficient, as applicable, using Graphpad PrismVI software.

Main results and the role of chance:

A2-Group women whose DHEAS levels **increased to optimal/average** after 3 months oral DHEAS supplementation (n=98) showed significantly improved fertilization (80 vs.55%;p<0.0001), cleavage (78.5 vs.53%;p<0.0001), blastocyst formation (43 vs.22%;p=0.002), live-births (35vs.15%;p=0.0006), reduced early miscarriages (3.5vs.9%;p=0.008), compared to no-supplementation A1 group (n=107).

Metformin treatment is known to lower DHEAS levels in women with raised baseline DHEAS, whereas it has no effect on women with normal baseline DHEAS. Indeed, **Group-C2** women whose DHEAS levels **reduced to optimal/average** after 3 months metformin treatment (n=105) displayed significantly enhanced fertilization (79vs.53%;p<0.0001), cleavage (76vs.52%;p=p=0.0005), blastocyst formation (40vs.20%;p=0.0001), live-births (31vs.14%; p=0.0003), reduced early miscarriages (4vs.11%;p=0.0005) compared to no-supplementation C1 group (n=109).

As expected, post-treatment improved parameters in A2 and C2 groups were comparable with the results observed in the normal-control/average B-group women (Fertilization 88%, Cleavage 87%, Blastocyst-formation 48%, Live-births 39%, early miscarriage 2.5%; p=ns).

Follicular-fluid DHEAS levels were also classified into **Low-I** (<760ng/ml), **Medium-II** (760-1850ng/ml) and **High-III** (>1850ng/ml) groups. All evaluated parameters in A1 and C1 groups were comparable with Low-I and High-III groups respectively whereas those in A2, C2 and B groups corroborated with Medium-II group. Fertilization rates strongly correlated with Follicular-fluid DHEAS levels (Pearsonr=0.78). Odds of fertilization, embryo development and live-births increased post-treatment in both A2 and C2 groups.

Limitations, reasons for caution:

Instead of directly measuring Ca^{2+}oscillations to evaluate OA, we indirectly assessed fertilization/embryo development/pregnancy outcomes, since ethical considerations prevented use of oocyte-destructive methods. Measuring Ca^{2+}oscillations in mice is impractical as results cannot be extrapolated to humans. Future plan involves measuring Ca^{2+}oscillations in donated human oocytes by epi-fluorescence microscopy using radiometric dyes.

Wider implications of the findings:

This study sets new paradigms by introducing DHEAS as a **potential first-messenger oocyte-related factor** in OA. Results suggest that since not all poor-responders have lower thresholds, nor all PCOS women have higher thresholds of DHEAS; treatment modality should be based on baseline serum DHEAS levels rather than providing empirical treatment.

O-281 Effect of MVT-602, a potent kisspeptin receptor agonist, on luteinizing hormone (LH) concentrations in healthy pre-menopausal women undergoing a minimal controlled ovarian stimulation (COS) protocol

A. Abbara[2], I. Duijkers[3], M. Ezzati[4], C. Voors-Pette[5], C. Romeijn[6], L. Berman[7], X. Fan[8], E. Migoya[1], W.S. Dhillo[2]

[7]Develop BioPharma Consulting, None, Barcelona, Spain
[8]Myovant Sciences- Inc., Biostatistics, Brisbane, U.S.A.

Study question:

What is the effect of MVT-602 on luteinizing hormone (LH) concentrations in healthy women undergoing a minimal COS protocol?

Summary answer:

Peak LH concentrations occurred 20 hours after MVT-602 following minimal COS achieving an endocrine milieu similar to the preovulatory phase of the menstrual cycle.

What is known already:

Kisspeptin-54, the endogenous peptide ligand of the kisspeptin receptor (KISSR), is known to be responsible for GnRH release from the hypothalamus. Kisspeptin is therefore considered to play an essential role in the regulation of the hypothalamic-pituitary-gonadal (HPG) axis. In a previous Phase 1 study, MVT-602, a potent KISSR agonist, showed increases in LH and follicle-stimulating hormone (FSH) after administration of MVT-602 to healthy premenopausal women in the follicular phase of their menstrual cycle. The peak post-MVT-602 LH concentrations occurred later than those observed using native kisspeptin-54 (Dhillo et al).

Study design, size, duration:

A randomized, double-blind, placebo and active comparator-controlled, parallel-group, phase 2a study conducted May and October 2018. Seventy-five women (<36 years, body mass index 18.0 to 30.0 kg/m^2) underwent minimal ovarian stimulation (initially 100 IU rFSH [follitropin alfa] and 0.25 mg GnRH agonist [ganirelix]). Once the dominant follicle reached ≥17 mm, women were randomized to single dose MVT-601 (0.1, 0.3, 1 or 3 µg), triptorelin 0.2 mg or placebo (3:1:1 ratio).

Participants/materials, setting, methods:

Follicular growth was monitored by transvaginal ultrasound (TVUS) beginning on day 3-5 of their menstrual cycle. Once the dominant follicle reached ≥13 mm, minimal stimulation with rFSH and GnRH commenced. The trigger agent (MVT-602, triptorelin, or placebo) was administered once the dominant follicle reached ≥ 17 mm, 12 hours following the last ganirelix dose. Hormone levels were measured every 2 to 8 hours for 48 hours post-dose, then daily until discharge

Main results and the role of chance:

After MVT-602, mean peak LH concentrations of 50 IU/L occurred at approximately 20 hours (range: 16 to 36 hours) after all doses of MVT-602 and returned towards baseline by 60 hours post-dose. In contrast, mean LH concentrations reached a higher amplitude after triptorelin (150 IU/LH) and occurred sooner (approximately 12 hours post-dose). The proportion of subjects who achieved a maxiumum LH concentration > 50 IU/L increased with increasing dose of MVT-602. Changes in FSH concentrations followed a similar pattern to those observed for LH. Estradiol levels after MVT-602 administration were approximately 2000 pmol/L or less in subjects whose pre-dose baseline values were 1000 pmol/L or less. In all MVT-602 dose groups, progesterone concentrations rose from approximately 50 hours post-dose and continued to increase up to 120 hours post-dose. Administration of MVT-602 was generally well tolerated in this study with no apparent dose-dependent trends in safety parameters and, as expected, no ovarian hyperstimulation was observed.

Limitations, reasons for caution:

A minimal stimulation protocol was used to avoid unethical unnecessary stimulation of healthy women who were not seeking conception. Further research is indicated in subfertile women treated with a full COS protocol to establish the safety and efficacy of MVT-602 as a trigger of oocyte maturation in IVF treatment.

Wider implications of the findings:

The LH profile after MVT-602 is of lower amplitude and longer duration than GnRH agonist. However, the LH profile was still a shorter duration than following hCG suggesting MVT-602 could offer an ideal novel agent to trigger oocyte maturation during IVF treatment, that balances the risks of over and under-stimulation.

[2]Arcispedale Santa Maria Nuova, Department of Obstetrics and Gynaecology-Fertility center, Reggio Emilia, Italy

[3]Merck KGaA, Merck Serono S.p.A - Rome- Italy, Darmstadt, Germany

Study question:

Is the individual response to gonadotropins predictable?

Summary answer:

Granulosa cells (hGLC) from normo-responder women display higher cAMP and progesterone production *in vitro*, as well as estradiol levels *in vivo*, than sub-responders.

What is known already:

The various stimulation protocols do not provide the best stimulation setting and some patients may be subjected to inadequate stimulation resulting in clinical treatment failure. It is expected that hGLC discarded samples donated by normo-responder and sub-responder women undergoing assisted reproduction (ART) feature specific follicle-stimulating hormone (FSH) receptor (FSHR) expression and response to gonadotropins in vitro, suggesting they may be used for predicting the response *in vivo* of normo- *versus* sub-responder women.

Study design, size, duration:

hGLC samples from anonymized donor women undergoing oocyte retrieval for ART are collected during a 30-months period (2017-2019). Cells are purified, cultured, genotyped and treated by gonadotropins *in vitro* and intracellular signaling endpoints are collected. Data obtained by cells from 105 normo-responder women are compared to those from 105 sub-responders, which are identified as patients providing ≤4 oocyte retrieved. Experiments are performed under the local Ethics Committee permission (n°2018/0080377, 16/07/2018) and donor written consent.

Participants/materials, setting, methods:

hGLC donor women undergone ART without endocrine abnormalities and infectious diseases. hGLC samples are genotyped for FSHR polymorphisms known to modulate the response to FSH (rs6166, rs6165, rs1394205) and stimulated by increasing doses (nM range) of recombinant FSH (Gonal-F, Merck KGaA, Darmstadt, Germany). cAMP and progesterone are measured by immunoassays and dose-response curves performed. Results from samples will be used as reference Control Group and/or compare different sample populations, together with clinical data.

Main results and the role of chance:

To date, 76 samples resulted to be eligible for *in vitro* stimulation. 3-h cAMP data from normo- *versus* sub-responder women resulted in different potency, as demonstrated by 50% effective concentrations (EC50) *in vitro* (FSH EC50 normo-responders=5.8±4.9 nM; EC50 sub-responders=2.4±9.8 nM; $p<0.05$; t-test), and different *plateau* levels, indicating phenotype-specific efficacy (cAMP *plateau* normo-responders=37.34±5.3 pmol/ml; cAMP *plateau* sub-responders=15.69±4.2 pmol/ml). 24-h basal progesterone production of cells from normo-responder women is about 1.3-fold higher than that of cells from sub-responders. Most importantly, both the groups of data confirmed that FSH elicit phenotype-specific response, depending on the normo- or sub-responder *status*. Indeed, FSH EC50, and progesterone basal and *plateau* levels are higher in cells from normo-responders versus sub-responders ($p<0.05$; t-test). Distribution of FSHR genotypes was evaluated by contingency analysis. No different allele frequencies and *FSHR* expression levels between normo- versus sub-responders were found (Chi square and t-test; $p>0.05$; n=55), demonstrating that each the two groups are genetically homogeneous. Estradiol levels are higher in normo- than sub-responders (2026±903.5 *versus* 1375±898.9 pg/ml; t-test; $p>0.05$; n=49). We demonstrate that normo-responders display higher sensitiveness to FSH than sub-responders, revealing association between intracellular signaling, estradiol production and follicle growth.

Limitations, reasons for caution:

To date, patient recruitment is still ongoing and about one hundred individuals should be required to achieve proper statistical power.

Wider implications of the findings:

This study may predict the individual response to personalize ART protocol, in case of stimulation cycle planning after previous failures. Given the different in-vitro response between cells from normo- vs sub-responders, we expect that this in-vitro assay could lead to future clinical trials that may confirm in vitro results.

O-283 Pharmacokinetics and pharmacodynamics of a new recombinant human chorionic gonadotropin (rhCG) in healthy women and men after single and multiple subcutaneous administration

L.E.B. Kyhl[1], P. Larsson[2], K. Bruzelius[3], B. Mannaerts[4]

[1]Ferring Pharmaceuticals A/S, Translational Medicine, Copenhagen, Denmark

[2]Ferring Pharmaceuticals A/S, Global Biometrics, Copenhagen, Denmark

[3]Ferring Pharmaceuticals A/S, Department of Bioanalysis, Copenhagen, Denmark

[4]Ferring Pharmaceuticals A/S, Reproductive Medicine and Women's Health, Copenhagen, Denmark

Study question:

Do pharmacokinetic and pharmacodynamic characteristics differ between rhCG expressed in a human cell line and rhCG expressed in a Chinese hamster ovary (CHO) cell line?

Summary answer:

The pharmacokinetics of the two rhCG preparations were different, causing higher exposure and a higher pharmacodynamic response for hCG expressed in a human cell line.

What is known already:

In current clinical practice, urinary or recombinant hCG is administered for treatment of infertility either during ovarian stimulation or to trigger final follicular maturation. The new rhCG (FE 999302) currently in development is produced by a human-derived cell line, PER.C6. The amino acid sequence of the α- and β-chains are identical to that of rhCG expressed by CHO cells (choriogonadotropin alfa, Ovitrelle®), but the glycosylation profile differs between the two rhCG preparations.

Study design, size, duration:

Part 1 treated five female cohorts with single ascending doses from 4 to 256 µg of FE 999302 or placebo (N=35). Part 2 treated two female cohorts with

multiple ascending doses of 8 or 16 µg FE 999302 or placebo for 10 days via daily injections (N=16). Part 3 administered single 125 µg injections of both FE 999302 and rhCG expressed in a CHO cell line to 33 males in a randomised crossover design.

Participants/materials, setting, methods:

Women and men were pituitary-suppressed by contraceptives and triptorelin, respectively and all rhCG injections were administered subcutaneously in the abdominal wall. Serum hCG and testosterone levels (men only) were assessed at pre-dose and up to 264 hours. Pharmacokinetic parameters of hCG and pharmacodynamic parameters of testosterone were calculated using non-compartmental methods. Analysis of serum hCG and testosterone concentrations was performed by means of a validated immunoassay, and validated liquid chromatography and mass spectrometry method, respectively.

Main results and the role of chance:

In women, the area under the curve (AUC) and the peak serum concentration (C_{max}) increased consistently with dose proportionality following single and multiple doses of FE 999302. The apparent clearance (CL/F) was approximately 0.5 L/h, the mean terminal half-life approximately 45 hours and the apparent distribution volume (Vz/F) approximately 30 L. After single administration of rhCG in down-regulated men, mean AUC was 1.5-fold greater for FE 999302 than for rhCG expressed in CHO cells. Mean C_{max} was similar for the two preparations. In accordance with the differences in AUC, the apparent clearance (i.e. the ratio CL/F) was lower for FE 999302 (CL/F 0.5 vs 0.8 L/h), respectively, explained by a longer terminal half-life (47 vs 32 hours). The apparent distribution volumes (Vz/F) were comparable. The concentrations of testosterone (reflecting production of testosterone as a response to hCG exposure) reflected the pharmacokinetic profiles with a slight delay, resulting in 59% higher AUC with FE 999302. The pharmacokinetic parameters for FE 999302 were comparable in men and women at doses of 125 and 128 µg, respectively.

Limitations, reasons for caution:

Differences between rhCG expressed in a human cell line and in a CHO cell line were assessed in men only. However, since the PK differences of gonadotropins between men and women are known to be limited, differences similar to those found in men would also be expected in women.

Wider implications of the findings:

Due to pharmacokinetic differences, the therapeutic dose(s) for rhCG expressed in a human cell line are likely to be different from those of rhCG expressed in a CHO cell line.

O-284 Association between leukaemia inhibitory factor (LIF) gene polymorphism (rs929271) and sperm quality and sperm DNA integrity

R.L. Baruffi[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], B. Petersen[1,2], M.C. Mattila[1], A. Nicoletti[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], J.G. Franco Jr[1,2]

[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil

Study question:

Is there an association between leukaemia inhibitory factor (LIF) thymine (T)>guanine (G) (rs929271) gene polymorphism and sperm quality and sperm DNA integrity?

Summary answer:

Males carrying the G allele(TG/GG genotypes) exhibited decreased counts of sperm with normal morphology and impaired sperm protamination when compared to males carrying the TT-genotype.

What is known already:

LIF is a cytokine that plays a critical role in the human reproductive process. Changes in the expression of the LIF gene have been associated with infertility. A higher prevalence of mutations near the start codon of exon 1 and exon 3 was observed in infertile women.The single nucleotide polymorphism (SNP) T>G (rs929271) located in the untranslated region 3′ of the LIF gene has been associated with use of fertility medication, human embryo survival, and implantation and pregnancy outcomes after ART. However, the influence of LIF gene polymorphisms on semen quality is not usually analysed.

Study design, size, duration:

The study enrolled 364 men from couples submitted to infertility assessment. Individuals with genital tract disorders/azoospermia were excluded. The semen analysis results derived from one sample of semen of each enrolled man were recorded (WHO criteria/morphology:motile sperm organelle morphology examination/MSOME). For DNA integrity analysis, the proportions of DNA fragmentation (by TUNEL assay), abnormal chromatin packaging/underprotamination (by chromomycin A3/CMA3), abnormal mitochondrial membrane potential (MMP/by MitoTracker Green), and apoptosis (by annexin-V) were recorded.

Participants/materials, setting, methods:

DNA was extracted from peripheral blood samples taken from each participant and the LIF T>G SNP (rs929271) was genotyped by real-time PCR. The men were divided into three genotype groups according to their results: TT; TG; or GG. Potential confounders (age, abstinence, smoking, drinking alcohol, and varicocele) were also observed. The level of significance was set at $P<0.05$. Hardy-Weinberg genotype distributions of the entire sample indicated concordance between the observed and expected frequencies.

Main results and the role of chance:

No correlation was observed between LIF T>G and age, abstinence, smoking, drinking alcohol, or varicocele. The LIF genotypes carrying the G allele were associated with higher proportions of spermatozoa with abnormal chromatin packaging and lower proportions of normal spermatozoa. There was no association between LIF genotypes and other semen parameters (Table 1).

Limitations, reasons for caution:

A possible limitation is the cross-sectional nature of the data. Furthermore, the study was conducted with couples seeking fertility treatment and might therefore be biased toward infertility. Differences in the genetic backgrounds of various ethnic populations might also be considered.

Wider implications of the findings:

The results indicated that a simple genetic variation (LIFT>G rs929271 gene polymorphism) apparently affects semen quality. Additional validation of the analysed SNP (increasing the number of cases) is required to confirm these findings and provide information about clinical implications

Trial registration number:

Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

O-285 The role of sperm surface galectin-3 in zona pellucida binding and its association with fertilization in vitro

P.C.N. Chiu[1], S. Mei[1], P. Chen[2], C.L. Lee[1], W. Zhao[2], Y. Wang[1], K.K.W. Lam[1], P.C. Ho[1], W.S.B. Yeung[1], C. Fang[2]

[1]The University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

[2]The Sixth Affiliated Hospital of Sun Yat-Sen University, Reproductive Medicine Research Center, Guangzhou, China

Study question:

Is sperm surface galectin-3 involved in spermatozoa-zona pellucida (ZP) interaction?

Summary answer:

Galectin-3 is transferred to sperm surface by extracellular vesicles (EVs) during post-testicular maturation and plays a critical role in sperm-ZP binding after capacitation.

What is known already:

Human spermatozoa leaving the testis can fertilize an oocyte only after post-testicular maturation and capacitation. These processes involve modification and reorganization of molecules on the sperm plasma membrane, resulting in acquisition of the binding ability of the spermatozoa to the ZP of the oocyte. Defects in the binding are major causes of male subfertility. Galectin-3 is a secretory lectin well known for its action on cell adhesion and surface receptor trafficking/clustering. In the male reproductive tract, galectin-3 protein has been identified in Sertoli cells, epididymis, seminal plasma, ejaculated spermatozoa and EVs.

Study design, size, duration:

The expression of galectin-3 in seminal plasma/spermatozoa and its association with fertilization rate in clinical assisted reproduction were studied. The roles of galectin-3 on sperm function were assessed by functional blocking anti-galectin-3 antibody and galectin-3 competitive carbohydrate substrate.

Participants/materials, setting, methods:

Spermatozoa were obtained from semen samples from normozoospermic men. Human oocytes were obtained from an assisted reproduction program. EVs were isolated from the cell-free seminal plasma by sequential centrifugation and microfiltration. The localization and expression of galectin-3 was studied by immunostaining, Western blotting, ELISA, immunogold transmission electron microscopy and flow cytometry. Sperm functions including motility, viability, acrosome reaction and ZP-binding capacity were assessed by standard assays.

Main results and the role of chance:

The acrosomal region of ejaculated and capacitated spermatozoa possesses strong galectin-3 immunoreactivity, which is much stronger than that of epididymal spermatozoa. Expression of galectin-3 can also be detected on seminal plasma-derived EVs which can be transferred to the sperm surface. Blocking of sperm surface galectin-3 function by specific antibody against galectin-3 or competitive carbohydrate substrate reduced the ZP-binding capacity of human spermatozoa. Galectin-3 level in seminal plasma-derived EVs was positively associated with fertilization rates.

Limitations, reasons for caution:

The mechanisms by which galectin-3 regulates spermatozoa-ZP binding have not been depicted.

Wider implications of the findings:

Seminal plasma galectin-3 may be a biomarker for male infertility, relating to spermatozoa-ZP binding capacity. In addition, modulation of the surface galectin-3 content of the spermatozoa of subfertile men may help to increase fertilization rate in assisted reproduction.

O-286 Sperm membrane Glucose regulated protein 78 (GRP78) crosstalk with activated alpha-2-macroglobulin (α2M*) chaperones sperm motility

V. LOBO[1], P. Parte[1]

[1]ICMR- National Institute for Research in Reproductive Health, Gamete Immunobiology, Mumbai, India

Study question:

What is the role of sperm membrane-bound Glucose regulated protein 78 (GRP78) in sperm function?

Summary answer:

Alpha-2-macroglobulin (α2M) secreted by Sertoli cells, upon activation, binds to sperm surface GRP78 during epididymal transit thereby facilitating sperm motility via actin reorganization.

What is known already:

GRP78, a resident endoplasmic reticulum (ER) chaperone is expressed on the cell surface in exceptional conditions as seen in cancer cells and macrophages. α2M from blood plasma upon activation (α2M*) reportedly binds surface GRP78 regulating macrophage motility. We have previously reported membrane localization of GRP78 on rat and human sperm and have shown that its tyrosine phosphorylation significantly increases during epididymal maturation. In human sperm, we have reported GRP78 phosphorylation to be significantly reduced in asthenozoosperm as compared to normozoosperm. Literature suggests significantly low levels of seminal plasma α2M in asthenozoosperm.

Study design, size, duration:

α2M presence, its co-localization and interaction with sperm surface GRP78, cofilin pathway proteins and intracellular calcium levels [$(Ca^{2+})_i$] in testicular (immature) sperm [Tsp] and caudal epididymal (mature) sperm [Cdsp] were determined. Upon incubation of Tsp with α2M*, the influence of this interaction on i) $[Ca^{2+}]_i$ levels ii) Membrane GRP78 tyrosine phosphorylation iii) Activation of downstream cofilin signaling pathway using specific inhibitors iv) Flagellar F-actin v) Cofilin translocation vi) motility changes in sperm was studied.

Participants/materials, setting, methods:

Cdsp and Percoll purified Tsp from adult Holtzman male rats were used. Western blot (WB) analyses performed for α2M, GRP78, cofilin pathway proteins. Surface- α2M and GRP78 determined by IIF and ELISA. Fura-2AM employed for $[Ca^{2+}]_i$ assays. Interaction studies and membrane-GRP78

phosphorylation status determined by Immunoprecipitation. Sperm- head and tail fraction proteins analyzed by WB in cofilin translocation studies. Sperm motility studied under light microscope. F-actin status and cofilin abundance demonstrated by IF. (n≥ 3)

Main results and the role of chance:

α2M expression was observed on the head, midpiece and principal piece of mature sperm (Cdsp). A weak and speckled localization was observed on immature sperm (Tsp). It co-localizes and interacts with membrane GRP78 in Cdsp but not in Tsp. The key proteins involved in cofilin pathway are present in both Tsp and Cdsp, however the pathway is more active in Cdsp than Tsp. $[Ca^{2+}]_i$ levels were significantly higher in Cdsp compared to Tsp. Treatment of Tsp with α2M* significantly increased $[Ca^{2+}]_i$ levels and activated the cofilin signalling pathway significantly. Cofilin-, LIMK-, Rac-, Cdc42-, & PAK phosphorylation, GRP78 tyrosine phosphorylation in lysate obtained from Tsp incubated with α2M* increased significantly as compared to Tsp treated with α2M. Significant increase of F-actin was observed with significant decrease of cofilin (actin severing protein) in the flagella, when Tsp were exposed to α2M*. This increase was abrogated in presence of PI3K inhibitor (LY294002) and tyrosine kinase inhibitor (Genistein) whereas Ras FTase inhibitor (Manumycin A) had no effect. Thus, profiles observed with mature sperm (Cdsp) could be re-created when immature sperm (Tsp) were exposed to α2M*. The basal motility levels of Tsp was maintained upon exposure with α2M* as compared to Tsp incubated with α2M.

Limitations, reasons for caution:

Rat Tsp and Cdsp used as representation of immature- and mature sperm respectively, due to difficulty in obtaining testicular biopsies from fertile individuals to obtain immature sperm required to address the research question. Evidences that α2M is largely in native form in testis and as α2M* in epididymis, is indirect.

Wider implications of the findings:

α2M interacts with sperm surface GRP78 during epididymal transit, increases GRP78 phosphorylation thereby activating cofilin pathway which prevents flagellar F-actin depolymerization. As F-actin is required for maintaining sperm motility, our finding has significant implication as our previous reports show reduced GRP78 phosphorylation and altered actin based motility pathway in asthenozoosperm.

O-287 Aberrant vitamin A and K signaling in the local testis microenvironment and their impact on extracellular matrix (ECM) composition

F. Pederzoli[1], I. Locatelli[1], P. Capogrosso[1], E. Ventimiglia[1], M. Nebuloni[2], F. Montorsi[1], A. Salonia[1], M. Alfano[1]

[1]IRCCS Ospedale San Raffaele, Division of Experimental Oncology/Unit of Urology-URI - Urological Research Institute, Milan, Italy

[2]L. Sacco Hospital- Università degli Studi di Milano, Pathology Unit- Department of Clinical Sciences, Milan, Italy

Study question:

To study pathogenic features of the somatic testicular microenvironment associated with idiopathic germ cell aplasia.

Summary answer:

Impaired vitamin A and K signaling in human Sertoli and Leydig cells are associated with an unbalanced composition of testicular ECM and germ cell aplasia.

What is known already:

Several studies have established the relevance of the somatic microenvironment, including the ECM, in supporting spermatogonial stem cell differentiation. Indeed, germ cells of an infertile man or an aged mouse show to retain their capability of generating functional spermatozoa for a long time when, upon transplantation into a healthy or younger recipient's testis, they mature into functional spermatogonia. Conversely, spermatogonial stem cells from young mice transplanted into atrophic testicles are unable to promote and support spermatogenesis. Moreover, the testis contains 102 proteins ascribed to the ECM, whose role in supporting human spermatogonial stem cell survival was recently described.

Study design, size, duration:

Cross-sectional study carried out at a single tertiary referral center for male infertility. 20 testicular specimens from infertile men affected by idiopathic non-obstructive azoospermia, undergoing micro testicular sperm extraction (microTESE). Primary Sertoli cells with normal karyotype and phenotype were also used.

Participants/materials, setting, methods:

Proteomic analysis of the ECM from testicular specimens with positive vs. negative sperm retrieval. Gene ontology enrichment was used to identify upstream regulators based on the 11 deregulated ECM proteins, which were validated by immunohistochemistry and quantitative PCR. Continuous variables were expressed as medians and interquartile range.

Main results and the role of chance:

Germ cell aplasia was characterized by an increased signaling of the retinoic acid in Sertoli cells, and associated with decreased expression of the basal membrane markers Nidogen-2 and Heparan sulfate proteoglycan-2. In vitro stimulation of Sertoli cells with retinoic acid down regulated the expression of Nidogen-2 and Heparan sulfate proteoglycan-2, but not Laminin-4 and Laminin-5. The immature phenotype of Sertoli cells in the testis parenchyma with germ cell aplasia was further demonstrated by the high systemic level of the Anti-Mullerian Hormone. Decreased levels of the interstitial matrisome-associated Factor-IX and its regulator vitamin K epoxide reductase complex subunit 1 (VKORC1) were, rather, coupled with decreased signaling of vitamin K in Leydig cells. An altered expression of 8 further ECM proteins was also found, including Laminin-4 and Laminin-5. Peripheral levels of the two vitamins were within the reference range in the two cohorts of iNOA men.

Limitations, reasons for caution:

Limited number of patients from a single center. Further studies are needed to better define the causative mechanism of vitamin A and K dysfunction in the testis of men with complete germ cell aplasia.

Wider implications of the findings:

Our findings open new perspectives to look for the dysregulating mechanisms of the metabolic cycle of vitamin A and vitamin K in the Sertoli and Leydig cells, respectively, such as epigenetics silencing, post-transcriptional modifications, detrimental effect of commensal microbiome, eventually shedding light on male azoospermia.

O-288 High-throughput differential proteomics identifies altered mitochondrial and proteasomal sperm function in repeated fertilization failure

M. Torra[1], M. Jordar[2], M. Barragan[1], A. Soler-Ventura[2], D. Delgado-Dueñas[2], A. Rodríguez[1], R. Oliva[2], R. Vassena[1]

[1]Clinica Eugin, Assisted reproduction, Barcelona, Spain

[2]University of Barcelona, Molecular Biology of Reproduction and Development Group, Barcelona, Spain

Study question:

Do sperm samples from patients who suffered repetitive fertilization failure (FF) after ICSI present alterations in their protein contents?

Summary answer:

Sperm samples producing FF after ICSI show several alterations in the expression of mitochondrial and proteasomal proteins.

What is known already:

Unexplained fertilization failure, occurring in 1-3% of ICSI cycles, results in both psychological and financial burden for the patients, and it is often challenging for the clinicians because its causes remain largely unknown. Although altered PLCz function can cause FF, other mechanisms are also likely to be involved. Mass spectrometry is a powerful technique to identify and quantify proteins across samples, however, no study so far has used it to dissect the proteomic signature of sperm with FF after ICSI. We aim at identifying target mechanisms and pathways that could explain FF aetiology and, potentially, predict its recurrence.

Study design, size, duration:

We compared the sperm protein profile of 12 men undergoing ICSI according to fertilization rates by high-throughput proteomics (4 patients with >2 consecutive FF cycles and 8 patients with fertilization rates >75%). Differential

expression of proteins was validated by Western Blot and functional analysis of mitochondrial and proteasomal activity was determined by FACS analysis of JC-1 staining and AMC-peptide fluorimetric assay, respectively. The study period was 24 months.

Participants/materials, setting, methods:

Sperm samples were processed by 50% density-gradient, lysed, and protein extracts were used individually for TMT-labelling, followed by two-dimensional liquid chromatography and tandem mass-spectrometry (2D-LC-MS/MS) to identify and quantify proteins. Conventional (t-test on the relative quantification values) and novel approaches (stable-protein pairs) were carried out to analyze quantitative proteomic data to assess altered proteins in repetitive FF patients. Those altered proteins were validated in 11 samples by other techniques.

Main results and the role of chance:

A total of 1400 proteins were identified with at least one unique peptide and 232 proteins were considered for further analysis using our quantification strict criteria (<1% FDR, ≥2 PSM per unique peptide, <50% variation among samples). Four proteins presented lower abundance (FMR1NB, FAM209B, RAB2B, PSMA1) in the FF group compared to the control group ($p<0.05$), while five mitochondrial proteins had higher abundance in the FF group (DLAT, ATP5H, SLC25A3, SLC25A6, FH). Stable-protein pairs analysis identified 146 correlations comprising 28 proteins in controls, while in the FF samples >50% of correlations were lost, mainly for proteins related to mitochondrial function (i.e. PDHA2, PHB2, ATP5F1D). Altered abundance of DLAT (member of the pyruvate dehydrogenase complex) and PSMA1 (essential for proteasome function) in patients with repetitive FF was validated by Western-Blot. The mitochondrial function assessment revealed that FF patients have a slightly lower percentage of sperm containing active mitochondria (71.98 ± 20.2) compared to controls (59.12 ± 12.9) *but not reaching* statistical significance. Moreover, proteasome activity was lower in FF samples compared to controls (0.206 ± 0.08 vs. 0.352 ± 0.18 proteasome activity units, respectively). Altogether, these results suggest that mitochondrial and proteasomal functions could be altered in patients with repeated FF.

Limitations, reasons for caution:

Although strict criteria were used to select the couples in the study, an oocyte contribution to FF cannot be completely ruled out. Repeated FF cases are rare, and 4 cases were included. However, this is in line with other studies to identify molecular causes of infertility by high-throughput proteomics.

Wider implications of the findings:

This is the first proteomic analysis of sperm from patients with repeated FF after ICSI. The differentially expressed proteins and the dysregulation of mitochondrial and proteasomal functions could help to identify diagnostic/prognostic markers of FF and further dissect the paternal molecular contribution to successful fertilization.

O-289 Mapping the genital tract: Using male gamete genomic integrity to guide reproductive outcome

R. Setton[1], P. Xie[1], D. Keating[1], A. Parrella[1], M. Goldstein[2], Z. Rosenwaks[1], G.D. Palermo[1]

[1]*Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.*

[2]*Weill Cornell Medicine, Center for Male Reproductive Medicine, New York, U.S.A.*

Study question:

Does sperm chromatin fragmentation (SCF) vary in different areas of the male genital tract, and is it useful for enhancing reproductive treatments?

Summary answer:

SCF decreases closer to the seminiferous tubule, suggesting that the utilization of surgically retrieved spermatozoa enhances implantation and clinical pregnancy rates.

What is known already:

Sperm genome integrity plays a crucial role in male reproduction. Physiological DNA severing is a prerequisite for supercoiling and nuclear compaction during spermiogenesis. The sequential process is highly conserved and ordained by DNAse and ligase mechanisms. If proper repair fails, suboptimal spermatozoa are picked up by the epididymis and phagocytized. When this downhill mechanism fails, leakage of abnormal spermatozoa may manifest in the ejaculate. Higher SCF can also be attributed to reactive oxygen species hindering the gametes during their permanence in and transit through the male genital tract.

Study design, size, duration:

In a preliminary assessment, clinical outcome was compared between men with normal (n=200) and abnormal (n=122) SCF. A total of 83 consenting men with abnormal ejaculate SCF who had failed to conceive with ICSI utilizing ejaculated spermatozoa agreed to undergo surgical retrieval in order to assess the genomic integrity of their spermatozoa at different levels of the genital tract. Some of these men (n=45) underwent 78 ICSI cycles utilizing surgically retrieved spermatozoa.

Participants/materials, setting, methods:

Ejaculated specimens were screened by terminal deoxynucleotidyl dUTP nick-end labeling (TUNEL) assay using a commercially available kit, or SCSA. For TUNEL, a minimum of 500 spermatozoa were counted per specimen using fluorescent microscopy with a threshold of 15% as normal. Surgical samples were analyzed by TUNEL assay on specimens isolated from the vas deferens, epididymis, and testes before being cryopreserved in multiple vials for subsequent ICSI cycles.

Main results and the role of chance:

In the preliminary assessment, ICSI outcomes utilizing ejaculated spermatozoa were compared between men with normal (n=200, 9.3±3%) and abnormal (n=122, 22.6±9%) SCF. While fertilization and clinical pregnancy rates (CPR) did not differ between the 2 groups, the implantation rate was significantly impaired (P=0.04) in men with abnormal DNA fragmentation.

Surgical mapping showed that SCF decreased from 32.9±20.0% in the ejaculate to 20.0±9.6% in the vas deferens, 15.8±7.7% in the epididymis, and 11.5±5.7% in the testis.

In ICSI cycles utilizing ejaculated spermatozoa (n=35) with fragmented chromatin (n=85), the fertilization, implantation, and clinical pregnancy rates were 68.2%, 7.6%, and 13.9%, respectively. Of those clinical pregnancies, 20% resulted in a miscarriage.

For the men (n=45) who failed to conceive using ejaculated spermatozoa, frozen epididymal or testicular spermatozoa with normal SCF were used for a subsequent ICSI cycle (n=78). For this cycle, the fertilization rate was 66.9%, the implantation rate was 19.6% (P = 0.001), the clinical pregnancy rate was 40.0% (P < 0.001), and the clinical pregnancy loss fell to 14.3%.

Limitations, reasons for caution:

Surgical retrieval of spermatozoa is an invasive approach that carries a surgical risk. It should only be considered after extensive patient counseling and should be limited to cases in which other approaches have failed. This study utilizing surgically retrieved spermatozoa to treat this form of male-factor infertility is still preliminary.

Wider implications of the findings:

Topographic mapping of SCF demonstrated that sperm DNA integrity was progressively compromised as the gamete advanced through the male genital tract. Surgical retrieval of spermatozoa may be beneficial in men who struggle to achieve pregnancies due to compromised genomic integrity of their gametes.

Wednesday 26 June 2019 Haydn 3 14:00 - 15:30

O-290 Predicting the euplody status of the embryos by using evolutionary algorithm in IVF PGT cycles – A 10793 embryos review

O. Barash[1], K. Ivani[1], M. Hinckley[2], D. Wachs[2], M. Homer[2], S. Pittenger Reid[2], L. Weckstein[2]

[1]*Reproductive Science Center of the San Francisco Bay Area, IVF laboratory, San Ramon, U.S.A.*

[2]Reproductive Science Center of the San Francisco Bay Area, IVF Team, San Ramon, U.S.A.

Study question:
Can evolutionary algorithms, model ensembling, and synthetic features be used to evaluate euploidy rates in autologous IVF PGT-A cycles?

Summary answer:
Evolutionary algorithms can be used to evaluate euploidy rates in autologous IVF PGT-A cycles and define factors affecting euploidy rates with high accuracy.

What is known already:
The number of chromosomal aneuploidies in preimplantation embryos progressively increases with advancing maternal age. Euploidy rates may vary significantly and can be affected by clinical as well as IVF laboratory protocols.

Study design, size, duration:
2052 cycles of IVF PGT-A treatment between January 2013 and January 2019 were included in the study (average age 36.4 ± 4.5). A total of 10793 embryos were analyzed (5.2±2.9 per case). 175 clinical factors (age, BMI, AMH, FSH, AFC, gravidity history, etc.) and 145 morphological and kinetic parameters (number of eggs, number of 2PNs, embryo morphology, euploidy rate, biopsy day, etc.) were recorded for each PGT-A cycle.

Participants/materials, setting, methods:
From 320 original features, 38719 synthetic features were created (by Weight of Evidence for columns, Encoding of categorical levels of the feature, Cross Validation Target Encoding, Time series, etc.), tested, and 331 features were selected for each PGT-A cycle. 40 statistical models were trained and ensembled in the final model. Predictive accuracy was evaluated by 10-fold cross-validation and AUC value (ROC curve). In order to select the most relevant features, the evolutionary algorithm was used

Main results and the role of chance:
Analysis of the combined predictions from multiple weak learners (generalized logistic regression, random forest, gradient boosting, etc.) processed by Generalized Model Stacking produced a predictive performance of AUC = 0.7106 ± 0.0072, Logloss = 0.619 ± 0.006, GINI = 0.414 ± 0.019. Sensitivity (true positive rate) of the final model was 0.821 and specificity (true negative rate) was 0.771. In order to evaluate precision and recall of the model, F-measure was calculated (harmonic mean) – 0.732 ± 0.008. The probability of normal chromosomal status was calculated for each embryo and ranged from 0.133 to 0.946 (baseline prediction – 0.536). All contributing variables were evaluated: the variables of highest importance affecting euploidy rates in the ensembled model were the maternal age, morphological characteristics of the blastocysts, and time when blastocysts became available for biopsy (0.372, 0.233, and 0.118 respectively).

This statistical model can be used to: a) estimate euploidy rates in non-PGT-A cycles and determine the number of embryos to transfer based on unique patients' input parameters and priorities; b) define, rank, and evaluate the factors affecting euploidy rates in IVF PGT-A cycles.

Limitations, reasons for caution:
Retrospective study and heterogeneity of patients included.

Wider implications of the findings:
Analysis of data proved that euploidy rates can be accurately estimated from the large clinical datasets in order to create a reliable model and make predictions on prospective data with high accuracy.

Trial registration number:
Not applicable.

O-291 Segmental aneuploidies detection shows mosaic patterns from different biopsies of human blastocyst with consequent reduced predictive diagnostic value compared to whole chromosome aneuploidies

Study question:
Does NGS-based PGT-A provide reproducible results in detecting whole chromosome and segmental aneuploidies in multifocal trophectoderm (TE) and ICM biopsies of the same embryo?

Summary answer:
NGS-based PGT-A confirms consistent results for whole chromosome aneuploidies in multifocal biopsies, while recurrent mosaic patterns are observed for segmental aneuploidies lowering its predictive value.

What is known already:
The introduction of highly sensitive NGS platforms for PGT-A applications concurred with an increased detection of segmental aneuploidies. Whilst whole chromosome aneuploidies are common features of human preimplantation embryos, it is not yet clear whether the detection of segmental alterations represents a true biological finding or a technical variation in the analytical process. Recent studies focused on understanding whether segmental aneuploidies derive from mitotic or meiotic events, however, definitive data are still lacking. To further contribute on the characterization of segmental aneuploidies and their biological significance, here we evaluated multifocal portions of TE tissues and Inner Cell Mass (ICM).

Study design, size, duration:
Following technical validation on cell lines carrying segmental aneuploidies, a cohort study, blinded to the geneticist, was performed between January 2018 and October 2018. 55 embryos known to carry segmental aneuploidies, either in concomitance (n=24) or not (n=31) with whole chromosome aneuploidies were subjected to re-biopsy. PGT-A results from the second biopsies were compared with the original clinical results in order to define the uniformity of segmental alterations in different TE sections.

Participants/materials, setting, methods:
After initial PGT-A analysis and genetic counselling, patients who wanted diagnostic confirmation for embryos carrying segmental aneuploidies >15Mb were enrolled. Embryos were warmed, allowed to re-expand and subjected to a second TE biopsy. An additional subset of 14 donated embryos was subjected to dissociation and ICM isolation. Each biopsy was processed using Ion ReproSeq PGS kit and sequenced on Ion S5 platform. Sequencing data were blindly analyzed with Ion-Reporter software and compared with original diagnosis.

Main results and the role of chance:
Regarding whole chromosome aneuploidies, comparisons between PGT-A results obtained from the first and second TE biopsy showed a concordance rate of 96.36% (n=53/55;95%CI=87.47-99.56) per sample and 99.84% (n=1263/1265;95%CI:99.43-99.98) per chromosome. Sensitivity per chromosome was 94.29% (n=33/35; 95%CI=80.84-99.30) and specificity 100% (n=1230/1230;95%CI=99.70-100.00). Regarding segmental aneuploidies, technical validation on cell lines resulted in 100% concordance (n=12/12;95%CI=73.5-100.0). Subsequently, overall PGT-A results showed that only 53.97% (n=34/63;95%CI=40.64-66.61) of segmental alterations were confirmed in the second TE biopsy. In this group of results, 30.16% (n=19/63;95%CI=19.23-43.02) of paired samples showed the same alteration, suggesting a meiotic origin. Of the remaining results, 23.8% of the alterations (n=15/63;95%IC=13.98-36.21) showed a different aneuploidy pattern. In detail, 11.11% (n=7/63;IC95%=4.59-21.56) carried the reciprocal segmental aneuploidy of the same chromosome fragment and 12.7% (n=8/63;IC95%=5.65-23.50) showed the corresponding whole chromosome aneuploidy. These findings suggest that a percentage of TE segmental alterations are present in a mosaic constitution, consistent with mitotic origin. Discordant results, defined as the absence of any other alteration on the chromosome affected by the segmental aneuploidy, were 46.03% (n=29/63; IC95%=33.39-59.06). Considering ICM samples, showing segmental aneuploidies in their corresponding clinical TE, 7 out of 13 showed concordant karyotype whilst in 6 of 13 samples the segmental alteration was not confirmed.

Limitations, reasons for caution:
The presence of equally-represented reciprocal aberrations in the second biopsy specimen could have reduced the concordance rate of segmental aneuploidies detection. The preliminary dataset of ICM examined is a further

limitation that we are filling up. The clinical value of embryos showing segmental abnormalities shall be evaluated in future studies.

Wider implications of the findings:

These data are important for patient counselling in cases when the embryo carries only segmental alterations, practitioners should inform patients that they might be mosaic. Concomitantly, the high rate of intra-blastocyst concordance observed for whole chromosome aneuploidies confirms their high clinical predictive value and diagnostic robustness of NGS for PGT-A.

O-292 The influence of ploidy status on the expression of DNA repair and cell cycle checkpoint genes in human preimplantation embryos

X. Sun[1], R. Odia[2], C. Williams[1], M. Campbell-Forde[1], I. Orach[1], G. Sugumar[1], J. Ben-Nagi[3], P. Serhal[3], S. Sen Gupta[1]

[1]University College London, Institute for Women's Health, London, United Kingdom
[2]The Centre for Reproductive & Genetic Health, Embryologist Team, London, United Kingdom
[3]The Centre for Reproductive & Genetic Health, Clinician Team, London, United Kingdom

Study question: Does ploidy status (euploid or aneuploid) of human preimplantation embryos affect the expression of DNA repair and cell cycle checkpoint genes in these embryos?

Summary answer: Expression of some DNA repair and cell cycle checkpoint genes including *GADD45A* and *CDKN1A* can be affected by ploidy status of human preimplantation embryos.

What is known already: In order to maintain the genetic integrity, human somatic cells established complex DNA repair and cell cycle checkpoint systems to respond to genetic errors. In human preimplantation embryos, a similar system responds to genetic errors, resulting in the loss or the arrest of embryonic cells when repair fails. However, in the early stage of development, cell cycle checkpoints allow rapid cell division despite the presence of genetic errors in embryos. Currently, how DNA repair and cell cycle checkpoint systems are regulated in human preimplantation embryos remains unclear.

Study design, size, duration: This is a prospective cohort study. Between 2016 and 2018, 114 human blastocysts were analysed in order to compare expression of DNA repair and cell cycle checkpoint genes between euploid embryos and aneuploid embryos. Among these embryos, 20 embryos were identified as euploid and 94 embryos were identified as simply aneuploid (<5 chromosomes were lost or gained) by trophectoderm biopsy followed by clinical aneuploidy screening using next-generation sequencing or array comparative genomic hybridisation.

Participants/materials, setting, methods: Before gene expression analysis, embryo and couple -related baseline data were collected from the fertility clinic. Gene expression of 16 genes including *GADD45A*, *PARP1*, *CDKN1A*, *BRCA2*, *RB1*, *TP53BP1*, *MPG*, *CREBBP*, *ERCC4*, *TUFM*, *FANCA*, *TP53*, *NF1*, *BRCA1*, *CHEK2*, and *XRCC6* was examined via qPCR. Correlations between ploidy status of embryos and expression of these genes were identified via multiple linear regressions, where all results were adjusted for baseline data of embryos and couples.

Main results and the role of chance: Both of *GADD45A* and *CDKN1A* are DNA damage response genes regulated by *TP53*. Results of this study showed that the expression of *GADD45A* (B = 14.487, *P* = 0.000) and *CDKN1A* (B = 16.726, *P* = 0.006) was positively correlated with the total number of chromosomes wholly lost or gained in blastocysts. The expression of *GADD45A* (B = 1.651, *P* = 0.039) and *CDKN1A* (B = 3.027, *P* = 0.028) was also positively correlated with the maternal age of embryos. This result indicated that human blastocysts responded to aneuploidy via upregulation of the expression of *GADD45A* and *CDKN1A*. When ploidy status was controlled for in linear regressions, the positive correlations between the maternal age and the expression of the two genes still existed. This indicated that embryos also responded to factors that were only advanced maternal age –related but not aneuploidy-related. In addition, this study identified that gene expression of many genes including *GADD45A*, *PARP1*, *RB1*, *MPG*, *CREBBP*, *TUFM*, *FANCA*, *BRCA1*, *CHEK2*, and *XRCC6*, was DNA-dose-dependent. In other words, for a gene A located on chromosome B, trisomy B and monosomy B lead to significantly increased and decreased expression of gene A in human preimplantation embryos, respectively.

Limitations, reasons for caution: This study was not a randomised trial and only limited samples were analysed. As qPCR is not a high-throughput analysis method, only a few genes were analysed. We plan to reanalyse all the samples via RNA-seq using next-generation sequencing in order to identify more related genes.

Wider implications of the findings: By RNA profiling of DNA repair and cell cycle checkpoint genes, quality of human preimplantation embryos can be assessed indirectly. An RNA-analysis-based method for human preimplantation embryo selection can be established in future, and infertile couples may benefit from the new method.

Trial registration number: Not applicable

O-293 Clinical outcome of balance chromosome rearrangement carrier diagnosis in preimplantation human embryos by MicroSeq technique

Study question:

Is microdissecting junction region (MicroSeq) a reliable method to distinguish between balanced carrier and non-carrier embryos in preimplantation genetic testing (PGT) cycles for balanced chromosome rearrangements (BCRs)?

Summary answer:

Combination of MicroSeq and breakpoint junction adjacent informative single nucleotide polymorphisms (AISNPs) analysis of BCRs is powerful for distinguishing between carrier and noncarrier balanced embryos.

What is known already:

Preimplantation genetic testing for structural chromosome abnormalities (PGT-SC) is widely applied in chromosome balanced rearrangement (CBR) carriers to increase the chance of a successful live birth. MicroSeq has been proven to be a powerful tool to distinguish between balanced/euploid carrier and non-carrier embryos in preimplantation genetic testing cycles for balanced translocation carriers.

Study design, size, duration:

This was a prospective study for 746 BCR carrier couples who requested for preimplantation genetic testing for structural chromosome abnormalities with a informed consent. The cohort patients were treated with the combination of a next-generation sequencing (NGS) based MicroSeq and PCR breakpoint junction region adjacent informative single nucleotide polymorphisms analysis of BCRs derivatives to distinguish between balanced/euploid carrier and non-carrier embryos in our IVF clinics between October 2014 and December 2018.

Participants/materials, setting, methods:

This study was conducted at the Reproductive and Genetic Hospital of CITIC-Xiangya, China. A total of 746 carrier couples (527 reciprocal translocation, 197 Robertsonian translocation, and 22 inversion) were recruited and participated in the two-phase study. In phase I, the rearrangement breakpoint and AISNPs were characterized by NGS and the microdissecting junction region for all 746 carriers. In phase II, AISNPs of junction region was used for linkage analysis to identify the truly normal embryos.

Main results and the role of chance:

MicroSeq can distinguish normal embryos and embryos with BCRs in all 746 cases. Trophectoderm biopsy was performed in 3883 blastocysts derived from 866 PGT-SC cycles. The signals of 3513 blastocysts were detected. Among them, 1351 blastocysts were diagnosed to be chromosomal balance with comprehensive chromosome testing. 690/1351 (51.07%) blastocysts were identified to be carriers and 661/1351 (48.93%) to be normal. The proportions of normal karyotype embryos obtained in reciprocal, Robertsonian and inversion carriers' couples were 16.8% (424/2523),

23.6%(208/883) and 29.9%(32/107), respectively. The proportions of carriers karyotype embryos obtained in reciprocal, Robertsonian and inversion carriers' couples were 17.2% (435/2523), 25.7% (227/883) and 28%(30/107), respectively. Cumulative 523 FET cycles (185 cycles with transfer of carrier embryos and 338 cycles with transfer of noncarrier embryos) were performed and resulted in 332 clinical pregnancies (120 from carrier embryo transfer and 212 from noncarrier embryo transfer). To date, 83 patients had prenatal diagnoses and 54 of them (65.1%) were confirmed normal fetus.

Limitations, reasons for caution:

These are preliminary results and the final clinical outcomes of the remaining 249 PGT-SC cycles are still not obtained. Further randomized clinical trials are needed to confirm the clinical benefit of MicroSeq for PGT-SC patients.

Wider implications of the findings:

The combination of MicroSeq and PCR breakpoint AISNPs analysis of BCRs derivatives is a universal, reliable, and accurate strategy for distinguishing between carrier and noncarrier balanced/euploid embryos. The method has potential application in clinical PGT-SC cycles for patients with BCRs.

Trial registration number:

Not applicable.

O-294 Parallel analysis of copy number aneuploidies and ploidy level by NGS and SNP array on single biopsy provides accurate results and improves PGT-A applications range

V. Romanelli[1], M. Fabiani[1], L. Girardi[1], L. Albricci[2], L. Rienzi[2], F.M. Ubaldi[2], S. Caroselli[1], D. Cimadomo[2], C. Patassini[1], M. Poli[1], C. Rubio[3], C. Simon[3], A. Capalbo[1]

[3]igenomix Valencia - molecular biology laboratory, Molecular Biology Laboratory, Valencia, Spain

Study question:

Can aneuploidies and ploidy level be effectively tested on the same embryo biopsy specimen?

Summary answer:

The combined use of NGS and SNP's B-Allele Frequency (BAF) was successfully validated for chromosome copy number and ploidy level assessments on single biopsy specimens

What is known already:

The inability to determine embryo ploidy level is a limitation of current NGS protocols. The development of a complementary PGT-A strategy combining ploidy assessment with aneuploidy testing using a single biopsy specimen expands the range of PGT-A applications. In particular, this approach improves PGT-A diagnostics for male patients showing high rate of diploid spermatozoa and couples with recurrent triploid conceptions. Additionally, it rescues euploid embryos derived from abnormally fertilized zygotes (1PN and >2PN). This strategy could be highly beneficial for those patients that show high rates of abnormal oocyte fertilization (AFO) and those with poor response to ovarian hyperstimulation protocols

Study design, size, duration:

Prospective blinded validation study. The effectiveness of our in-house algorithm at determining ploidy levels was evaluated by performing BAF analysis on nine embryo rebiopsies processed using SNP arrays (five 2PN and four AFO-derived embryos: two 1PN, one 3PN and one 2.1PN). Additionally, the accuracy of SNP-array and NGS-based combined analysis was evaluated by performing both PGT-A and PGT-SR on individual WGA products produced by 23 rebiopsied samples and 12 cell lines with known karyotype

Participants/materials, setting, methods:

SNP-array was performed by HumanKaryomap-12 kit on NextSeq550 (Illumina). Ploidy assessment algorithm was based on the genome-wide BAF obtained: expected BAFs were 1, 0.5 or 0 for diploids, 1 or 0 for haploid and 1, 0.66, 0.33 or 0 for triploids, as determined by the frequency of each allele for a specific locus investigated. PGT-A was performed by NGS ReproSeq kit on IonTorrent S5 (ThermoFisher) on the same MDA product used for SNP-array

Main results and the role of chance:

SNP-array data analysis with our custom-made algorithm confirmed the ploidy status in 100% of the samples with known ploidy (9/9,95%CI,65.5-100.0). Karyotypes obtained through NGS on the same MDA product used for SNP-array, showed high concordance with known expected karyotypes. In detail, we obtained PGT-A results on 91.3% of rebiopsies (21/23,95%CI,72.0-98.8), whilst 8.7% failed to amplify (2/23,95%CI,1.3-2.8). Per amplified sample, 85.7% karyotypes were confirmed (18/21,95%CI,64.5-95.9). The unconfirmed results, 14.3% (3/21,95%CI,4.1-35.5) showed previously undetected segmental aneuploidies. At the chromosome level, copy number of 99.4% of chromosomes were confirmed (480/483,95%CI,98.1-99.9), whilst 0.6% (3/483,95%CI,0.1-1.9) showed additional segmental aneuploidies. In parallel protocol validation experiments on cell lines, both NGS and SNP produced consistent results in all samples (6 NGS + 6 SNP, 12/12; 100.0%, 95% CI, 71.8-100.0). Hence, the lack of amplification or chromosome copy number confirmation in embryonic specimens is likely due to intrinsic biological variability of the sample rather than to analytical variability. These results demonstrate the effectiveness of our combined protocol to assess embryo ploidy status, both in regards of the algorithm developed, and the possibility of effectively employing SNP-array and NGS using the same WGA product generated from a single embryo biopsy specimen

Limitations, reasons for caution:

Ploidy assessment protocol was not tested to distinguish 3N triploids from 4N tetraploids. Furthermore, parents can be tested at their discretion. If parents were not tested, the parental origin of each chromosomal set could not be determined; therefore, in these cases, uniparental heterodisomy cannot be excluded in 2N diploid embryos

Wider implications of the findings:

The improved PGT-A scheme will allow extending the application of PGT-A to male patients with high rate of diploid sperm and couples with recurrent triploid conception. Importantly, the possibility of evaluating ploidy status of embryos derived from AFO, will allow clinical use of viable embryos otherwise considered non-transferable in IVF

Trial registration number:

none

O-295 Accuracy of mosaicism calling in PGT-A may be affected by cell numbers in biopsy specimens.

J. Wei[1], C. Zhang[1], X. Qin[1], C.J. Davidson[2], A. Harris[3], Z. Rosenwaks[1], K. Xu[1]

[1]Weill Cornell Medical College, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

[2]Thermo Fisher Scientific, research and development, South San Francisco, U.S.A.

[3]Thermo Fisher Scientific, research and development, Carlsbad, U.S.A.

Study question:

Would cell numbers of biopsy specimens influence the accuracy of diagnosis of various types of mosaicism in PGT-A?

Summary answer:

Comparing to a 5-cells model mimicking typical biopsy specimens, a larger sample size model of 10-cells tends to provide more accurate diagnostic result of mosaicism.

What is known already:

Recently, the application of Next Generation sequencing (NGS) in PGT-A has greatly enhanced the reporting of mosaicism. However, the clinical and diagnostic significance of mosaic profiles on NGS-based PGT-A results is still not well defined. This is mainly due to lack of systematic studies of contributing factors in the NGS-based PGT-A workflow that affecting the accuracy of mosaicism reporting, such as technique of laser ablation, biopsy size, methods of whole genome amplification, NGS platforms and mosaic calling algorithm.

Study design, size, duration:

From September to December 2018, an optimized NGS-PGT-A protocol to detect both aneuploidy and mosaicism was developed and validated using 4 Coriell cell lines with known karyotypes (46,XY; 47,XX,+21; 46,XY,del(4P) and 47,XY,+13). To test the effect of biopsy sample size to the sensitivity and specificity of the protocol, two models were used: 5-cells model mimicking typical biopsy specimens and 10-cells model. Precise number of cells were picked under dissection microscope and loaded into PCR tubes.

Participants/materials, setting, methods:

Cells from two cell lines were pooled with defined combinations to generate samples with known mosaic profile of 0%, 20%, 40%, 60%, 80% and

100%. A total of 96 samples, with 4 replications per combination were analyzed. A ReproSeq™ PGS protocol using Ion Chef™ and S5 sequencer was employed for whole genome amplification, library preparation and sequencing (Thermofisher). Ploidy and mosaicism were assessed using ReproSeq Mosaic PGS w1.1 pipeline with either 2Mb or 0.5Mb baseline.

Main results and the role of chance:

To evaluate full chromosome mosaic calling, 46,XY and 47,XX,+21 cell lines were used. While mosaic profiles of Chr21 in 10-cells samples mostly equaled expected values at all tested combinations, those of 5-cells samples revealed an approximately 30% mosaic mixture instead of value expected for both 20% and 40% groups. Meanwhile, in both models, mosaic profiles of ChrX showed 10-14% less than expected values at 40%, 60% and 80% groups and mosaic profiles of ChrY demonstrated a 10% overestimation at 40% and 60% groups. Moreover, mosaic calling pipeline failed in both models to consistently detect 80% mosaic loss of ChrY, which resulted in either 100% or 65% loss.

For assessing segmental chromosome mosaic calling, 46,XY,del(4p) and 47,XY,+13 cell lines were analyzed. Mosaic profiles of Chr13 in both 10-cells and 5-cells samples were closely matched expected values at all tested combinations. In contrast, mosaic calling pipeline failed to detect 20% segmental mosaic loss of Chr4 (27 Mb) in both models. In 10-cells model the pipeline could accurately detect 40% and 60% segmental loss of Chr4, but show a 15% overestimation at 80% groups, while in 5-cells model, it displayed 9%, 15% and 17 % overestimation at 40%, 60% and 80% groups, respectively.

Limitations, reasons for caution:

The sample size in this study is rather small. To have more comprehensive understanding of the effect of cell numbers in biopsy specimens on mosaic calling, more cell lines harboring either full and/or segmental changings in various chromosomes should be included. Also further validation in clinical embryo biopsy is necessary.

Wider implications of the findings:

Accuracy and sensitivity of mosaic calling may be affected by biopsy cell numbers and vary among different chromosomes. Segmental mosaic calling is less accurate than full chromosome mosaic calling. Algorithm of mosaic calling needs to be further modified and optimized. This study provides useful information for establishing NGS-based PGT-A guidelines.

SESSION 77: PREDICTING PREGNANCY OUTCOMES

Wednesday 26 June 2019 Haydn 2 14:00 - 15:30

O-296 Correlation between Anti mullerian (AMH) levels and miscarriage in preimplantation genetic testing for aneuploidy (PGT-A) cycles

S. Seshadri[1], X. Vinals Gonzalez[1], R. Odia[1], J. Ben Nagi[1], E. Yasmin[2], C. Maison[1], A. Capotescu[1], W. Saab[1], P. Serhal[1]

[1]CRGH, Assisted Conception Unit, London, United Kingdom

[2]UCLH, Reproductive Medicine, London, United Kingdom

Study question:

Can AMH be used as a predictor for miscarriage risk after transfer of euploid embryos?

Summary answer:

AMH levels were found to correlate with miscarriage after the transfer of an euploid embryo and irrespective of maternal age.

What is known already:

PGT-A improves time to pregnancy and reduces risk of miscarriage. Miscarriage risk remains after transfer of euploid embryos. AMH is thought to be useful for predicting pregnancy loss. The association between AMH and miscarriage rates has been equivocal with some studies demonstrating a link whilst others have refuted an association. A study concluded that AMH levels are inversely associated with the risk of miscarriage in women trying to conceive naturally and women with diminished ovarian reserve are at an increased risk of miscarriage. A meta-analysis concluded that AMH has clinical utility in counselling women undergoing fertility treatment regarding pregnancy rates.

Study design, size, duration:

Retrospective study involving 454 PGT-A cycles was conducted at the Centre for Reproductive and Genetic health (CRGH), UK from January 2016 to December 2017. Trophectoderm biopsy was performed on day 5/day 6 blastocysts and PGT-A was performed using next generation sequencing (Cooper Genomics). 7. *Female age was grouped according to HFEA categories (UK). The AMH levels was grouped in: <5 , 5-15, 15-25 and > 25 pmol/l.*

Participants/materials, setting, methods:

Female age was used to group the sample according to the Human Fertilisation and Embryology Authority (HFEA) categories into: <35 years (71/454), 35-37 years (90/454), 38-39 years (79/454), 40-42 years (137/454) and >42 (77/454). Number of euploid embryos, euploidy rate and relevant cycle parameters (i.e oocytes collected, embryos biopsied) was annotated for each of the categories. Statistical analysis was done using SPSS version 23 and statistical significance was set at the 5% level.

Main results and the role of chance:

5446 eggs collected, 1948 blastocysts biopsied. 546 euploid embryos available for transfer (28.0%), 1339 were aneuploid (68.7%) and 63 (3.3%) no result. Mean age for all the patients in the cohort was 38.6 ± 4.1 years. A negative correlation seen between female age (in years) and euploidy rate (%): <35 (51.04%), 35-37 (44.02%), 38-39 (24.01%), 40-42 (13.72%) and >42 (7.23%). AMH levels had no effect on euploidy rate (p=0.08) and only female age was contributing in the differences. Univariate analysis shows that there is a statistical difference in age in the different AMH groups (p<0.001), but this is only seen when comparing low with optimal groups (post-hoc test; p=0.01). A total of 137 single euploid embryo transfers were performed: 105 were pregnant (76.6%) and 32 were not (23.2 %). AMH levels were lower in the miscarriage group (p-value 0.001; 25.4 ±14.65 in LB vs 14.24 ±15.59 in miscarriage). The miscarriage rates for the different groups of AMH levels were 72.7%,56.5%,21.3% and 17.6% respectively. There was an inverse relationship between AMH and miscarriage risk i.e for a woman of an AMH level <5, the risk of having a miscarriage (OR 5.614 95%CI 1.22-25.67; p=0.026)compared to the group with a normal AMH.

Limitations, reasons for caution:

Larger studies (well-designed trials) with an increased number of biopsied embryos are needed to confirm our findings with analysis. The trials designed should also standardise the PGT-A technique being used as different laboratories have different reported sensitivity assays.

Wider implications of the findings:

This is the first study that has analysed the correlation between AMH and miscarriage rate where euploid embryos were transferred. AMH levels could be a predictive tool for miscarriage in ART cycles where PGT-A is performed. AMH levels has an important clinical utility for patient counselling in PGT-A cycles.

O-297 Design of novel experience-based embryo transference scoring system (TSS) to predict final reproductive outcome, in terms of pregnancy and healthy live births

A. Palomar[1], J.V. Martinez[2], M. Balasch-Bernat[3], I. Molina Botella[2]

[1]IVI Foundation, Instituto de Investigación Sanitaria La Fe, Valencia, Spain

[2]Hospital Universitari i Politecnic La Fe, Unit of Assisted Reproduction, Valencia, Spain

[3]Facultat de Fisioterapia. Universitat de Valencia., Department of Physiotherapy., Valencia, Spain

Study question:

To predict final reproductive outcome of double embryo transferences (DET) of cleavage embryos by means of proposed transference scoring system (TSS) based on individual scores of each embryo.

Summary answer:

TSS succeeded in sorting DET in five different categories according to likelihood of reproductive success in terms of both, pregnancy (PR) and live births (LB).

What is known already:

Despite the increasing tendency of transferring a single embryo (SET), DET are not scarce in most of IVF Units. Since the implementation of ARTs, the constant interest in selecting the top-quality embryo has been pursued; but fewer efforts have been addressed to determine which combination of embryos would lead to reproductive success, that can be defined as the achievement of pregnancy and the delivery of a healthy baby. Therefore, there is an urgent need to develop scoring systems that rank the final reproductive outcome when DET are performed, particularly when no top-quality cohorts are considered.

Study design, size, duration:

Cohort study held in HUiP La Fe from 2008 to 2018 including 7613 day-2 DET. TSS is described as a cumulative transference score based on partial scores of each embryo transferred. Partial scores were obtained using an experience-based embryo scoring system based on blastomeres number and grade, which referred to both, fragmentation's degree and blastomeres symmetry, developed in a previous study in a cohort of 11278 day-2 embryos where implantation rate was the primary outcome.

Participants/materials, setting, methods:

To design TSS, each transference was assigned a cumulative score created after combining partial scores of each embryo transferred. Logistic regressions were performed to rank transference scores according to PR and LB, respectively. Chi-square tests were used to compare differences regarding PR and LB among groups of transference scores exhibiting different PR and LB. Transference scores which did not show differences in terms of PR and LB were grouped in the same category.

Main results and the role of chance:

Categories including transference scores associated to similar PR are the same categories found when the likelihood of singleton delivery (SDR) is studied. DET of 4-cells grade one embryos were associated to the highest PR (>54%) and SDR (>36%). The second category, including at least one top-quality embryo, is associated to similar PR (40,85% to 53,33%, p>0.05) and SDR (30,23% to 35,34%, p>0.05). It is followed by the third category in which at least one of the embryos has 4 cells but exhibits mild to moderate fragmentation (PR:32,60%-36,60% p>0.05; SDR:23,35%-26% p>0.05). In DET included in the fourth category (PR:22,27%-27%, p>0.05; SDR:16,81%-20%, p>0.05) were transferred both embryos transferred showed impaired number of blastomeres and/or fragmentation degree. Interestingly, when the number of blastomeres of one of the embryo is different of 4 and the other embryo has more than 5 or less than 4 cells with severe fragmentation are associated to limited reproductive success (PR:14,29%-17,86%, p>0.05; SDR:8,2%-10,71%, p>0.05), only followed why DET in which both embryos transferred exhibit more than 5 or less than 4 blastomeres, regardless the fragmentation degree (PR:11%, p>0.05), that in all cases lead to miscarriage. It can be affirmed that TSS is not affected by female age.

Limitations, reasons for caution:

The current study is limited to day-2 DET since in our laboratories is the most common sort of embryo transference, although the methodology can be translated to day-3 DET.

Wider implications of the findings:

Experience-based transference-scoring demonstrates the necessity of developing this sort of tools to improve the final reproductive outcome. Moreover, the methodology used to construct TSS is worthy itself since it can be used for DET and SET of cleavage embryos of different days of development.

Trial registration number:

This is not a clinical trial

O-298 Progesterone supplementation in natural cycles improves live birth rates after frozen embryo transfers through higher implantation rate and reduced pregnancy loss

K. Wånggren[1]

[1]*Karolinska University Hospital and Karolinska Institutet- Huddinge, Reproductive medicine and CLINTEC, Stockholm, Sweden*

Study question:

Does supplementation with progesterone in natural cycle after frozen embryo transfer (FET) improve live birth rate, pregnancy rate and miscarriage rate?

Summary answer:

Supplementation with vaginal tablets of 100 mg progesterone two times daily in a natural FET cycle significantly improved live birth rate.

What is known already:

Progesterone is needed to support endometrial receptivity for embryo implantation as well as for continuous pregnancy until the eighth week of pregnancy. Implantation rates after FET in natural cycles are still relatively low. Women with regular menstrual cycles may have insufficient progesterone production in the luteal phase. Supplementation with vaginal progesterone during the luteal phase and early pregnancy could therefore improve the outcome of FET. There are so far only a few published trials on if FET and progesterone supplemented natural cycles increase pregnancy rate.

Study design, size, duration:

During a period of six years, 2013-2018, 500 women scheduled for FET in a natural cycle were enrolled in a randomized trial. Randomization was achieved using sealed envelopes. Primary endpoint was live birth rate. Secondary endpoints were pregnancy rate and miscarriage rate. The study was approved by the Regional ethical approval board, Stockholm Dnr: 2012/1845-32.

Participants/materials, setting, methods:

Infertile women with regular menstruation cycles, scheduled for FET were enrolled for the study at two university based reproductive medicine centers. After giving informed consent, the women were randomized to either supplementation with vaginal tablets of micronized progesterone 100 mg twice daily, starting at FET until eight weeks of pregnancy or no treatment. Pregnancies were followed up until the end of pregnancy. Comparison between the two groups was analyzed by use of Fisher´s exact test.

Main results and the role of chance:

The study group included 500 patients. Half the group received progesterone supplementation according to the study protocol. Primary endpoint was live birth. In the progesterone supplemented group, 82 patients (32.8%) and in the control group, 56 patients (23,6%) had a live birth, p=0.0286. Three patients in the progesterone treatment group had twin births while one patient in the control group had twins, all after single embryo transfers. Secondary endpoints, number of pregnancies were 100 (40%) and 84 (33.6%) p=0.1158, respectively. Pregnancy losses 9 (9.9%) and 15 (21.7%) p=0.2957, respectively. Biochemical pregnancies 12 (12%) and 13 (13.1%) p=0.8342, respectively. The mean ages were similar between the two groups 33.2 years in the progesterone group and 33 years in the control group, at embryo freeze and 34.6 versus 34.0 years at FET. There were no significant differences between day of freezing of the embryos between the two groups.

Limitations, reasons for caution:

The study was not blinded. The start of progesterone treatment was different depending on which day the embryos were frozen (day 2,3 or 5,6). This could affect the results negative for the patients having blastocysts transferred since they had a shorter period of supplementation with progesterone before implantation.

Wider implications of the findings:

The study confirms the result from a previous randomized controlled trial that progesterone supplementation in the luteal phase improves the live birth rate after FET in natural cycle. Therefore, patients undergoing FET in natural cycles should be offered luteal phase support with progesterone.

Trial registration number:

NTR4305

O-299 Low serum bHCG concentration on outcome day (trigger day +17) identifies a subgroup of women at risk of poor perinatal outcome

M. Gaudoin[1], **R. Payne**[2], **T. Hamilton**[3], **C. Fairbairn**[4], **J. Lyon**[4], **N. Gibson**[5], **P. Ambrose**[6], **R. Fleming**[4]

[1]*GCRM- Glasgow Centre For Reproductive Medicine, IVF Unit, Glasgow, United Kingdom*

[2]*University of Glasgow, Medical School, Glasgow, United Kingdom*

[3]*GCRM Ltd., Dept. of Nursing, Glasgow, United Kingdom*

[4]*GCRM Ltd., Biochemistry, Glasgow, United Kingdom*

[5]*GCRM Ltd., Embryology, Glasgow, United Kingdom*

[6]*GCRM Ltd., Nursing, Glasgow, United Kingdom*

Study question:

To determine the immediate and subsequent perinatal outcomes of patients whose βHCG concentration was less than 70 IU/L on trigger day +17.

Summary answer:

A βHCG concentration < 70 IU/L was associated with an increased risk of miscarriage, preterm delivery and small for gestational age and higher stillbirth rate.

What is known already:

Algorithms combining maternal age and various hormone concentrations, originally in the second trimester but progressively into the first trimester, have been used to predict adverse perinatal outcome (these include AFP, HCG, placental growth factor and PAPP-A, amongst others). HCG is the first known hormonal signal by the embryo, promoting embryo/endometrial molecular cross-talk, cytotrophoblast proliferation and subsequent invasion. HCG contributes to the maternal tolerance of the embryo via T-cell modulation and influences the degree of macrophage migration by up-regulation of macrophage migration inhibitory factor of the endometrial stromal cells. Failure of these mechanisms may result in miscarriage or poor placentation.

Study design, size, duration:

Retrospective analysis of outcomes from fresh ART cycles from 2008-2016 inclusive, in a single UK centre where the pregnancy outcome day was exactly 17 days after the pre-oocyte retrieval trigger injection. Subsequent perinatal outcomes (delivery after 24 weeks' gestation) were limited to singletons.

260 women had a βHCG < 70 IU/L, 534 had βHCG ≥ 70 IU/L.

Comparisons between groups of continuous data performed by Mann-Whitney test; comparisons of categorical data performed by Chi-squared analysis.

Participants/materials, setting, methods:

Serum bHCG measured using a Beckman Coulter Access II analyser.

Definitions. Positive pregnancy test: βHCG >10 IU/L. Biochemical pregnancy: non-viable pregnancy up to first pregnancy scan at 8 weeks' gestation. Miscarriage: fetal heartbeat identified but pregnancy loss up to 24 weeks' gestation. Preterm delivery: delivery < 37 weeks' gestation. Small for gestational age, SGA: birthweight $<10^{th}$ centile for expected gestation (UK birthweight charts). Stillbirth: fetal demise after 23 completed weeks' gestation.

Main results and the role of chance:

When βHCG was < 30 IU/L (N = 82), the biochemical pregnancy rate was 93% and only 2 pregnancies progressed to a positive heartbeat (2%).

When βHCG was 30-50 IU/L (N = 68), the biochemical pregnancy rate was 60% and the ongoing pregnancy rate was 24%.

When βHCG was 50-70 IU/L (N = 110), the biochemical pregnancy rate was 36% and the ongoing pregnancy rate was 53%.

For all women with βHCG < 70 IU/L (N = 260), the ongoing pregnancy rate was 29%.

When βHCG was ≥70 IU/L (N = 534), the biochemical pregnancy rate was 8%, and the ongoing pregnancy rate was 86%.

Comparing women with βHCG < 70 IU/L vs. ≥ 70 IU/L, there was no difference in age, AMH or BMI. However, the former group delivered singletons with a lower birthweight (P = 0.006), shorter gestational age at delivery (P = 0.005) and lower birth centile for gestational age (39 ± 28 vs. 52 ± 28 centile, P = 0.006). They were more likely to be born preterm (28% vs. 13%, P = 0.014) and be SGA (22% vs. 8%, P = 0.003). There were 3 stillbirths in each group (8% vs. 0.6%, P = 0.005).

Limitations, reasons for caution:

The analysis was limited to women with βHCG concentration on trigger day +17. Very few pregnancies with βHCG < 30 IU/L progressed to viability so the overall proportion of viable pregnancies when βHCG was < 70 IU/L was low, resulting in a relatively small dataset for analysis of perinatal outcomes.

Wider implications of the findings:

These data allow us to counsel women with greater certainty about the likelihood of a viable pregnancy. The low βHCG concentration also appears to be a marker of poor perinatal outcome, identifying an especially high-risk group and provides a model for future potential research into implantation and placentation.

[6]*Zealand University Hospital Roskilde, Department of Obstetrics and Gynecology, Roskilde, Denmark*

[7]*North Zealand Hospital- Copenhagen University Hospital, Department of Clinical Biochemistry, Copenhagen, Denmark*

Study question:

Can suPAR plasma levels improve location and viability diagnostics of early pregnancies compared with known and regularly used biomarkers?

Summary answer:

suPAR had a modest predictive value of early pregnancy location and viability inferior to progesterone especially before 6 weeks' gestation.

What is known already:

Early pregnancy loss is the most common complication of pregnancy, as roughly 25% of recognized pregnancies end in a miscarriage and 1-2% will be ectopic. Currently, serial hCG measurements and ultrasound examinations are used to diagnose early pregnancy location and viability.

suPAR, a part of the plasminogen activator system, is a novel biomarker increasingly used to monitor systemic inflammation. In healthy pregnancies circulating suPAR levels have been reported higher in first trimester compared with non-pregnancy levels, and thus plasma suPAR may have a role as a biomarker for early pregnancy location and viability, which has not previously been investigated.

Study design, size, duration:

A cross-sectional case control study merged two cohorts in total comprising 313 women and analysed plasma samples from biobanks. The first cohort included 201 women with a naturally conceived pregnancy between 4 and 8 weeks' gestation recruited from the public of the Copenhagen Capitol Region (2016–2017). The second cohort included 112 women diagnosed with a tubal pregnancy at three university hospitals in Denmark (2014–2016), who had blood samples biobanked before treatment.

Participants/materials, setting, methods:

The patients were divided into three groups: A) 164 women with a viable intrauterine pregnancy (IUP) resulting in a live birth; B) 37 women with an IUP resulting in early miscarriage; C) 112 women admitted and treated for a tubal pregnancy. Prediction of pregnancy location (C vs. A+B) and viability (A vs. C+B) was assessed using area under the receiver-operating characteristic curve (AUC) in pregnancies before and after full 6 weeks' gestation.

Main results and the role of chance:

The three groups were similar regarding age (p=0.06), BMI (p=0.57) and smoking status (p=0.38), but group C had higher parity (p<0.001) and gestational age (GA) with a median of 6.9 weeks (IQR 6.0-7.4) compared with 5.9 (IQR 5.1-6.6) and 5.9 (IQR 5.0-6.4) in group A and B, respectively (p=0.001). suPAR levels (median (IQR) in µg/L) were significantly lower in group C (1.9 (1.7-2.32)) compared with group A (2.4 (2.1-2.7)) and B (2.4 (2.0-2.7)), p<0.001. Likewise, hCG, estradiol and progesterone levels were all significantly lower (p<0.001) in group C compared to group A and B.

In pregnancies with GA<6 weeks (n=125), suPAR poorly predicted pregnancy location (AUC=0.69; 95% CI 0.54-0.83) and pregnancy viability (AUC=0.58; 95% CI 0.48-0.69), whereas progesterone was the best predictor of pregnancy location (AUC=0.95; 95% CI 0.87-1.00) and viability (AUC=0.84; 95% CI 0.75-0.92).

In pregnancies with GA>6 weeks (n=188) suPAR was a modest predictor of location (AUC=0.71; 95% CI 0.63-0.78) and viability (AUC=0.70; 95% CI 0.63-0.78) compared with hCG (AUC=0.96; 95% CI 0.93-0.99 and AUC=0.96; 95% CI 0.93-0.98), estradiol (AUC=0.92; 95% CI 0.88-0.97 and AUC=0.92; 95% CI 0.88-0.96) and progesterone (AUC=0.92; 95% CI 0.87-0.96 and AUC=0.88, 95% CI 0.83-0.93).

Limitations, reasons for caution:

Merging cohorts from different studies introduces an important methodological risk of selection bias. Our findings should be transferred with caution to the general population where the prevalence of ectopic pregnancies is several folds lower.

Wider implications of the findings:

Our findings demonstrate that suPAR levels are significantly lower in tubal compared with intrauterine pregnancies suggesting a relation to the formation of the placenta. However, in the present population progesterone and hCG outperformed suPAR as a predictor of very early pregnancy location and viability.

O-301 Adverse/ reproductive outcomes of reduced pregnancy and live birth rates after In Vitro Fertilization in women with previous caesarean section: a retrospective cohort study

J. Vissers[1], T. Sluckin[1], C. Repelaer van Driel- Delprat[1], R. Schats[1], C. De Groot[1], C. Lambalk[1], J. Twisk[2], J. Huirne[1]

[1]Amsterdam UMC- Vrije Universiteit Amsterdam, Obstetrics- Gynaecology and Reproductive Medicine, Amsterdam, The Netherlands

[2]Amsterdam UMC- Vrije Universiteit Amsterdam, Epidemiology and Biostatistics, Amsterdam, The Netherlands

Study question:

Does a previous caesarean section effect the reproductive outcomes including live births in women after In Vitro Fertilization or Intracytoplasmic Sperma Injection?

Summary answer:

A previous caesarean section does have a negative effect on pregnancy and live birth rates after In Vitro Fertilization or Intracytoplasmic Sperma Injection.

What is known already:

Rates of elective caesarean sections (CS) are rising worldwide. Late sequaelae of CSs related to a niche (CSdefect) include gynaecological symptoms and obstetric complications. A systematic review of Gurol-Urganci (2013) reported a lower pregnancy rate after a previous CS (RR 0.91 CI 0.87-0.95) compared to a previous vaginal delivery (VD). However the underlying cause is unclear, included studies do not differentiate between problems of fertilisation, embryo transportation, or implantation. Using an IVF population it is possible to study the effect of a previous CS on the implantation of embryo's in relation to a previous vaginal delivery.

Study design, size, duration:

In this retrospective cohort study we included all women who underwent an IVF or ICSI treatment at the IVF centre, Amsterdam UMC, location VU university, Amsterdam, the Netherlands between 2006 & 2016 with one previous delivery. In total 1317 women were included, 334 women with a previous caesarean section and 983 women with a previous vaginal delivery

Participants/materials, setting, methods:

All secondary infertile women, with only one previous delivery either by CS or VD were included. If applicable, only the first fresh embryo transfer was taken into account in the analyses. Patients without an intention for embryo transfer were excluded. The primary outcomes was live birth and clinical pregnancy. Multivariate logistic regression analyses were used with adjustment for possible confounders (age, BMI, smoking, indication for IVF/ICSI, uterine pathology, endometrioses, duration of infertility) if applicable.

Main results and the role of chance:

Baseline characteristics of both groups were comparable. Live births rates were significantly lower in women with a previous CS 15.9% (51/320) versus 23.3% (219/941) for women with a previous VD (OR 0.63 95% CI 0.45-0.87) in the ITT analyses. The rates were also lower for ongoing pregnancy (20.1% vs. 28.1% (OR 0.64 95% CI 0.48-0.87)) clinical pregnancy (25.7% vs. 33.8% (OR 0.68 95% CI 0.52 -0.90)) and biochemical pregnancy (36.2% vs. 45.5% (OR 0.68 95% CI 0.53-0.88)) in women with a previous CS. The quality of embryos did not differ between the two groups. 77% received a single embryo transfer. Rated difficulty concerning the embryo transfer was significantly higher in the caesarean section group (9.3% versus 1.0% (OR 10.0 95% CI 4.61-21.54)). The results of the per protocol analyses, including only patients who actually had an ET, were comparable.

Limitations, reasons for caution:

Despite its large size, this study was limited by its retrospective design. Furthermore, 55 (4,3%) cases missed data regarding delivery outcomes, but these were equally distributed between the two groups.

Wider implications of the findings:

The lower clinical pregnancy rates in combination with equal embryo quality, indicates that in particular implantation may be hampered after a CS. It's relation with a niche (CS defect) in the uterine CS scar needs to be studied. Our results should be discussed with women considering an elective CS.

Wednesday 26 June 2019 Haydn 4 14:00 - 15:30

O-302 Should we be performing blastocyst transfers at 120±12hrs post-ovulation? An analysis of 1,079 single frozen-thawed euploid blastocyst transfers

B. An[1], M. Chapman[1], L. Tilia[2], C. Venetis[3]

[1]University of New South Wales, School of Women's and Children's Health, Sydney, Australia

[2]IVFAustralia, Alexandria Specialist Day Hospital- Embryology Laboratory, Sydney, Australia

[3]University of New South Wales, Centre for Big Data Research in Health & School of Women's and Children's Health, Sydney, Australia

Study question:

Does performing single frozen-thawed euploid blastocyst transfers at 120±12hrs post-ovulation optimise live birth rates (LBR)?

Summary answer:

Performing a single frozen-thawed euploid blastocyst transfer at 120±12hrs post-ovulation is independently associated with higher LBR as compared to transfers outside this window.

What is known already:

There is compelling evidence for maintaining embryo-endometrial synchrony to optimise clinical outcomes following frozen embryo transfers (FETs). Although it seems physiologically intuitive to replace the blastocyst on the exact day of the embryo's developmental age after ovulation (i.e. ~120hrs post-ovulation for blastocysts), it has been suggested that the implantation window is actually significantly wider and earlier or later transfers can lead to similar or in some cases higher probability of live birth. Whether restricting embryo transfers to 24 hrs around this 120hrs post-ovulation period is beneficial has not yet been properly investigated.

Study design, size, duration:

This is a multi-centred retrospective cohort study analysing 753 patients who underwent 1,079 single frozen-thawed euploid blastocyst transfers following trophectoderm biopsy and PGT-A between January 2015 and May 2018. Limiting the analysis to single euploid embryo transfers allowed for a more accurate estimation of the endometrial synchrony factor by controlling for the developmental stage of the embryo (≥full blastocyst) and its genetic composition. Live birth rate (LBR) per FET was the primary outcome measure.

Participants/materials, setting, methods:

Patients underwent natural or ovulation-induction preparation of the endometrium and serial serum LH and progesterone measurements were obtained during the late follicular phase in order to estimate ovulation time. For triggered cycles (n=218), ovulation was assumed to occur 36hrs post-trigger. Optimally timed transfers were defined as those conducted 120±12hrs post-ovulation.

Statistical analysis was performed using the generalised estimating equations (GEE) framework to control for the clustered nature of the data while adjusting for potential confounders.

Main results and the role of chance:

The mean age of patients was 36.2 years and the main indications for PGT-A was patient/doctor request (n=378; 34.9%) and advanced reproductive age (n=244; 22.5%). The mean post-thaw survival rate (proportion of cells surviving the thaw) for the thawed embryos was 95.7% (Standard Deviation-SD: 7.9). The mean duration between estimated ovulation and transfer was 108.2hrs (SD: 21.2). Four hundred twenty-two embryo transfers (39.1%) were performed at 120±12hrs post-ovulation.

A multivariate regression GEE model including the pre-freezing embryo quality (top vs. good quality), the post-thaw survival rate and whether ovulation during the FET cycle was triggered or not, as covariates revealed that optimal timing was positively associated with LBR (OR 1.34, CI 1.03-1.73) per embryo transfer.

A sensitivity analysis in which all embryo transfers performed >24hrs before or after the optimal timing (120±12hrs post-ovulation) were excluded, yielded similar results (OR 1.35, CI 1.04-1.77).

Limitations, reasons for caution:

This study is retrospective and the presence of residual unknown bias cannot be excluded. Furthermore, the embryos included in this study had reached full blastocyst stage and had undergone trophectoderm biopsy for PGT-A prior to their freezing.

Wider implications of the findings:

The results of this study underline the significance of embryo-endometrial synchrony for the optimization of embryo transfer outcome. This study shows that although implantation and live birth is possible outside the optimal window, performing embryo transfers 120±12hrs post-ovulation can improve the probability of live birth.

O-303 Laser assisted hatching and continued culture of embryos within the same culture dish does not impact embryo development potential in PGT cycles

S. Dalati[1], N. Hesketh[1], S. McArthur[1], M. Bowman[1]

[1] *Genea, Embryology, Sydney- NSW, Australia*

Study question:

To determine whether laser assisted hatching and continued culture of embryos within the same culture dish is possible without compromising embryo development potential in PGT cycles?

Summary answer:

Hatching and culturing embryos within the same culture dish is possible, reduces embryo disturbance and has no impact on embryo development and quality.

What is known already:

The standard protocol for hatching embryos destined for PGT involves their movement to a separate dish for the laser hatching process performed on Day 3/4, followed by a move back to the culture dish. With the advent of time-lapse incubator systems there is a greater need for optimizing uninterrupted embryo culture, raising the possibility of performing the hatching process in-the same-dish. There is scant data assessing the impact of laser assisted hatching in-same-dish (HISD) on embryo development and quality. Initial in-house mouse studies indicated that HISD minimized environmental impact on embryos without any deleterious effects on embryo development potential.

Study design, size, duration:

A retrospective cohort study comparing human embryo development following laser assisted hatching in a separate dish from August-December 2017 to hatching in-same-dish August-December 2018 at Genea Sydney. A total of 6187 embryos were analyzed and development was compared. Embryos had to have reached a minimum of a blastocyst stage or above to be included in the study.

Participants/materials, setting, methods:

Embryos from IVF cycles were cultured in a well-in-well dish in a time-lapse system (Geri) in continuous medium (Genea-Biomedx). A total of 3136 2PN embryos were moved out on D4, hatched in a separate dish and returned to continuous culture. A total of 3051 2PN embryos were hatched on D4 within the culture dish. Laser assisted hatching was performed using a Hamilton Thorne near infra-red laser.

Main results and the role of chance:

Overall results showed that blastocyst development rates and utilization of embryos hatched in-same-dish (HISD) were comparable to those embryos hatched outside of the dish (HOD), and that embryos HISD did not impact embryo development and quality. There were no differences between D5 blastocyst development (HISD:48.8% and HOD:46.8%), D5 blastocyst development with grade1/2 embryos (HISD:31.3% and HOD:31.3%), D5/6 utilization rates (HISD:55.2% and HOD:52.9%) and D5/6 grade1/2 utilization rates (HISD:38.6% and HOD:37%) p>0.05. Whilst there were no statistical differences between the groups for developmental outcomes that were measured, the trends were in favor of HISD.

Limitations, reasons for caution:

Clinical outcomes should be closely monitored following the implementation of this hatching method into clinical practice. Implementation of a randomized control trial may be performed in the future to know the complete impact of laser assisted hatching within the same dish has on embryo development.

Wider implications of the findings:

This study has demonstrated that hatching and culturing embryos within the same environment is possible with no impact on embryo development potential. By limiting the exposure of embryos to environmental disturbances we can ensure that embryos are developing to their maximum potential in an IVF setting.

Not applicable

O-304 Paternal age over 50 years reduces the success of IVF/ICSI - ET

G. Morris[1], D. Mavrelos[1], R. Odia[2], X. Viñals Gonzalez[2], E. Yasmin[1], S. Cawood[2], W. Saab[1], S. Seshadri[1], P. Serhal[1]

[1] *Centre for Reproductive and Genetic Health, Clinician, London, United Kingdom*

[2] *Centre for Reproductive and Genetic Health, Embryology, London, United Kingdom*

Study question:

Does increasing paternal age affect clinical pregnancy rates (CPR) and miscarriage rates (MR) following in vitro fertilisation (IVF)/ intracytoplasmic sperm injection (ICSI) treatment?

Summary answer:

Paternal age over 51 years significantly decreases the clinical pregnancy rate (CPR) following IVF/ICSI when maternal age is controlled. Miscarriage rate (MR) is not affected.

What is known already:

Semen quality deteriorates with increasing paternal age however there is conflicting evidence for any impact paternal age may have on the outcome of in vitro fertilisation (IVF)/ intracytoplasmic sperm injection (ICSI). Several retrospective and prospective cohort studies have shown that paternal age increases the MR and reduces the CPR. Some studies have shown no effect of paternal age on CPR or MR. Studies involving donor oocytes have shown no impact of paternal age on outcomes. The age at which there is a significant change in outcome is not known and there is no limit to paternal age in IVF/ICSI treatment.

Study design, size, duration:

This was a retrospective cohort study conducted at the Centre for Reproductive and Genetic Health clinic, London UK. A total of 4271 men and 4833 cycles of IVF and ICSI, including all causes of subfertility, from 01/12/2009 to 01/08/2018 were analysed in the study.

Participants/materials, setting, methods:

All cycles of IVF/ICSI performed using freshly ejaculated sperm. Cycles using donor oocytes/sperm and surgically retrieved sperm were excluded.

Data for each ART cycle was held on IDEAS version 6 Mellowood Medical and analysed using SPSS version 24.0 and STATA version 15.

Male partners were grouped into age ranges ≤35; 36 – 40; 41-44; 45-50; ≥51 years for analysis. Male age and female age <35 years was used as the reference groups for comparison.

Main results and the role of chance:

Median maternal and paternal ages were 36 years (IQR 33 – 39) and 38 years (IQR 35 – 42) respectively.

Significantly fewer men over 51 years met WHO semen analysis criteria (56/133, [42.1%, 95% CI 34.1 – 50.6]) compared to men under 51 years (2530/4138 [61.1%, 95% CI 60.0 – 62.6]) (p = 0.001).

2019/4833 (41.8%, 95% CI 40.4 – 43.2) of cycles resulted in clinical pregnancy. CPR declined with increasing maternal age ≤35 (1074/2102, 51.1% 95% CI 49.0 – 53.2), ≥40 (202/929, 21.7% 95% CI 19.2 – 24.5) (p = 0.001). CPR also declined with increasing paternal age; ≤35 (715/1433, 49.9% 95% CI 47.3 – 52.5), 36 – 40 (735/1731, 42.5% 95% CI 40.2 – 44.8), 41 – 45 (379/1076, 35.2% 95% CI 32.4 – 38.1), 46 – 50 (129/393, 32.8% 95% CI 28.4 – 37.6), ≥51years (61/200, 30.5% 95% CI 24.5 – 37.2). We performed multivariate logistic regression analysis with clinical pregnancy as dependent variable and maternal and paternal age class as independent variables. Maternal and paternal age were retained in the model. For all maternal age subgroups the probability of pregnancy decreased with paternal age over 51years (OR 0.655, 95% CI 0.477 – 0.927) (p = 0.001).

Limitations, reasons for caution:

The main limitation of this study is that it is retrospective and therefore vulnerable to confounding and bias. 80% of men ≥51years received ICSI treatment even though 42% had normal semen parameters. This may have confounded the results and reduced the perceived effect of increased paternal age.

Wider implications of the findings:

Paternal age over 50 significantly affects the chance of success of ART and there should be a public health message for men to not delay fatherhood. Alternative options for procuring semen for men over the age of 50 years may be discussed at the time of consultation.

not applicable

O-305 Factors influencing live birth outcomes of day 7 blastocysts following autologous single vitrified-warmed blastocyst transfer: A single-centre large cohort study

S. Ueno[1], K. Uchiyama[1], T. Okimura[1], A. Yabuuchi[2], T. Kobayashi[3], K. Kato[3]

[1]Kato Ladies Clinic, IVF Laboratrory, Tokyo, Japan
[2]Kato Ladies Clinic, Research & Development, Tokyo, Japan
[3]Kato Ladies Clinic, Gynecology, Tokyo, Japan

Study question:

What factors influence live birth outcomes of day 7 blastocysts following single vitrified-warmed transfer (SVBT)?

Summary answer:

Live birth outcomes of day 7 blastocysts following SVBT are influenced by maternal age, time from insemination to blastulation, expansion time, and blastocyst diameter.

What is known already:

Preimplantation genetic testing has been promoted to prevent miscarriage after embryo transfer. Therefore, blastocyst culture has become standard for in vitro fertilisation (IVF), but it is unclear whether day 7 (d7) blastocysts should be cryopreserved and transferred. Clinical outcomes with d7-frozen blastocyst transfer (FBT) have been studied. However, as the usefulness of d7-blastocysts remains controversial, clinical outcomes of d7-FBT require further evaluation with a large cohort study. Investigation of factors influencing live birth (LB) after d7-FBT is also necessary to prioritize selection of blastocysts.

Study design, size, duration:

A retrospective cohort study of 49,044 autologous SVBTs (23,715 patients, mean age: 37.6±4.1) was conducted in a single centre between 2006 and 2015. Study 1: Factors influencing LB using d7-blastocysts following SVBT were investigated. Study 2: Cut-off values of factors influencing LB and criteria of d7-blastocysts were established and live birth rates (LBRs) for, d4-blastocysts (d4-SVBT), d5-blastocysts (d5-SVBT), d6-blastocysts (d6-SVBT) and d7-blastocysts (d7-SVBT) following SVBT were compared.

Participants/materials, setting, methods:

Blastocysts were vitrified using the Cryotop method according to criteria based on blastocyst diameter (Ueno et al., 2014). SVBT was performed in natural ovulatory cycles. Multivariable logistic regression (mLR) analysis was used to analyse the factors influencing LB. Multivariate receiver operating characteristic (ROC) curve analysis was used to establish cut-off values and criteria for d7-blastocysts. Chi-square tests were performed to compare LBR at >22 weeks of pregnancy among the groups.

Main results and the role of chance:

Study 1: mLR analysis to calculate adjusted odds ratios (aORs) included the following independent factors: age of females and males, number of previous IVF cycles, time from insemination to starting blastulation (tSB), expansion time (tExp: time from tSB to expanded blastocyst), and blastocyst diameter. mLR analysis revealed that age of females (aOR: 0.83, $P < 0.05$), tSB (aOR: 0.95, $P < 0.05$), tExp (aOR: 0.92, $P < 0.05$), and blastocyst diameter (aOR: 1.02, $P < 0.05$) were significantly correlated with LB in d7-SVBT. Study 2: ROC curve analysis determined cut-off values as follows: age of females < 39 years, tSB > 143 h post insemination, tExp: within 19 h, and blastocyst diameter > 210 μm (area under the curve: 0.76). The LBRs of d4-, d5-, d6- and d7-SVBT groups were 52.6% (n = 154), 40.1% (n = 23,484), 27.0% (n = 22,928), and 14.2% (n = 2,478), respectively. There were significant differences between the groups ($P < 0.05$). LBRs of d7-blastocysts that met the criteria (Adjusted-d7-SVBT group) were comparable to those of the d6-SVBT group (28.2% vs. 27.0%), but this rate was significantly lower compared to that for d4- and d5-SVBT groups (28.2% vs. 52.6% and 40.1%, $P < 0.05$).

Limitations, reasons for caution:

The present study did not include blastocyst morphology as an independent factor in the mLR analysis, because all d7-blastocysts analysed in this study had low-grade morphology. In addition, d7-blastocyst criteria may be influenced by clinical settings such as culture environment.

Wider implications of the findings:

Our results demonstrate that LBRs following d7-SVBT are comparable to those after d6-SVBT if d7-blastocysts fulfil strict criteria. Therefore, d7-blastocysts may have potential clinical usefulness for FBT.

None

O-306 The use of pronuclear transfer to overcome infertility disorders in mice

B. Heindryckx[1], M. Tang[1], A.K. Boel[1], P. Stamatiadis[1], M. Van der Jeught[1], R. Guggilla[1], D. Deforce[2], R. Van Coster[3], P. De Sutter[1]

[1]Ghent University Hospital, Ghent Fertility and Stem cell Team- Department for Reproductive Medicine, Gent, Belgium
[2]Ghent University, Laboratory of Pharmaceutical Biotechnology, Ghent, Belgium
[3]Ghent University Hospital, Department of Pediatric Neurology and Metabolism, Gent, Belgium

Study question:

Can pronuclear transfer (PNT) overcome inferior embryonic development or reproductive ageing in a mouse model?

Summary answer:

The PNT technology is very efficient to restore embryonic developmental potential in infertility disorders such as reproductive ageing or embryo arrest.

What is known already:

Nuclear transfer such as PNT is being used to avoid the transmission of mitochondrial disorders. There is increasing interest to also use PNT for infertility disorders, however, scientific evidence in both animal and human models to support the use of PNT for infertility is currently lacking. It is important to reveal which infertility indications could benefit from this novel technology.

Study design, size, duration:

We used a reproductively-aged model (B6D2F1 mice) with age ranging from 6-8-weeks (control), 13-months (aged) to 16-months (very-aged); corresponding to women of <30, ~36 and ~45-year-old respectively. Secondly, another mouse strain (NZB mice, 6-8w) showing two-cell block was used. Finally, cytoplasmic transfer (CT) was performed by injection of a limited amount of

young B6D2 cytoplasm in both reproductively-aged and embryo-arrest models. We evaluated embryonic development in reconstituted PNT (n = 572) and CT (n=365) embryos.

Participants/materials, setting, methods:

Ovarian reserve was assessed by histological analysis in reproductively-aged mice. The Mitochondrial membrane potential (△Ψm) was measured by JC-1 staining in MII oocytes. The spindle-chromosomal morphology was examined by confocal analysis. PNT was performed by transferring pronuclei from fertilized oocytes (after ICSI) to enucleated counterpart zygotes between aged/very-aged and young mice, or between NZB/OlaHsd (embryo-arrest) and B6D2F1 (non-arrest control) mice.

Main results and the role of chance:

In comparison to the young mice, the ovarian reserve in aged/very-aged females was severely diminished, reflected by a lower number of ovarian follicles and lower ovulation rate ($P<0.001$). The average △Ψm in aged/very-aged mouse oocytes was significantly reduced ($P<0.001$) compared to young mice. Moreover, the rate of abnormal spindle-chromosome configuration in MII oocytes of aged/very-aged group was significantly higher ($P<0.05$) than young mice. Following ICSI, oocytes from aged/very-aged mice showed significantly lower fertilization (60.7% and 45.3%) and blastocyst formation rates (51.4% and 38.5%) than the ICSI control with young mouse oocytes (FR = 89.7%, blastocyst 87.3%) ($P<0.001$). After PNT from aged/very-aged to young mice, the blastocyst formation rates were significantly improved (74.6% and 69.2%, respectively).

Similarly, as model of embryo arrest, most (61.8%) of *in vivo* zygotes of NZB/OlaHsd strain displayed two-cell block during *in vitro* culture, with a significantly decreased blastocyst rate compared to B6D2F1 strain (13.5% vs. 90.7%, respectively) ($P<0.001$). When transferring PN from embryo-arrested (NZB/OlaHsd) to non-arrested (B6D2F1) zygotes, most of reconstructed zygotes developed beyond two-cell stage, with significantly increased blastocyst rates (89.7%) ($P<0.001$). The application of CT did not overcome inferior embryonic development in both aged/very-aged and embryo-arrested mice ($P>0.05$).

Limitations, reasons for caution:

Considering the differences between animal models and women regarding various biological processes, validation of PNT in infertility patients to explore the reliability of this technique is still required.

Wider implications of the findings:

This is the first study in mice to determine whether PNT could overcome certain female infertility indications such as advanced maternal age or embryonic developmental arrest. Our data support that PNT, refreshing the oocyte or zygote cytoplasm, may represent a novel reproductive strategy to increase embryonic developmental potential.

NA

O-307 Impact of trophectoderm grade on infant physiological characteristics and gender after single frozen blastocyst transfers: an analysis of 1109 singletons after 3822 frozen blastocyst transfers

M. Kataoka[1], Y. Nakajo[1], H. Hattori[1], Y. Nakamura[1], M. Takahashi[1], N. Okuyama[2], N. Aono[1,2], T. Tai[1,2], M. Toya[1], T. Hashimoto[2], H. Igarashi[1], K. Kyono[1,2]

[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan

Study question:

Does trophectoderm (TE) morphology grade affect infants' physiological characteristics and gender ratio after frozen blastocyst transfer?

Summary answer:

TE morphology grade was uncorrelated with birth weight, height or congenital abnormality in infants. High TE grade was significantly associated with gender ratio towards male.

What is known already:

Gardner's scoring criteria is often used to evaluate blastocyst quality. A strong correlation between blastocyst morphology grade and clinical outcome has been reported by many studies. However, the correlations between TE grade and physiological characteristics and gender ratio of infants have not been fully understood.

Study design, size, duration:

This retrospective study was conducted at Kyono ART Clinic in Japan from 2012 to 2017. This study includes a total of 1109 singletons born after 3822 single frozen blastocyst transfer in 2166 patients.

Participants/materials, setting, methods:

TE morphology was graded according to Gardner's scoring system and divided into the three grades (Grades A, B, and C). Grade A includes 638 cycles, 447 patients, and 254 children; Grade B, 1731 cycles, 944 patients, and 526 children; and Grade C, 1453 cycles, 775 patients and 329 children. The correlations between TE grade and clinical outcomes (pregnancy rate, miscarriage rate and ongoing pregnancy rate), physiological characteristics, and gender ratio were evaluated.

Main results and the role of chance:

Average maternal age in Grade C was significantly higher than in Grades A and B (35.5±3.1 vs. 34.8±3.2 and 35.1±3.2, $p<0.01$). Pregnancy rates in Grades A, B, and C were 60.7%, 50.5%, and 36.9%, respectively; Grade A was significantly higher than Grade C ($p<0.01$). Ongoing pregnancy rates in Grades A, B, and C were 54.1%, 45.5%, and 30.6%, respectively; Grade A was significantly higher than Grade C ($p<0.01$). Miscarriage rates in Grades A, B, and C were 12.1%, 11.5%, and 10.7%, respectively (N.S: not significant). Average gestational age (weeks) in Grades A, B, and C were 38.8±1.8, 38.7±2.3, and 38.4±2.4, respectively (N.S). Average height (cm) and weight (g) in Grades A, B, and C were 49.3±2.4, 49.0±3.7, and 49.0±3.2 (N.S), and 3,066±0.4, 3,047±0.5, and 3,040±0.5, respectively (N.S). Premature birth rates and low birth weight rates in Grades A, B, and C were 5.5% (n=14), 8.4% (n=44) and 7.9% (n=26) (N.S), and 6.3% (n=16), 9.3% (n=49), and 8.5% (n=28), respectively (N.S). Congenital abnormality rates in Grades A, B, and C were 2.8%, 2.9%, and 1.5% (N.S). Gender ratios (male:female) in Grades A, B, and C were 1.92:1, 1.26:1, and 0.94:1, respectively; Grade A was significantly higher than Grade C ($p<0.01$).

Limitations, reasons for caution:

In this study, we did not assess the correlation between inner cell mass and infants' physiological characteristics and gender ratio. Since male embryos grow faster than female embryos, high TE grade male embryos might be selected as transferred blastocysts in our study.

Wider implications of the findings:

It was particularly noteworthy that high grade TE clearly skews gender ratio towards male. Blastocyst TE grade is responsible for pregnancy rate. However, miscarriage rate, infants' physiological characteristics and congenital abnormality are not affected by TE grade.

Trial registration number:

None.

O-308 Association of childhood adiposity with irregular menstruation and polycystic ovary syndrome in adulthood: the Childhood Determinants of Adult Health Study and the Bogalusa Heart Study

H. Ye[1], J. Tian[1], L. Blizzard[1], W. Oddy, H[1], T. Dwyer[2], L. Bazzano, A[3], E. Harville[3], A. Venn, J[1]

[1]Menzies Institute for Medical Research, University of Tasmania, Hobart, Australia
[2]The George Institute for Global Health, University of Oxford, Oxford, United Kingdom
[3]School of Public Health and Tropical Medicine, Tulane University, New Orleans, U.S.A.

Study question:

Is abdominal obesity in childhood associated with menstrual irregularity and polycystic ovary syndrome (PCOS) in later life?

Summary answer:

Abdominal obesity measured as waist-to-height ratio (WHtR) in childhood was positively associated with a significantly increased risk of self-reported menstrual irregularity and PCOS in adulthood.

What is known already:

While adult obesity, particularly abdominal obesity, is associated with irregular menstruation and PCOS in women, few studies have explored the relationships with childhood adiposity. Increased childhood body mass index (BMI) has been associated with irregular menstrual cycles and PCOS symptoms in adulthood in two longitudinal studies but no study has reported on associations with childhood abdominal obesity. Few studies have investigated whether there are racial differences in the associations of adiposity with PCOS though there has been some suggestion that associations with high BMI may be stronger in white girls than in black girls.

Study design, size, duration:

The study included 3,152 participants aged 7-15 years at baseline from two cohorts (1,551 from the Childhood Determinants of Adult Health Study (CDAH) in Australia and 1,601 from the Babies sub-study of the Bogalusa Heart Study (BBS) in the United States). At follow-up, questions about menstruation (current for CDAH or before age 40 for BBS) and PCOS were asked in two follow-ups in CDAH (between ages 26-41) and once in the BBS (ages 27-57).

Participants/materials, setting, methods:

Childhood anthropometrics including measured height, weight and waist circumferences. Race was available in BBS (59% white; 41% black). In CDAH, a single childhood visit was conducted in 1985. In BBS, multiple childhood visits occurred from 1973-2000. Obesity was defined by international age-sex-specific standards for BMI. Waist/height ratio (WHtR) was considered as an indicator of abdominal obesity. Multilevel mixed-effects Poisson regression estimated relative risks (RRs) adjusting for education and age at menarche.

Main results and the role of chance:

The prevalence of childhood obesity was 1.1% in CDAH and 7.1% in BBS (white:5.0%; black:10.1%). At follow-up, the prevalence of menstrual irregularity was 13.9% in CDAH and 17.4% in BBS (white:18.9%; black:15.2%). PCOS was reported by 7.5% in CDAH and 6.5% in BBS (white:8.7%; black:3.4%). In CDAH, compared with normal weight girls, those who were obese in childhood were more likely to report menstrual irregularity (RR=2.94, 95% confidence interval [CI]:1.24-6.99) and PCOS (RR=4.35, 95% CI:1.17-16.19). Each 0.01unit increase in childhood WHtR led to a 5% (95% CI:1%-9%) greater likelihood of menstrual irregularity and 5% (95% CI:0%-10%) greater likelihood of PCOS. Overall, in BBS, childhood obesity was associated with an increased risk of menstrual irregularity (RR=2.67, 95% CI:1.77-3.12) and PCOS (RR=1.70, 95% CI:1.03-2.79). A 0.01unit increase in childhood WHtR was associated with an 8% (95% CI:2%-14%) increase likelihood of PCOS. However, when stratifying by race in BBS, the association of childhood adiposity measures with PCOS was not present in black girls. In white girls in BBS, childhood obesity increased the risk of self-reported PCOS when compared with normal weight girls (RR=2.46, 95% CI:1.41-4.30) and an average 0.01unit higher childhood WHtR was associated with a 9% (95% CI:3%-15%) greater risk of PCOS.

Limitations, reasons for caution:

The classification of menstrual irregularity and PCOS was based on self-report by questionnaire, which may have led to misclassification of these outcomes. While the study samples were population-based, loss to follow-up means the generalizability of the findings is uncertain.

Wider implications of the findings:

Greater childhood adiposity indicates a higher risk of menstrual irregularity and PCOS in adulthood. Whether this is causal or an early indicator of underlying hormonal or metabolic disorders needs clarification. The stronger associations of adiposity with PCOS in white girls suggest that other environmental or genetic factors are also important.

O-309 Quantitative differences in TGF-β superfamily growth factors measured in small antral follicle fluids from women with PCOS

S.G. Kristensen[1], A. Kumar[2], S.E. Pors[1], S. Franks[3], K. Hardy[3], C.Y. Andersen[1]

[1]Copenhagen University Hospital, Laboratory of Reproductive Biology- Section 5712, Copenhagen, Denmark

[2]Ansh Labs, Ansh Labs, Texas, U.S.A.

[3]Imperial College London- Hammersmith Hospital, Institute of Reproductive and Developmental Biology, London, United Kingdom

Study question:

Are there measurable differences in intrafollicular levels of TGF-β superfamily growth factors in small antral follicles from women with and without PCOS?

Summary answer:

Altered levels of Inhibins and Growth-and-Differentiation-Factor-9 (GDF9), but not Anti-Müllerian-Hormone (AMH), were found in the follicle fluids (FF) of small antral follicles from polycystic ovaries.

What is known already:

PCOS is the most common endocrine disorder in women. Anovulation in PCOS is characterized by growth-arrest of small antral follicles (hSAF) (2–9 mm in diameter) in the ovary due to the abnormal endocrine environment. Members of the TGF-β superfamily have been implicated in aberrant follicle development in PCOS, but there is no data on FF from hSAF during the natural cycle due to the scarcity of such material and assay limitations. Previous studies have shown that AMH levels in both serum and large antral follicles are significantly higher in women with PCOS compared to controls.

Study design, size, duration:

Donated FF were aspirated and collected from small antral follicles found in the ovaries of 55 women undergoing ovarian tissue cryopreservation for fertility preservation at the University Hospital of Copenhagen, Denmark, from 2011-2018.

Participants/materials, setting, methods:

Follicle fluids (N=192) were aspirated from whole ovaries laparoscopically removed from patients during their natural cycle and before initiation of gonadotoxic treatment. Women with PCOS were identified in the cohort by ovarian volume, number of antral follicles, and hormone profiles. A new line of hypersensitive immunoassays from Ansh Labs in Texas, USA were used to detect levels of GDF9, AMH, Inhibin-A and -B, Activin-A, -B and AB, and Follistatin.

Main results and the role of chance:

A total of 90 FF were collected from 15 women with PCOS (median age: 25 years) and 102 FF were collected from 40 control women without PCOS (median age: 25 years). The diameters of small antral follicles ranged from 4.6-10.7 mm in both groups. Intrafollicular levels of both Inhibin-A and -B were significantly lower in FF from women with PCOS compared to controls, and the low levels were especially pronounced in follicles just before selection of the dominant follicle (hSAF $<$ 8 mm). Moreover, intrafollicular levels of GDF9 were found to be significantly higher in PCOS FF in hSAF exceeding 6 mm in diameter compared to controls. Interestingly, intrafollicular levels of AMH did not differ between PCOS and controls, only in the hSAF larger than 8 mm AMH levels were significantly higher in PCOS FF compared to control FF. Thus, intrafollicular AMH levels remain high after follicle selection in polycystic ovaries instead of decreasing to low levels like in the control ovaries with normal follicle growth. Intrafollicular levels of Activin-B, Activin-AB and Follistatin did not differ between PCOS and controls, and levels of Activin-A were under the assay detection limit.

Limitations, reasons for caution:

Only a small number of hSAF larger than 8 mm in diameter were available for analysis. Further studies are needed to elucidate on the molecular mechanisms and functional effects of the altered levels of Inhibins, GDF9 and AMH at specific stages of small antral follicle development in polycystic ovaries.

Wider implications of the findings:

This is the first time oocyte-specific GDF9 has been measured in small antral human FF using a hypersensitive immunoassay. Altered levels of TGF-β superfamily growth factors at certain follicular stages of small antral follicle development may reflect molecular defects of folliculogenesis, especially around follicle selection, in women with PCOS.

O-310 Favorable changes in characteristics, phenotype and androgens as result of weight loss in a randomised controlled three-component lifestyle intervention in women with PCOS

A. Dietz de Loos[1], R. Timman[2], G. Jiskoot[3], A. Beerthuizen[2], J. Van Busschbach[2], J. Laven[1]

[1]Erasmus Medical Center, Reproductive Medicine, Rotterdam, The Netherlands
[2]Erasmus Medical Center, Medical Psychology and Psychotherapy, Rotterdam, The Netherlands
[3]Erasmus Medical Center, Reproductive Medicine and Medical Psychology and Psychotherapy, Rotterdam, The Netherlands

Study question:
What is the effect of weight loss on PCOS characteristics ovulatory dysfunction, hyperandrogenism and polycystic ovarian morphology during a three-component lifestyle intervention.

Summary answer:
Weight loss had a significant impact on ovulatory dysfunction and hyperandrogenism, resulting in a milder phenotype in the majority of overweight/obese women with PCOS.

What is known already:
The first line treatment for women with PCOS is a multicomponent lifestyle intervention to improve weight. Overweight and obesity seem to worsen PCOS characteristics and phenotypic expression. Although insights in the dynamic character of PCOS characteristics have been described due to female aging or anthropomorphic appearance, little is known about the effect of weight loss due to a lifestyle intervention on PCOS characteristics, phenotypic expression and androgens.

Study design, size, duration:
An RCT was performed consisting of a three-component (cognitive behavioral therapy, healthy diet and physical therapy) one-year lifestyle intervention (LS) compared to care as usual (CAU). Overall, 209 women were included between May 2009 and August 2016. The lifestyle intervention group received 20 group sessions during one year addressing the three components. The control group received CAU which consisted of advices to lose weight autonomously.

Participants/materials, setting, methods:
Women diagnosed with PCOS, aged 18-38 years, having a wish to conceive and a BMI above 25 kg/m^2 were included at the Erasmus MC, The Netherlands. Outcome variables were evaluated every three months and included anthropomorphic measurements, ultrasound and an endocrine assessment. Multilevel linear and logistic regression was applied for longitudinal analyses.

Main results and the role of chance:
No differences were found between the LS and the CAU group concerning changes in PCOS characteristics, phenotype expression and androgens after 12 months except for a significant decrease of testosterone ($p<0.05$) and androstenedione ($p<0.05$) serum levels in the LS group. However, when we evaluated weight loss in general we observed a significant decrease in the prevalence of ovulatory dysfunction (OD) ($p<0.001$) and hyperandrogenism (HA) ($p<0.001$). When a 5% and 10% weight loss was achieved, 10.2% and 26.4% improvements in ovulatory function and 6.3% and 15.1% improvements in HA were found respectively. Changes in polycystic ovarian morphology were not observed. Furthermore, the chance to be classified as phenotype A (full blown phenotype) was significantly lower due to weight loss ($p<0.001$). In case of achieving 5% or 10% weight loss the chance of having phenotype A diminished with 12.7% and 27.9% respectively.

Limitations, reasons for caution:
Improvement in ovulatory function was defined as regaining cycle regularity, however progesterone serum levels were not used to confirm ovulation, a limitation of the study.

Wider implications of the findings:
These findings confirm the dynamic character of PCOS which is apparently modulated by BMI. Additionally, they support the necessity of multicomponent lifestyle interventions in overweight and obese women with PCOS to achieve weight loss.

Trial registration number:
This study was registered at the Dutch Trial Register, number NTR2450.

O-311 Cardiometabolic health in offspring of women with polycystic ovary syndrome (PCOS) compared to healthy controls: A systematic review and Individual Participant Data Meta-analysis.

Study question:
Are cardiometabolic features in PCOS offspring, both females and males, between the age of 1 to 18 years less favorable in comparison with controls?

Summary answer:
We observed subtle signs of compromised cardiometabolic health in children born to women diagnosed with PCOS, predominantly in female offspring.

What is known already:
The Barker hypothesis implies that children's health and development is distinctly affected by the intrauterine environment. An association between maternal health and offspring health has been convincingly demonstrated in the general population. Women with PCOS often present with unfavorable cardiovascular risk factors such as obesity and insulin resistance. Currently confirmation of this association within women with PCOS and their offspring is limited. The sample size of these studies is too small to draw definitive conclusions, and the majority does not report on sex differences. Moreover, existing literature concerning cardiometabolic outcomes in PCOS offspring is inconsistent.

Study design, size, duration:
We conducted a systematic review and individual participant data meta-analysis. For each included study approval of the local medical ethics committees, and written informed consent from all parents was obtained before measurement of offspring outcomes.

Participants/materials, setting, methods:
PubMed, Embase and grey literature were searched (updated: February 1th, 2018). Relevant key terms such as "offspring" and "PCOS" were combined. Internal validity was assessed using the Newcastle Ottawa Quality Assessment Scale. Outcomes were reported as age-specific standardized deviation scores of cardiometabolic parameters: body mass index, blood pressure, insulin resistance, lipid profile and metabolic sum score. Linear mixed models were used for analyses with age-standardized estimated mean differences as outcome, corrected for multiple testing.

Main results and the role of chance:
Nine relevant observational studies could be identified which jointly included 1,367 children originating from the Netherlands, Chile and the United States. After removal of neonates, duplicate records and follow-up screenings 885 subjects remained, of which 298 children were born to mothers with PCOS and 587 controls.

PCOS offspring exhibited increased plasma levels of fasting insulin (β=0.21(SE:0.10), p=0.046), insulin–resistance (β=0.21(Standard Error

(SE:0.10)), p=0.042), triglycerides (β=0.19(SE:0.09), p=0.030) and HDL-cholesterol concentrations (β=0.31(SE:0.12), p=0.008), but reduced birth weight (β=-116(SE:40), p=0.004) compared to controls.

Interaction tests for sex revealed differences between males and females comparing PCOS offspring versus controls. Higher 2-hour fasting insulin was observed within females (estimate for females (β_f)=0.45(Standard Error(SE:0.20)) compared to males (estimate for males (β_m)=-0.20(SE:0.20)), interaction-test: p=0.030). LDL-cholesterol differences were lower within females (β_f=-0.39(SE:0.12), β_m=0.27(SE:0.15), interaction-test: p<0.001). Total cholesterol was also lower in female PCOS offspring versus female controls (β_f=-0.31(SE:0.13)) in comparison to the difference within males (β_m=0.28(SE:0.15), interaction-test: p=0.012). HDL-cholesterol was higher in female PCOS offspring versus controls (β_f=0.53(SE:0.17)), compared to the difference within males (β_m=0.13(SE:0.09)), interaction-test: p=0.007). The overall metabolic sum score appeared lower in females (β_f=-0.23(SE:0.46)), than within males (β_m=0.84(SE:0.48)), interaction-test: p=0.004).

After multiple testing correction (significance level: p=0.05/3=0.017) however, differences in insulin and triglycerides lost their statistical significance.

Limitations, reasons for caution:

We used international external reference sources to calculate standardized deviation scores for BMI and systolic blood pressure which already takes sex of the child into account. The additional correction for sex by using interaction terms and stratification methods, may have resulted in an underestimation of differences between males and females.

Wider implications of the findings:

We observed subtle signs of a compromised cardiometabolic health predominantly in female offspring between 1 and 18 years of age of women with PCOS. Further high validity studies should elucidate the influence of PCOS diagnosis on males and females during the fetal development and consequently during childhood.

O-312 Effects of a three-component lifestyle intervention on emotional well-being in women with PCOS

L. Jiskoot[1], R. Timman[2], A. Beerthuizen[2], A. Dietz de Loos[3], J. Busschbach[2], J. Laven[3]

[1]*Erasmus MC, Dept. of Reproductive Medicine and Dept. of Psychiatry- section Medical Psychology and Psychotherapy, Rotterdam, The Netherlands*

[2]*Erasmus MC, Dept. of Psychiatry- section Medical Psychology and Psychotherapy, Rotterdam, The Netherlands*

[3]*Erasmus MC, Dept. of Reproductive Medicine, Rotterdam, The Netherlands*

Study question:

Is a multidisciplinary one-year cognitive-behavioural lifestyle treatment more effective to decrease emotional well-being than usual care?

Summary answer:

Depression scores only decreased significantly more in the lifestyle group compared to the usual care group during the first 5.38 months, thereafter the difference decreased.

What is known already:

Women with PCOS experience more depressive and anxiety complaints, have a lower self-esteem and have a more negative body-image compared to women without PCOS. Especially obese women with PCOS have higher depression rates compared to non-obese women with PCOS. Lifestyle interventions based on two-components have demonstrated short-term effects on well-being in women with polycystic ovary syndrome (PCOS). In general, three-component interventions including diet, exercise, and cognitive behavioral therapy (CBT) have shown to be effective at the long-term to improve emotional well-being. This has not yet been studied in women with PCOS.

Study design, size, duration:

The present study is a longitudinal RCT to study the effectiveness of a three component 1-year cognitive-behavioural lifestyle intervention on emotional well-being in overweight/obese women with PCOS. A total of 164 participants were randomly assigned to three groups: 1) CBT provided by the multidisciplinary team or; 2) CBT provided by the multidisciplinary team and Short Message Service (SMS) or; 3) usual care: women are encouraged to lose weight through publicly available services (control group).

Participants/materials, setting, methods:

Women with menstrual cycle disorders are systematically screened using a standardised protocol. Data of 164 women diagnosed with PCOS according to the Rotterdam criteria, a Body Mass Index above 25 kg/m^2 were included. We measured depression with the Beck Depression Inventory, self-esteem with the Rosenberg Self-Esteem Scale and body image with the Fear of Negative Appearance Evaluation scale, all measured at start and at three, six, nine and twelve months.

Main results and the role of chance:

Depression scores only decreased significantly (26.7%, P=0.04) during the first 5.38 months of lifestyle compared to care as usual. After 5.38 months the difference decreased while weight loss continued. In the long-term, depression scores in lifestyle were not significantly lowered compared to care as usual (P=0.376). Self-esteem scores improved 11% comparing lifestyle to care as usual at 12 months (P=0.053). Body image improved 17.7% comparing the lifestyle group to the care as usual at 12 months (P=0.038). Also, a lower depression score at baseline was significantly associated with 5% weight loss (OR 0.96; CI 95% 0.93-1.00; P=0.039) but not with 10% weight loss. A more positive body image at baseline was significantly associated with 10% weight loss (OR 0.93; CI 95% 0.87-0.99; P=0.020).

Limitations, reasons for caution:

A limitation of our study is that we did not use a structured clinical interview such as the SCID-I to diagnose clinical mood disorder to verify clinically relevant depression scores.

Wider implications of the findings:

A three-component lifestyle intervention program for obese women with PCOS resulted in temporal lower depression scores and long term improvements for self-esteem and body image if we compared lifestyle to control. Women with PCOS need long-term three-component lifestyle interventions for weight loss and additional psychological treatment to improve mood.

[6]*Oulu University Hospital, Department of Clinical Chemistry, Oulu, Finland*

[7]*University of Oulu, Medical Informatics and statistics Research Group, Oulu, Finland*

Study question:

What are the clinical, hormonal or metabolic parameters that associate with pregnancy and live-birth (LB) during metformin in anovulatory women with polycystic ovary syndrome (PCOS)?

Summary answer:

Decrease in serum anti-Müllerian hormone(AMH) levels during metformin treatment was the only parameter that associated significantly with improved pregnancy and LB rates in PCOS women.

What is known already:

Metformin treatment has been shown to improve pregnancy and LB rates in women with PCOS and anovulatory infertility. However, one third of PCOS women do not respond to metformin treatment. Whether the responsiveness to metformin treatment in PCOS is related to the severity of menstrual disorders, metabolic disturbances, obesity, degree of insulin resistance or androgen

excess remains controversial. Previously, metformin treatment has been shown to decrease serum AMH levels in women with PCOS, however, the possible association with improvement in the pregnancy and LB rates has not been investigated.

Study design, size, duration:

Multicenter, randomized (1:1), double-blind, placebo-controlled study investigating the efficacy of metformin in anovulatory infertility. Three-hundred-twenty women with PCOS women were randomized receiving metformin or placebo until the 12th week of pregnancy or maximally nine months. Women with BMI≥27kg/m^2 received 1000 mg×2/day and women with BMI<27kg/m^2 500mg+1000mg/day, or identical placebo. Serum samples were obtained at 0 and 3 months. After 3 months of treatment with metformin/-placebo alone, another appropriate infertility treatment was combined, if necessary.

Participants/materials, setting, methods:

Clinical (weight, waist/hip circumferences, BMI, hirsutism), metabolic (fasting insulin and glucose, area under curve for insulin and glucose during OGTT, insulin resistance indexes), and hormonal (testosterone, sex hormone binding globulin [SHBG], free androgen index, androstenedione, AMH) parameters were assessed at baseline and at 3 months. Women getting pregnant before 3 months or cases with missing sample at 3 months were excluded. Comparisons were done between the women achieving and not achieving pregnancy/LB after 3 months'treatment.

Main results and the role of chance:

Metformin group (N=126): Women achieving pregnancy (N=56) or LB (N=49) had shorter duration of infertility (p=0.031 and p=0.004, respectively). During 3 months of treatment, serum AMH levels decreased significantly more among women later achieving pregnancy (decrease: 10.13±6.93ng/mL to 8.98±5.90ng/mL vs. 9.20±5.16ng/mL to 9.22±5.06mg/mL, change:-1.15±3.37ng/mL vs. 0.02±2.74ng/ml,p=0.039) or LB (decrease: from 10.49±7.29ng/mL to 9.24±6.21ng/mL vs. 9.05±5.00ng/mL to 9.02± 6.21ng/mL, change: -1.25±3.59ng/mL vs. -0.03±2.61ng/mL,p=0.034). In multivariate regression analysis, AMH decrease during 3 months of treatment was the only predictive factor for pregnancy and LB when previous pregnancies, infertility duration, age and BMI change were taken into account (pregnancy:OR 1.149[95%CI 1.004–1.315]p=0.044, LB:OR 1.149[95%CI 1.003–1.315]p=0.044).

Placebo group (N=125): Women achieving pregnancy (N=43) or LB (N=36) after 3 months of treatment were less hirsute (p=0.031 and p=0.047 respectively) and had higher serum SHBG levels (p=0.018 and p=0.029 respectively) at baseline. BMI (p=0.008 and p=0.003, respectively) and waist circumference (p=0.007 and p=0.012, respectively) decreased more during 3 months of treatment in women who later achieved pregnancy or LB. In multivariate regression analysis, BMI decrease was the only predictive factor for pregnancy and LB when previous pregnancies, infertility duration and age were taken into account (pregnancy: OR 1.841[95%CI 1.145–2.961]p=0.012, LB: OR 2.019[95%CI 1.233–3.308]p=0.005).

Limitations, reasons for caution:

All women did not attend the control visit at 3 months of treatment and the women who had achieved pregnancy before that point were excluded. Non-obese women used a lower metformin dose which may have biased the results in the metformin group.

Wider implications of the findings:

Among several clinical, metabolic and hormonal parameters, the decrease of serum AMH levels was the best indicator for patients' responsiveness to metformin treatment. These results open interesting new insights into the mechanisms of metformin action and possible use of AMH levels in predicting pregnancy outcomes in anovulatory women with PCOS.

Study question: Is there an association between Vascular Endothelial Growth Factor VEGF -1154 guanine(G)>adenine(A) (rs1570360) polymorphism and sperm DNA integrity?

Summary answer: The VEGF G>A polymorphism seems to influence sperm quality. Men carrying the A allele (GA or AA genotypes) exhibited increased levels of sperm apoptosis.

What is known already: VEGF is a major factor in angiogenesis and a prime regulator of endothelial cell proliferation. It is involved in oocyte maturation, trophoblast proliferation, embryo implantation and development, angiogenesis of the placenta, and the growth of maternal/foetal blood vessels. Reports indicate that several VEGF gene polymorphisms affect VEGF protein activity and expression. The VEGF -1154G>A polymorphism characterised in the promoter region of the gene has been correlated with variations in protein production and recurrent implantation failure. Unfortunately, the association between VEGF gene polymorphisms and male fertility is not commonly analysed.

Study design, size, duration: The study enrolled 363 men submitted to infertility assessment. Semen analyses were performed according to WHO guidelines/morphology motile sperm organelle morphology examination (MSOME). For DNA integrity analysis, the proportions of DNA fragmentation (TUNEL), abnormal chromatin packaging/underprotamination (chromomycin A3/CMA3), and apoptosis (annexin-V) were recorded. At least 200 spermatozoa were examined in each evaluation. Potential confounders (age, abstinence, smoking, drinking alcohol, and varicocele) were also observed.

Participants/materials, setting, methods:

DNA was extracted from peripheral blood samples taken from each participant and the VEGF single nucleotide polymorphism (SNP) -1154G>A was genotyped by real-time PCR. For purposes of comparison, the subjects were divided into three genotype groups according to their results: GG; GA; or AA. The level of significance was set at $P<0.05$. Hardy-Weinberg genotype distributions of the entire sample indicated concordance between the observed and expected frequencies.

Main results and the role of chance: No correlations was observed between VEGF-1154G>A and age, abstinence, smoking, drinking alcohol, or varicocele. Genotypes carrying the A allele (GA or AA genotypes) were associated with higher proportions of spermatozoa apoptosis (Table 1). No association was observed between genotypes VEGF-1154G>A and other semen parameters (Table 2).

Table 1 VEGF-1154G>A vs. DNA integrity analysis

VEGF Genotypes	DNA fragmentation (%)	Apoptosis (%)	CMA3 positivity (%)
GG	13.3±6.9	**18.2±7.2[a,b]**	56.4±17.4
GA	13.4±7.9	**21.1±9.0[a]**	55.2±16.8

P	0.77	**[a]0.01;[b]0.04**	0.76
GG+GA	13.4±7.4	19.4±8.1	55.9±17.1
AA	14.8±9.6	21.0±7.7	54.5±15.9
P	0.37	0.29	0.64
GG	13.3±6.9	**18.2±7.2**	56.4±17.4
GA+AA	13.8±8.4	**21.0±8.6**	55.0±0.3
P	0.61	**0.005**	0.49

Table 2 VEGF-1154G>A vs. general and semen parameters

Parameters	VEGF Genotypes			
	GG	GA	AA	*P*
n	179	132	52	
Age (years)	38.1±5.8	38.1±6.1	37.7±6.3	0.87
BMI (Kg/m^2)	28.6±4.4	28.3±4.2	28.4±4.4	0.76
Abstinence (days)	3.2±1.9	3.2±2.1	3.7±2.7	0.62
pH	8.1±0.2	8.1±0.3	8.1±0.2	0.32
Volume (ml)	2.9±1.4	2.7±1.3	3.0±1.8	0.37
Concentration (mlx10^6)	64.3±52.9	59.8±53.6	67.4±42.7	0.30
Progressive motility (%)	52.5±17.2	53.8±15.8	54.5±15.6	0.84
Total motility (%)	59.6±16.7	61.0±16.4	61.0±14.7	0.89
Normal sperm structure (%)	0.6±0.8	0.7±0.78	0.7±0.6	0.40
Leukocytes (x10^6/ml)	0.5±0.8	0.4±0.6	0.3±0.3	0.77
Vitality (%)	61.8±16.2	62.5±14.8	62.8±15.6	0.97

Limitations, reasons for caution: Differences in the genetic backgrounds of various ethnic populations should be considered. The sperm were obtained from men submitted to fertility assessment. Generalization of these results to the general population should be performed with caution

Wider implications of the findings: The results indicated that VEGF -1154G>A (rs1570360) gene polymorphisms were related to sperm apoptosis. Further investigations with larger populations should be conducted to confirm these findings and to determine their clinical implications.

Trial registration number: Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

P-002 Is there an association between the TP53 codon 72 polymorphism and sperm DNA damage?

M. Mattila[1], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], B. Petersen[1,2], C. Zamara[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil

Study question: Is there an association between the TP53 codon 72 polymorphism (which encodes arginine [Arg] or proline [Pro]) (rs1042522) and sperm DNA damage?

Summary answer: The TP53 codon 72 polymorphism seems to be linked to sperm DNA damage.Sperm DNA fragmentation was more pronounced in the presence of the Arg allele.

What is known already: The TP53 protein plays a critical role in maintaining genomic stability and mediates pregnancy by regulating the activation of steroid hormones and functionally related genes essential for foetal-maternal interactions during implantation. The literature provides evidence that maternal genotype for the TP53 codon 72 polymorphism (rs1042522) is associated with repeated implantation failure after IVF/ICSI or recurrent miscarriage. However, the relevance of male genotypes has not been determined yet.

Study design, size, duration: This cross-sectional study included the semen samples of 364 men (38.1±6.0 years) from couples seeking care at a fertility clinic. The semen analyses derived from one semen sample of each enrolled subject were recorded. For DNA integrity analysis, the following proportions were determined:

- Spermatozoa with DNA fragmentation using the TUNEL assay;
- Spermatozoa with abnormal chromatin packaging/underprotamination using chromomycin A3 (CMA3);
- Spermatozoa with abnormal mitochondrial membrane potential (MMP) using MitoTracker Green;
- Spermatozoa apoptosis using annexin-V.

Participants/materials, setting, methods: DNA was extracted from peripheral blood, and the TP53 gene codon 72 single nucleotide polymorphism(SNP) Arg>Pro was genotyped using real-time PCR with the Taqman Universal PCR Master Mix and Taqman SNP genotyping assays. The subjects were categorised based on their genotypes into three groups: Arg/Arg(n:187); Arg/Pro(n:151); or Pro/Pro(n:26). Potential confounders(age, abstinence time, smoking, drinking alcohol, and varicocele) were also observed. Hardy-Weinberg genotype distributions of the entire sample indicated concordance between the observed and expected frequencies.

Main results and the role of chance: No correlation was observed between TP53 gene codon 72 SNP Arg>Pro and age, abstinence, smoking, drinking alcohol, or varicocele. Although there was no observed association between TP53 genotype or alleles and underprotamination, apoptosis or mitochondrial damage, the proportions of sperm DNA fragmentation were higher in men carrying the Arg allele (Arg/Arg and Arg/Pro genotypes). Table 1 shows the results.

Table 1 TP53 gene codon 72 single nucleotide polymorphism vs. DNA damage parameters: group comparisons.

TP53 Genotypes	DNA fragmentation (%)	Apoptosis (%)	CMA3 positivity (%)	Abnormal MMP (%)
Arg/Arg	**14.6±7.8^{a,b}**	20.1±9.3	56.4±17.1	26.5±17.7
Arg/Pro	**12.4±7.4^{a}**	19.0±6.2	55.5±17.0	26.0±16.2
Pro/Pro	**9.7±3.1^{b}**	19.6±6.8	53.3±16.3	22.4±17.0
P	**^{a}0.02, ^{b}0.004**	0.85	0.70	0.73
Arg/Arg+ Arg/Pro	**13.7±7.9**	19.6±8.1	56.0±17.0	26.3±17
Pro/Pro	**9.7±3.1**	19.6±6.8	53.3±16.3	22.4±17.0
P	**0.03**	0.98	0.50	0.39
Arg/Arg	**14.6±7.8**	20.1±9.3	56.4±17.1	26.5±17.7
Arg/Pro+ Pro/Pro	**12.0±6.9**	19.1±6.3	55.1±16.8	25.3±16.3
P	**0.002**	0.64	0.55	0.65

Values within each column with the same superscript letter were significantly different.

Limitations, reasons for caution: The data are cross-sectional and specifically focus on the association between a specific TP53 polymorphism and DNA damage. Only males from infertile couples were sampled. Differences in the genetic backgrounds of various ethnic populations should also be considered.

Wider implications of the findings: The TP53 gene codon 72 SNP Arg>Pro (rs1042522) might impair sperm DNA integrity and probably affects male reproductive capacity. Additional validation of the analysed SNP with a greater number of cases is required to confirm these findings and provide more robust evidence of possible clinical implications

Trial registration number: Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

P-003 Evaluation of the Herpes Virus-Associated Ubiquitin-Specific Protease (HAUSP) gene polymorphism (rs1529916) on semen quality and sperm DNA damage

A. Nicoletti[1], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], B. Petersen[1,2], A. Renzi[2], M. Mattila[1], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil

Study question: Are there correlations between the herpes virus-associated ubiquitin-specific protease (HAUSP) gene guanine (G)>adenine (A) (rs1529916) polymorphism and semen quality or sperm DNA damage?
Summary answer: There seems to be no association between HAUSP G>A polymorphism and semen or DNA damage parameters.
What is known already: Single nucleotide polymorphisms (SNPs) in the p53 pathway have been linked to fertility in humans. An important regulator of this pathway is HAUSP (or USP 7), a specific deubiquitinase that stabilises the p53 protein. The literature provides evidence that the HAUSP gene G>A (rs1529916) polymorphism in women is associated with fertility. However, the impact of the HAUSP gene polymorphism on male fertility is often disregarded.
Study design, size, duration: This prospective cohort study enrolled 359 males seeking fertility care. DNA was extracted from peripheral blood, and the HAUSP gene G>A (rs1529916) was genotyped using real-time PCR with the Taqman Universal PCR Master Mix and Taqman SNP genotyping assays. Patients were genotyped for HAUSP polymorphisms GG (n=186), GA (n=145) and AA (n = 28). The different genotype groups were compared for their semen analysis results
Participants/materials, setting, methods: A portion of each semen samples was used for analysis according to the WHO guidelines/morphological analysis by motile sperm organelle morphology examination(MSOME). The remainder of the semen samples were tested for sperm DNA fragmentation using TUNEL assays; sperm apoptosis was analysed using the annexin V assay; sperm chromatin packing/protamination was assessed using chromomycin A3(CMA3) staining; and sperm mitochondrial membrane potential(MMP) was analysed using MitoTracker Green. At least 200 spermatozoa were examined in each evaluation
Main results and the role of chance: Hardy–Weinberg genotype distributions indicated concordance between the observed/expected frequencies. No correlation was observed between HAUSP genotype and potential confounders (age, abstinence time, smoking, drinking alcohol, or varicocele). No association was observed between HAUSP genotype and general semen parameters or sperm DNA damage. Table 1 shows the data.
Limitations, reasons for caution: Additional validation of the analysed SNP (using a greater number of cases) will be important to provide more information. Although all available eligible males were enrolled in the study, the sample size was limited. Differences in the genetic backgrounds of various ethnic populations should also be considered
Wider implications of the findings: Despite previous reports of an association between the HAUSP G>A (rs1529916) polymorphism and human fertility, there appeared to be no relation between genotypes and semen quality or sperm DNA damage. This polymorphism is probably not useful in the evaluation of male infertility
Trial registration number: Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

P-004 The methylenetetrahydrofolate reductase (MTHFR) gene C677T polymorphism (rs1801133) might increase the risk of sperm DNA fragmentation

L. Vagnini[1], C.G. Petersen[1,2], A.L. Mauri[1,2], A. Renzi[1], B. Petersen[1,2], M. Mattila[2], A. Nicoletti[2], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]

[1]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[2]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil

Study question: Is it possible to determine association between methylenetetrahydrofolate reductase (MTHFR) gene C677T polymorphism (rs1801133) and impaired structure of sperm DNA and/or general sperm parameters?
Summary answer: Genotypes with the T allele appear to be an additional molecular genetic risk for increased in DNA sperm fragmentation and for worse seminal quality.
What is known already: The 5-methylenetetrahydrofolate reductase is a key regulatory enzyme involved in folate metabolism, critical factor in DNA methylation and spermatogenesis. The change from C to T at the nucleotide position 677 of the MTHFR gene causes the substitution of alanine for valine in the MTHFR enzyme with consequent reduction in its activity. Meta-analyses have associated MTHFR C677T polymorphism and the risk of male infertility. However, the results are still inconsistent, frequently presenting significant heterogeneity between the studies analysed. On the other hand, association between MTHFR C677T polymorphism and damage in sperm DNA structure (fragmentation) has been paucity evaluated.
Study design, size, duration: 348 men from couples who underwent infertility evaluation/treatment was recruited. Pathological conditions of the genital tract, varicocele, azoospermia and vitamine suplemente use were exclusion criteria.

For DNA integrity analysis, the following percentages were determined:

- DNA fragmentation(by TUNEL assay);
- Abnormal chromatin packaging/underprotamination(by chromomycin A3/CMA3);
- Abnormal mitochondrial membrane potential(MMP/by MitoTracker Green);
- Apoptosis(by annexin-V).

The remainder portion of each sample was used for analysis according to the WHO guidelines/morphological analysis by motile sperm organelle morphology examination(MSOME).
Participants/materials, setting, methods: DNA was extracted from peripheral blood samples taken from each participant and the MTHFR C677T single nucleotide polymorphism (SNP) (rs1801133) was genotyped by real-time PCR TaqMan SNP genotyping assay**.** For comparisons the men were divided into three genotype groups according to their result: CC (n:155), CT (n:141) and TT (n:52). The level of significance was set at $P<0.05$.
Main results and the role of chance: No correlation was observed between MTHFRC677T and age, BMI, abstinence, smoking, or drinking alcohol.

Table 1 MTHFRC677T vs. semen parameters parameters

Parameters	MTHFRC677T Genotypes						
	CC	CT	TT	*P*	CC	CT+TT	*P*
pH	8.0±0.2	8.1±0.3	8.1±0.2	0.37	8.0±0.2	8.1±0.3	0.29

Normal sperm(%)	**0.8±0.9[a,b]**	**0.6±0.7[a]**	**0.5±0.7[b]**	**[a]0.02;[b]0.04**	**0.8±0.9**	**0.5±0.7**	**0.008**
LNV(%)	**32.1±19.0[a,b]**	**37.0±18.1[a]**	**38.5±18.6[b]**	**[a]0.02;[b]0.03**	**32.1±19.0**	**37.7±18.2**	**0.002**
DNA fragmentation(%)	**13.7±7.5[a]**	**16.2±8.2[a]**	**16.3±8.6[a]**	**[a]0.007;[b]0.03**	**13.7±7.5**	**16.2±8.3**	**0.003**
Apoptosis(%)	18.8±7.1	20.2±7.0	20.2±8.9	0.46	18.8±7.1	20.2±8.2	0.10
CMA3 positivity(%)	55.9±16.2	54.9±16.1	56.0±17.7	0.88	55.9±16.2	55.2±16.5	0.82
Abnormal MMP(%)	25.8±17.5	25.3±16.5	24.9±18.0	0.92	25.8±17.5	25.2±16.8	0.82

Despite the lack of an association with sperm apoptosis, protamination and mitochondria damage, males carrying the T allele (genotypes C/T and T/T) presented higher proportions of sperm DNA fragmentation. In addition, T allele was associated with decreased sperm concentration, motility, vitality, and normal forms, and increased proportions of sperm with large nuclear vacuole(LNV:vacuoles occupy >50% of the nuclear area)(Table 1).

Limitations, reasons for caution: This study was conducted in couples seeking fertility treatment and might, therefore, be biased toward infertility. Folate and homocysteine measurements might help in data analysis. Differences in the genetic backgrounds of various ethnic populations should also be considered.

Wider implications of the findings: Infertile men with high DNA fragmentation and/or poor semen quality should be screened for MTHFR C677T. A folate-rich diet or folate supplementation (e.g.: 5-methyl tetrahydrofolate) should be recommended as part of therapy. Other mutations of the MTHFR gene should also be considered.

Trial registration number: Not applicable. The local ethics committee authorised the study. This study was supported by Merck Grant for Fertility Innovation (GFI-2014-16).

P-005 The obstructive interval predicts pregnancy chance in post-vasectomy patients undergoing intracytoplasmic sperm injection with surgical sperm retrieval

E. Borges Junior[1,2], D. Braga[2,3], R. Provenza[4], A. Iaconelli Jr.[1,2], A. Setti[2,3]

[1]*Fertility Medical Group, Clinical Department, Sao Paulo, Brazil*
[2]*Associação Instituto Sapientiae, Scientific research, Sao Paulo, Brazil*
[3]*Fertility Medical Group, Scientific research, Sao Paulo, Brazil*
[4]*Fertility Medical Group, Andrology laboratory, Sao Paulo, Brazil*

Study question: What is the influence of the obstructive interval (OI) on surgical sperm retrieval (SSR) and intracytoplasmic sperm injection (ICSI) in couples with previous vasectomy?

Summary answer: Higher OI reduces the chance of finding epididymal sperm, increasing the necessity of testicular sperm retrieval. Moreover, it reduces blastocyst development, implantation and pregnancy rates.

What is known already: Nearly 6% of the couples with obstructive azoospermia due to prior vasectomy often seek medical care for vasectomy reversal. Although satisfactory pregnancy rates have been demonstrated after reversal, some patients still struggle to achieve pregnancy after reversal or even opt to undergo ICSI with SSR, namely, percutaneous epidydimal sperm aspiration (PESA) and testicular sperm aspiration (TESA). The OI is an important factor to consider, since higher incidence of anti-sperm antibodies and sperm clumping with decreased motility have been reported to occur over time in vasectomized men. The literature addressing the influence of OI on ICSI outcomes, with SSR, is scarce.

Study design, size, duration: This historical cohort study analyzed the medical records of 148 patients (194 cycles) with azoospermia due to vasectomy, who presented for PESA and ICSI, between Jan/2012 and Feb/2017. The sample size calculation revealed that a sample of at least 132 treatment cycles had 95% power to detect a 10% effect (α of 5%). The OI was recorded for each couple. Couples were included only in the presence of isolated secondary azoospermia due to vasectomy.

Participants/materials, setting, methods: This study was performed in a private university–affiliated in vitro fertilization center. General Mixed Models were used to investigate the associations between OI and the outcomes of SSR and ICSI. Receiver operating characteristic (ROC) curve analysis was performed to assess the predictive value of OI on pregnancy achievement. The best cutoff value was defined by Youden's index (J), according to the maximized sensitivity and specificity.

Main results and the role of chance: The obstructive interval was negatively correlated with the presence of sperm (β: -0.032, p: 0.009) and motile sperm (β: -0.031, p: 0.010) during PESA. The need to convert to TESA was significantly influenced by the obstructive interval (β: 0.012, p: 0.003). The obstructive interval did not influence the fertilization rate (β: -0.098, p: 0.747) and the high-quality embryos rates on days 2 (β: -0.001, p: 0.777) and 3 (β: 0.001, p: 0.472). The blastocyst development rate on day 5 was inversely correlated with the obstructive interval (β: -0.011, p: 0.014). Implantation and pregnancy rates were negatively influenced by the obstructive interval (β: -1.107, p: 0.039 and β: -0.016, p: 0.031, respectively). The miscarriage rate was not significantly associated with the obstructive interval (β: 0.006, p: 0.483). The ROC curve analysis demonstrated that the obstructive interval has a predictive value on the achievement of pregnancy (AUC: 0.667, CI: 0.573 - 0.752, p: 0.001). The cutoff value defined by Youden's index demonstrated a negative predictive value on the chance of pregnancy with > 17 years of vasectomy (J: 0.3385, sensitivity: 90.32, specificity: 43.53).

Limitations, reasons for caution: The main limitation of this study is its retrospective design. Although being the largest cohort series, our study is still limited in size when compared with the large cohort of couples undertaking ICSI.

Wider implications of the findings: For the patients planning on being vasectomized, we recommend sperm banking. For those who are already vasectomized, we suggest that they seek for reproductive medical help as soon as the fatherhood desire is felt. The use of ICSI with TESA should be considered when pregnancy has failed with PESA.

Trial registration number: None.

P-006 Male infertility treatment for cancer survivors: Do anticancer agents affect infertility treatment?

H. Hibi[1], N. Fukunaga[2], M. Sonohara[3], Y. Asada[4]

[1]*Kyoritsu General Hospital, Urology, Nagoya, Japan*
[2]*Asada Ladies Clinic, IVF & Scientific laboratory, Nagoya, Japan*
[3]*Asada Ladies Clinic, IVF Coordinator, Nagoya, Japan*
[4]*Asada Ladies Clinic, Obstetrics and Gynecology, Nagoya, Japan*

Study question: We investigated whether anticancer agents affected infertility treatment in cancer survivors who consulted our male infertility division.
Summary answer: Anticancer agents did not affect the sperm retrieval rate.
What is known already: The cancer survivors of the reproductive age increase according to the recent advanced cancer treatment. It is well known that cancer treatments are harmful for spermatogenesis.
Study design, size, duration: Cancer survivors who desired to have their own genetic offspring between 2008 and 2018, were enrolled in this study.
Participants/materials, setting, methods: Of 1,525 male infertility patients who consulted our division between 2008 and 2018, 56 (3.7%) were cancer survivors who desired to have their own genetic offspring. Of these, 32 had received anticancer treatment (group A) and 24 were treated with surgery alone or were seen before anticancer treatment (group B).
Main results and the role of chance: The pathology in group A included hematologic cancer (11 cases), testicular cancer (8), colorectal cancer (4), osteosarcoma (3), extragonadal cancer (2), parotid cancer (1), adrenal glioblastoma (1), rhabdomyosarcoma (1), and prostate cancer (1). Group B included testicular cancer (11), colorectal cancer (4), kidney cancer (3), extragonadal cancer (2), lung cancer (1), gallbladder cancer (1), thymus cancer (1), and leukemia (1). Sperm cryopreservation before anticancer treatment was performed in testicular, colorectal, lung, and thymus cancer cases. Semen analysis in the leukemia case in group B revealed azoospermia due to Klinefelter's syndrome. Sperm retrieval surgery was performed in 13 cases in group A and 10 cases in group B. Motile sperm were recovered in 7 cases in group A and in 8 cases in group B. Four healthy deliveries in group A and 2 in group B were achieved and two ongoing pregnancy were observed in group B with intracytoplasmic sperm injection.
Limitations, reasons for caution: The size of our sample was limited in a single-institute setting. A larger sample size is needed.
Wider implications of the findings: Anticancer treatment did not affect successful sperm retrieval in this study. However, some patients abandoned infertility treatment due to the cost of testing and sperm retrieval surgery. Support for the cost of infertility treatment in cancer survivors is necessary.
Trial registration number: not applicable

P-007 Effect of antioxidant supplementation on the sperm proteome in idiopathic infertile men

A. Agarwal[1], M.K. Panner Selvam[1], R. Sharma[1]

[1]*Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland- Ohio, U.S.A.*

Study question: What changes are observed in the sperm proteome after antioxidant therapy in idiopathic infertile men?
Summary answer: The protein profile of spermatozoa before and after-antioxidant treatment are different. There is an upregulation of proteins that are beneficial to spermatozoa after antioxidant treatment.
What is known already: Antioxidant supplementation is one of the treatment option for idiopathic male infertility. Several studies have reported the beneficial effect of antioxidants on semen parameters. However, its role in modulating spermatozoa at molecular level has not been reported. The objective of this study was to evaluate the sperm protein profile of idiopathic infertile men before and after antioxidant supplementation.
Study design, size, duration: A prospective case controlled study was conducted in men with idiopathic infertility. Patients were provided with antioxidant capsules (FH Pro for Men) for a period of 6 months. Semen samples were collected before and after antioxidant supplementation.
Participants/materials, setting, methods: Proteomic profiling of pooled sperm samples from before (n=5) and after antioxidant (n=5) groups were performed using liquid chromatography-tandem mass spectrometry. Ingenuity pathway analysis software was used to select the key differentially expressed proteins (DEPs) associated with normal sperm function. DEPs associated with oxidative phosphorylation (NDUFS1), sperm binding (CCT3) and sperm motility (PRKARA1) were validated by western blot.
Main results and the role of chance: Out of 379 DEPs identified 274 DEPS were overexpressed in men after antioxidant supplementation. Bioinformatic analysis revealed the activation of canonical pathway such as oxidative phosphorylation, and involvement of key upregulated DEPs in spermatogenesis, maturation of sperm, binding of sperm, fertilization and normal reproductive function. Transcriptional factors associated with sperm motility and capacitation (PPARGC1A), and free radical scavenging system (NFE2L2 & HSF2) were functionally activated after antioxidant supplementation. Western blot validation revealed the overexpression of NDUFS1 (6.62 fold change, P=0.0163), CCT3 (5.91 fold change, P=0.0452) and PRKARA1 (4.24 fold change, P=0.0451) after antioxidant supplementation.
Limitations, reasons for caution: Sample size (n=5) is one of the limitation of the study.
Wider implications of the findings: Our proteomic findings suggest antioxidant supplementation of 'FH Pro for Men' in idiopathic infertile men has beneficial effect on sperm function proteins associated with fertility at molecular level.
Trial registration number: None

P-008 Identification of fertility associated proteomics biomarkers in normozoospermic infertile men

A. Agarwal[1], M.K. Panner Selvam[1], P. Pushparaj[2]

[1]*Cleveland Clinic, American Center for Reproductive Medicine-Department of Urology, Cleveland, U.S.A.*
[2]*King Abdulaziz University, Center of Excellence in Genomic Medicine, Jeddah, Saudi Arabia*

Study question: What are the molecular changes in the spermatozoa affecting the fertility as potential of normozoospermic infertile men?
Summary answer: Differential expression of sperm proteins in normozoospermic infertile men alters the homeostasis of development and function of reproductive system.
What is known already: Up to 30% of men with normal semen parameters are diagnosed infertile and the reason for their infertility is unknown. Change in the expression of the sperm proteins may be a major cause of fertility issues in these men.
Study design, size, duration: Proteomic profiling was performed on pooled semen samples from 20 normozoospermic fertile men and 9 infertile patients with normal semen parameters. Four proteins identified by global proteomic analysis as differentially expressed (SPA17, SERPINA5, ANXA2 and PRDX2) were selected for validation by western blot in individual samples from normozoospermic fertile men (n=10) and infertile men (n=10).
Participants/materials, setting, methods: Global proteomic analysis was performed using liquid chromatography-tandem mass spectrometry. The abundance of each protein was categorized as very low, low, medium or high based on the spectral count. The normalized spectral abundance factor ratio was calculated to categorize the expression profile of differentially expressed proteins (DEPs) as underexpressed, overexpressed or unique to one of the groups. Functional pathway analysis of the DEPs was done using the Ingenuity Pathway Analysis (IPA) software.
Main results and the role of chance: LC-MS/MS detected a total of 1139 and 1095 proteins in normozoospermic fertile and infertile groups, respectively. 162 proteins were identified as DEPs. Canonical pathway related to free radical scavenging was enriched with upregulated DEPs in fertile healthy men. Thus, suggesting the presence of poor antioxidant defense system in normozoospermic infertile men. The proteins associated with reproductive system development and function were overexpressed in fertile men. In addition the proteins related to ubiquitination pathway were underexpressed in normozoospermic infertile men. Western blot analysis revealed the overexpression of SPA17 (3.25-fold change), SERPINA5 (2.39-fold change), and underexpression of ANXA2 (0.49-fold change) in normozoospermic fertile group. Validation of proteins associated with acrosome reaction and fertilization process (SPA17), spermiation and sperm maturation process (ANXA2) and morphology of sperm (SERPINA5) showed that the sperm functions such as hyperactivation,

capacitation and acrosome reaction are compromised in normozoospermic infertile men.
Limitations, reasons for caution: Validation of additional proteins by large sample size is a limitation of the current study.
Wider implications of the findings: We have demonstrated by proteomic analysis defective/ altered reproductive pathways in spermatozoa of normozoospermic infertile men. Our data suggests that SPA17, ANXA2 and SERPINA5 may serve as potential non-invasive protein biomarkers to assess the fertilizing ability of the spermatozoa in unexplained male infertility.
Trial registration number: None

P-009 Comparative sperm proteomics of cancer patients and fertile healthy men using LC-MS/MS

A. Agarwal[1], M.K. Panner Selvam[1], P. Pushparaj[2]
[1]*Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland, U.S.A.*
[2]*King Abdulaziz University, Center of Excellence in Genomic Medicine, Jeddah, Saudi Arabia*

Study question: Does cancer have an adverse effect on the sperm proteins associated with fertility potential?
Summary answer: Sperm proteome of the men with cancer is different from that of fertile healthy men.
What is known already: Cancer affects the reproductive health of males. Fertility in these men are compromised after cancer treatment. Sperm banking before cancer treatment is the recommended procedure to preserve their fertility. However the effect of cancer on fertility status in these men cannot be explained using conventional semen analysis. Proteomics can identify the subcellular changes and molecular factors related to the fertilization potential of spermatozoa. Therefore, the main objective of the study was to compare the sperm proteome of cancer patients before initiating cancer therapy with that of healthy fertile men.
Study design, size, duration: Cryopreserved semen samples from cancer patients before starting cancer therapy were used in the current study. Type of cancer patients included were: Testicular cancer (n=28), Hodgkin's disease (n=20), Lymphoma (n=8) and Leukemia (n=5). Pooled samples from the cancer patients were used for proteomic analysis. Proteome of cancer group was compared with fertile men (n=7).
Participants/materials, setting, methods: Pooled samples from cancer group and fertile healthy men were run in triplicates on 1D-SDS PAGE. Each lane was cut into six gel pieces. The proteins and peptides eluted from the gel were subjected to quantitative global proteomic profiling using liquid chromatography-tandem mass spectrometry (LC-MS). Proteins and peptides were identified using search programs MASCOT and SEQUEST. The functional bioinformatic analysis of the differentially expressed proteins (DEPs) was done by Ingenuity Pathway Analysis (IPA) software.
Main results and the role of chance: A total of 1138 proteins were quantifed in the cancer and fertile groups. 460 DEPs were identified between the two groups. 208 DEPs were underexpressed and 62 overexpressed in cancer group. In addition, 182 proteins were uniquely expressed in fertile group, whereas only 8 were unique to cancer group. Bioinformatic analysis revealed mitochondrial dysfunction ($P=7.41E^{-24}$),oxidative phosphorylation ($P= 1.31E^{-15}$) and protein ubiquitination pathway ($P=1.51E^{-09}$) as the top most canonical pathways. These findings suggest that sperm function in cancer patients is compromised as a result of defective mitochondrion and ubiquitination system. In addition, upstream regulation analysis predicted that rapamycin-insensitive companion of mTOR was activated (P= 2.54E-29), suggesting that the progression of cancer affects the spermatogenic process in cancer patients.
Limitations, reasons for caution: The study lacks validation of DEPs due to fewer samples with adequate sperm concentration for western blot analysis.
Wider implications of the findings: Our proteomic findings indicate pathways associated with normal physiological sperm function are compromised in cancer patients. Fertility of these patients is at risk due to altered expression of critical sperm proteins. Screening of sperm proteome from cancer patients before treatment helps in the identification of molecular factors dysregulated in spermatozoa.
Trial registration number: None

P-010 Association of sleep quality, bedtime, and sleep duration with semen quality in males seeking fertility treatment

J. Hvidt[1], U.B. Knudsen[1], R. Zachariae[2], H.J. Ingerslev[1], M.T. Philipsen[1], Y. Frederiksen[2]
[1]*Aarhus University, Clinical Medicine, Aarhus, Denmark*
[2]*Aarhus University, Psychology, Aarhus, Denmark*

Study question: Are sleep quality, bedtime, and self-reported sleep duration associated with semen quality in males seeking fertility treatment?
Summary answer: Early bedtimes (<22:30) and sleep durations of 7.5-7.99 hours were associated with higher semen quality. No association found between global sleep quality and semen quality.
What is known already: Relationships between sleep characteristics and semen quality remain poorly understood. One study found an inverse u-shaped association between sleep quality and semen quality. Another study found that the association between subjective sleep quality and semen quality became non-significant when adjusting for sleep duration. Late bedtimes have also been linked to impaired semen quality, and studies on sleep duration and semen quality suggest that an optimal amount of sleep may exist. Of the limited number of studies regarding sleep and male fertility, only one study included males referred to a fertility clinic and did not rigorously investigate sleep quality nor duration.
Study design, size, duration: As a part of a randomized controlled trial, 104 men and their partners receiving treatment in cooperating fertility clinics in Denmark between 2010-2012, completed an online-version of the Pittsburgh Sleep Quality Index (PSQI). The result of the semen analysis (normal/reduced) was self-reported by the participants based on the information given at the fertility clinics, where the semen analysis was measured in according to WHO specifications.
Participants/materials, setting, methods: Only when both the man and his partner agreed that the male had either reduced (56 men) or non-reduced semen quality (48 men) was the male included. Data analyses included non-parametric statistical analyses including bivariate logistic regressions to investigate potential associations between semen quality and global sleep quality, bedtime, and sleep duration. Results are presented as odds ratios (ORs).
Main results and the role of chance: Early bedtimes (<22:30) were associated with better semen quality than both regular (22:30-23:29) or late (≥23:30) bedtimes (OR: 2.75, 95% CI: 1.1-7.1, p = 0.04 and OR: 3.97, 95% CI: 1.2-13.5, p = 0.03 respectively). Conventional sleep durations (7.5-7.99 hours) were associated with better semen quality than very short (<7.0 hours) or short (7.0-7.49 hours) sleep durations (OR: 6.18, 95% CI: 1.6-24.2, p = 0.01 and OR: 1.36, 95% CI: 1.2-12.9, p = 0.03 respectively). No association was found between long sleep durations (≥8 hours) and semen quality (OR: 0.75, 95% CI: 0.6-7.5, p = 0.25). Furthermore, no association was found between optimal (PSQI ≤6) vs. borderline (PSQI 7-8) or poor (PSQI ≥9) sleep quality in relation to semen quality (OR: 1.19, 95% CI: 0.4-3.4, p = 0.75 and OR: 2.43, 95% CI: 0.8-7.1, p = 0.11 respectively).
Limitations, reasons for caution: The relatively small number of respondents may reduce the statistical power, increase the risk of type-2 error, and limit generalizability of the results. The limited response rate (23%) may increase the risk of biased responses. Lastly, sleep parameters were self-reported rather than measured objectively.
Wider implications of the findings: The present study offers further insight into links between sleep quality, bedtime, and sleep duration and semen quality, suggesting potential areas of optimization in relation to treatment of male infertility.
Trial registration number: The original study: Clinicaltrials.gov, trial no. NCT01187095.

P-011 Effect of a high-fat diet on male fertility and sperm physiology in high fertility performance mice

D. Cohen[1], M. Gómez-Elías[1], T. Rainero Caceres[1], M.M. Giaccagli[1], N. Dalton[2], A. De Siervi[2], P.S. Cuasnicu[1], V. Da Ros[1]
[1]*Instituto de Biología y Medicina Experimental, Laboratorio de Mecanismos Moleculares de la Fertilización, Buenos Aires, Argentina*

[2]Instituto de Biología y Medicina Experimental, Laboratorio de Oncología Molecular y Nuevos Blancos Terapéuticos, Buenos Aires, Argentina

Study question: Does high-fat diet (HFD) induced metabolic syndrome (MetS) affect male fertility and sperm physiology in mice with high reproductive performance?
Summary answer: Although HFD altered some sperm functional parameters, it did not impair male fertility in high reproductive performance mice.
What is known already: The prevalence of the MetS has increased in alarming proportions, being currently around 20-25% in the global population. The MetS has been defined as an increase in at least 3 of the following factors: abdominal obesity, blood pressure, triglycerides, cholesterol and fasting glucose. Although MetS had been originally associated with advanced age, changes in lifestyle have advanced the appearance of symptoms, coinciding now with the reproductive age. Therefore, the study of the effect of MetS on fertility emerges as a novel area of research.
Study design, size, duration: This basic research study was an *in vitro* and *in vivo* experimental approach involving the use of mouse males from a hybrid strain presenting high reproductive performance. Nine animals were included in both control and experimental groups.
Participants/materials, setting, methods: Three-week-old hybrid (C57BL/6xBALB/c) F1 male mice received *ad libitum* control (CD, 6% fat) or high-fat diets (HFD, 30% fat) for 19 weeks. Food intake and animal weight were determined weekly. Triglycerides, cholesterol, fasting glucose and glucose intolerance were measured at the end of the treatment. The impact of MetS on fertility was evaluated through *in vivo* and *in vitro* fertilization experiments. Sperm count, viability, motility, and acrosome reaction were determined through standard determinations.
Main results and the role of chance: HFD mice ingested a higher amount of fat ($p<0.01$) but less total food ($p<0.01$) and only 12% more calories than CD animals ($p<0.05$), indicating that HFD animals received a poor-quality diet. Since week 13 of treatment, HFD mice gained more weight compared to CD mice ($p<0.001$). At the end of the treatment, serum triglycerides levels were similar in both groups but there was a significant increase in cholesterol ($p<0.001$), fasting glucose ($p<0.05$) and glucose intolerance ($p<0.05$) in HFD mice, compatible with MetS. When fertility was evaluated, there was no significant difference between groups in the *in vivo* fertilization rate or in the percentage of embryos that developed to blastocysts *in vitro*. The male reproductive tracts from both groups were similar under macroscopic observation including testicular weight, although there was a higher amount of gonadal fat in HFD mice compared to controls ($p<0.01$). *In vitro* studies were performed as a more restricted condition to unveil sperm defects. Whereas there was no difference in sperm viability, motility or acrosome reaction between groups, sperm count was lower in HFD compared to controls ($p<0.05$). Finally, *in vitro* fertilization assays showed no differences in either fertilization or embryo development rates between groups.
Limitations, reasons for caution: The use of a mouse model to explore human aspects of male fertility which cannot be performed in human subjects and gametes because of ethical and technical limitations.
Wider implications of the findings: The lack of severe effects of HFD on male fertility in animals with high reproductive performance may have clinical relevance for young men with MetS seeking for pregnancy. A point of caution could be the lower sperm counts in combination with other own individual defects or the partner´s fertility status.
Trial registration number: This study was supported by CONICET (PUE 2017) and Roemmers´ Grant.

P-012 Noninvasive evaluation of testicular function by measurement of oxygen saturation of scrotum-testicular tissue using near-infrared spectroscopy

S. So[1], H. Masuda[2], N. Tamura[3], N. Murabayashi[1], F. Tawara[4], N. Kanayama[3]

[1]Hamamatsu University School of Medicine, Reproductive and Perinatal Medicine, Shizuoka, Japan
[2]Tesseikai Neurosurgery Hospital, Urology, Osaka, Japan
[3]Hamamatsu University School of Medicine, Obstetrics and Gynecology, Shizuoka, Japan
[4]Tawara IVF clinic, Reproductive Medicine, Shizuoka, Japan

Study question: To study whether the scrotum-testicular tissue oxygen saturation (S-T StO_2) measured by finger-mounted near-infrared spectroscopy (NIRS) is useful for the evaluation of testicular function.
Summary answer: S-T StO2 was lower than in almost other measurable tissues and had a significant negative correlation with testicular size and positive correlation with LH.
What is known already: It has been reported that partial pressure of oxygen of testes in mammals is lower than that of other tissues, and that Hypoxia Inducible Factor-1 (HIF-1), the expression of which is induced by hypoxic environments is important for normal testicular function. We used NIRS as a noninvasive method of evaluating oxygen saturation (arterial-venous oxygen content) of testis.
Study design, size, duration: Between Jan 2017 and May 2018, 73 men making their first visit to the Tawara IVF clinic (Shizuoka, Japan) for possible causes of male infertility were recruited for this cross-sectional study.
Participants/materials, setting, methods: Seventy-three patients (average age: 35.2 ± 5.6) with measured S-T StO2 were recruited. The causes of infertility were: 14 patients with non-obstructive azoospermia (NOA), two with obstructive azoospermia (OA), 34 with varicocele and 29 with other causes, including poor semen parameters and sexual problems. Among non-NOA patients, 52.6% (n = 30) had low sperm concentration (one patient had no semen analysis data).
Main results and the role of chance: We found that S-T StO2 was low compared to the oxygen saturation of other measurable tissues. The relationship between S-T StO_2 and the following factors was evaluated by simple linear regression: age ($r = 0.04$), scrotum temperature ($r = 0.04$), and testis size ($r = 0.49$). We found a negative correlation between S-TStO_2 and testis size ($p < 0.05$). Consistent with this, S-T StO_2 was significantly higher in NOA patients who have small testis size than in non-NOA patients (NOA patients: 41.4 ± 6.3%, non-NOA patients: 34.5 ± 4.2%, $p < 0.05$). Furthermore, we found that there was a significant positive correlation between S-T StO2 and LH even in non-NOA patients ($r = 0.34$, $p < 0.05$). On the other hand, S-T StO2 did not differ between patients with low sperm concentration and patients with normal sperm concentration (34.4 ± 4.3 vs. 34.4 ± 4.4), suggesting that S-T StO2 correlated with testicular function rather than sperm production. Finally, we found that S-T StO2 tended to be lower in the left-sided testis than right-sided testis, and varicocele affected the S-T StO2.
Limitations, reasons for caution: This study has some limitations. One is that we could not obtain the cutoff value of S-T StO2 for evaluating decreased testicular function. Another is that the S-T StO2 value could not be compared with the oxygen partial pressure of the testes at the tissue level.
Wider implications of the findings: Male infertility contributes to half of infertility cases. In this study, we found that S-T StO2 may be useful for the evaluation of testicular function and the presence or absence of varicocele. Our noninvasive approach provides a new perspective on the novel male infertility assessment method.
Trial registration number: not applicable

P-013 clinical usefulness of groin color doppler ultrasound (CDU) for artery preservation in microsurgical varicocelectomy (MV)

T. Tai[1,2], H. Hattori[1], M. Kataoka[1], M. Tsunoda[2], N. Sugaya[1,2], C. Tanaka[2], E. Funahashi[2], E. Sakamoto[1], M. Takahashi[1], T. Hashimoto[2], M. Toya[1], H. Igarashi[1], K. Kyono[1,2]

[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan

Study question: In MV, is it possible to predict the number of arteries to be preserved by groin CDU?
Summary answer: CDU is capable of imaging blood flow in arteries measuring more than 1.5mm in diameter, and 50% in arteries measuring 1 to 1.5mm in diameter.
What is known already: In MV, ligating the spermatic vein and securing blood flow by preserving arteries are key to better outcomes. To preserve arteries, an ultrasonic blood flowmeter (UBF) is useful. Since the number of arteries varied, it is unclear how many arteries can be preserved before surgery. Although there are reports of a technique to preserve only the deferential artery, it

cannot be ignored that testicular arteries also have blood flow in the testis. Several testicular arteries are found in the spermatic cord, and these are difficult to identify, because the spermatic veins surround the testicular artery as the pampiniform plexus.

Study design, size, duration: Patients (19-50y.o. 35.0+/-6.84) with grade 2 and 3 varicoceles (n=85) were candidates for surgery (Lt=65, Rt=1, Bil=19), from April 2018 to December 2018. y.o. Before CDU was performed in an operating room, the number of arteries with a flow was counted. We compared semen parameters and serum hormone before and 3 months after the surgery. Clinical outcome was evaluated in cases where post-surgery progress follow-up was conducted.

Participants/materials, setting, methods: CDU was performed with a 12MHz probe on the external inguinal ring before incision. MV was performed with local anesthesia. UBF was used to preserve arteries. Then, the arteries were counted and their diameters were measured in surgery. The arteries were separated into three groups depending on their diameter. (group A: >1.5mm, group B: 1mm to 1.4mm, group C: <1mm).

Main results and the role of chance: By CDU, the average number of preserved arteries was 2.49 (1-4) in one side. In surgery, the average number of arteries was 4.36 (2-7). The average artery count was 2.17 (1-4) in group A, 1.24 (0-4) in group B, and 1.05 (0-3) in group C.

The number of arteries in group A was smaller than that of total count of arteries by CDU, and the detected rate in group B was 45.6% by CDU.

There is a significant middle correlation between the number of A+B and CDU ($P<0.05$, $r=0.55$).

Sperm concentration (SC) ($19.42x10^6$/ml vs $32.03x10^6$/ml), sperm motility (SM) (41.66% vs 50.07%), progressive sperm motility (PSM) (33.73% vs 42.67%), and total motile sperm count (TMSC) ($23.22x10^6$/ml vs $42.67x10^6$/ml) were significantly improved after 3 months ($p<0.01$). Semen volume (SV) (2.70cc vs 2.73cc) showed no significant change ($p<0.05$).

In semen parameters, testosterone (5.24ng/ml vs 6.25 ng/ml) had changed significantly after 3 months ($p<0.01$). FSH (6.70 mlU/mL vs 6.39 mlU/mL), LH (6.51 mlU/mL vs 5.55mlU/mL), and E2 (19.73pg/mL vs 23.73 pg/mL) had not changed significantly ($p>0.05$).

Improvement rate of TMSC was 84.5%. No recurrence, testicular atrophy or other adverse event was observed after 3 months.

Limitations, reasons for caution: Only the results of semen examination were evaluated. In the future, it is necessary to evaluate clinical outcomes of ART.

Wider implications of the findings: By CDU, it is possible to predict the number of high-flow arteries, and lead to the improvement of semen parameters. Before surgery, predicting the number of arteries can increase the accuracy of surgery, and it can be expected to reduce the stress of the surgeon.

Trial registration number: none

P-014 Evaluation of seminal plasma proteomic profile in patients with secondary infertility

A. Agarwal[1], A. Martins[1], L. Samanta[2], R. Sharma[1], B. Gopalan[3], B. Willard[4], D. Durairajanayagam[5]

[1]Cleveland Clinic, American Center for Reproductive Medicine - Department of Urology, Cleveland, U.S.A.

[2]Ravenshaw University, Zoology, Odisha, India

[3]Yorg Corporation, Bioinformatics, Plano, U.S.A.

[4]Cleveland Clinic, Research Core Services - Proteomics, Cleveland, U.S.A.

[5]Universiti Teknologi MARA, Physiology - Faculty of Medicine, Selangor, Malaysia

Study question: What are the differentially expressed proteins in the seminal plasma proteome of men with secondary infertility?

Summary answer: Differential expression of seminal plasma proteins in infertile men with secondary infertility affects the normal physiological functions of spermatozoa.

What is known already: Male factor is estimated to contribute to approximately 50% of all infertility cases. Basic semen analysis is the first step in the assessment of the male fertility potential. However, men with normal semen parameters can be infertile. The seminal plasma protein profile is a reflection of spermatozoa homeostasis. Alterations in the seminal plasma proteome can have adverse effects on the fertilization potential of spermatozoa. The aim of this study was to analyze the seminal plasma proteomic profile of patients with secondary infertility in comparison with that of proven fertile donors.

Study design, size, duration: The study included 10 seminal plasma samples, divided into two groups: 1) proven fertile donors, and 2) patients with secondary infertility (n=5/group). Following basic semen analysis, the seminal plasma was separated from the spermatozoa by high-speed centrifugation.

Participants/materials, setting, methods: Seminal plasma proteins were extracted and quantified. For the comparative proteomic analysis, a pooled sample from each group was analyzed using LC-MS/MS and differentially expressed proteins (DEPs) were identified. To analyze the seminal plasma proteomic profile of each group, a quantitative proteomic analysis by liquid chromatography tandem mass-spectrometry (LC-MS/MS) was performed. Mascot and SEQUEST software were used to search the Human Reference Sequence database. Biological relevance of the identified DEPs was evaluated by bioinformatics analysis.

Main results and the role of chance: Proteomic analysis identified a total of 523 proteins, of which 418 were common to both groups, 4 unique to proven fertile donors, and 101 unique to patients with secondary infertility. Among the 53 DEPs identified, 2 were underexpressed (SEMG1, SEMG2), 38 overexpressed (e.g. ANXA2, C3, C4) and 13 unique to patients with secondary infertility (e.g. HSPA8, APP). Semenogelins help form a gel matrix surrounding ejaculated spermatozoa while ANXA2 is critical for blood-testis barrier integrity and timely release of spermatids. As proteins of the immune system, C3 is involved in membrane fusion during fertilization while C4 is essential to the classical complement pathway. HSPA8 enhances sperm membrane fluidity and increases sperm-oviduct binding ability. APP is involved in cell adhesion, cell motility, cell signaling, and apoptosis. Bioinformatics analysis revealed cellular movement, cell-to-cell signaling, interactions and metabolic diseases, carbohydrate metabolism, and inflammatory response as the processes affected in the top protein interaction networks of DEPs. Additionally, inflammation (complement system), immune response (phagocytosis), and phagosome antigen presentation were the other processes enriched with many DEPs. The main transcriptional regulators were androgen receptor and zinc finger protein 143. Dysregulation of the androgen receptor and the pathways essential for the sperm function affected the fertilization process.

Limitations, reasons for caution: The sample size is a major limitation in this study. The use of only 5 different samples for each group is not enough to overcome the biological variability seen in fertile men and that of infertile males with secondary infertility.

Wider implications of the findings: We have demonstrated that men with secondary infertility have altered cellular pathways. Differences in seminal plasma proteome between proven fertile men and males with secondary infertility suggest that these proteins play an important role in fertility impairment. Seminal plasma proteins are a promising source for identification of secondary infertility-related biomarkers.

Trial registration number: Not applicable

P-015 Clinical evaluation of a fully automated semen analysis system (LensHooke X1 PRO) based on the new AIOM (Artificial Intelligence Optical Microscopic) technology

A. Agarwal[1], M.K. Panner Selvam[1], C.T. Hsu[2]

[1]Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland, U.S.A.

[2]Bonraybio Co.- LTD., General Manager, Taichung City, Taiwan R.O.C.

Study question: The performance and efficiency of the LensHooke X1 PRO (X1 PRO) semen analysis device was evaluated by the clinical application of precision, accuracy and time.

Summary answer: LensHooke X1 PRO offers excellent accuracy and efficiency in analyzing the bulk semen parameters.

What is known already: The major shortcomings of standardizing manual semen analysis (MSA) are due to the subjective nature of this test and its dependence on the operator (laboratory technologist). The development of computer-assisted semen analyzers (CASA) over three decades ago has allowed partial automation of routine semen analysis but with limited success due to a complicated operation, lack of accuracy at low and high sperm count range and a high cost of virtually all CASA devices.

Study design, size, duration: 1) Compare speed of analysis (volume, pH, concentration, motility and morphology) between MSA and X1 PRO by a single operator on twenty samples, 2) intra observer correlation (48 readings of sperm count and motility from 16 samples; each sample repeated 3 times) and last 3) inter device correlation (100 readings of sperm count and motility from 20 samples and each sample tested on 5 different X1 PRO devices). The study was conducted during August 2018.
Participants/materials, setting, methods: Semen samples from seven volunteers were tested for sperm count and motility by 1) MSA using Leja slides and by 2) a X1 PRO using semen test cassette. The operator of this study was skilled in routine microscopy but has no experience in using X1 PRO. This pilot study approved by the Ethics Committee was conducted at the Cleveland Clinic's Andrology Center.
Main results and the role of chance: A complete semen analysis by X1 PRO device as compared to MSA method took 90% less time (52.5 + 4.8 vs. 5.2 + 0.5 minutes, P< 0.001). Intra observer's precision between the MSA method and X1 PRO was 4.3% (median 3.8% [2.7 - 4.7%]) and 6.1% (median 5.5% [1.5 - 8.7%]) for sperm concentration, 6.1% (median 4.2% [2.8 - 9.0%]) and 7.4% (median 2.9% [1.9 - 12.9%]) for sperm motility, and 6.0% (median 5.1% [2.7 - 7.9%]) and 9.0% (median 2.3% [0.6 - 17.6%]) for progressive motility. The regression correlation (r) of the X1 PRO with manual method was > 0.95 for sperm concentration and motile sperm concentration (MSC). In addition, sperm concentration and motile sperm concentration were both greater than 85% in sensitivity and specificity as assessed by diagnostic reference values (World Health Organization, 2010 Fifth edition). Inter device precision results showed that the precision performance of X1 PRO was 9.2% (median 7.4% [5.3 - 12.4%]) for sperm concentration, 5.8% (median 5.9% [4.1 - 6.5%]) for sperm total motility, 7.1% (median 6.4% [3.7 - 8.7%]) for progressive motility and 13.7% (median 12.4% [10.5 - 16.1%]) for sperm morphology.
Limitations, reasons for caution: The sample size of seven specimens was a limitation.
Wider implications of the findings: The LensHooke X1 PRO is a simple device which offers fast, reliable and reproducible results of semen analysis.
Trial registration number: Not applicable

P-016 Reversal of oxidative stress by antioxidant therapy improves routine and advanced sperm functions

M. Arafa[1], A. Majzoub[1], A. Agarwal[2], S. AlSaid[1], K. Alrumaihi[1], H. Elbardisi[1]
[1]*Hamad Medical Corporation, Urology/Surgery, Doha, Qatar*
[2]*Cleveland Clinic, American Center for Reproductive Medicine, Cleveland- Ohio, U.S.A.*

Study question: Can supplementation with antioxidants reverse a seminal oxidative stress (OS) state?
Summary answer: Antioxidants can be used to treat seminal OS with subsequent significant improvements in conventional semen parameters and sperm DNA fragmentation (SDF) levels.
What is known already: OS has been recognized as an important cause of male factor infertility. It can trigger sperm lipid peroxidation, DNA fragmentation and abortive apoptosis. Oxidation reduction potential (ORP) measures the balance between oxidants and reductants in a given medium. While various measures of OS have been used to examine the effect of antioxidant treatment, ORP has not been particularly investigated. An ORP reference value of 1.38 mvolts/10^6 sperm has been reported previously to discriminate between abnormal and normal semen quality.
Study design, size, duration: This was a prospective study conducted in a tertiary medical centre between January to June 2018 including 148patients presenting with male infertility of >1year duration, at least one abnormal semen parameter and documented normal female partner fertility. Patients with varicocele, leukocytospermia, genitourinary infections, any febrile illness in the past 6 months and exposure to chemo-radiation were excluded from this study. Patients with seminal OS detected by a high ORP level were included in this analysis.
Participants/materials, setting, methods: All participants were treated with the antioxidant supplement FH-PRO (Fairhaven Health, Bellingham, WA) for a period of 3 months. Semen analysis, SDF (sperm chromatin dispersion test) and ORP (MiOXSYS, Aytu BioScience, Englewood, CO) tests were performed initially and immediately following treatment. Results were compared using Kruskal Wallis Test and a p value of <0.05 was considered statistically significant. The SPSS version 20 (IBM, Armonk, NY) was used to conduct the statistical analysis.
Main results and the role of chance: A total of 116 participants with high ORP value of 12.84 ± 1.6 mVolts/10^6sperm were included in this analysis. The study participants' mean age and body mass index were 36.3 ± 0.6 years and 29.8 ± 0.43 Kg/m^2 respectively. Following treatment, the ORP level decreased significantly in 99/116 (85.3%) but were normalized in only 41/116 (35%) patients. Overall, significant improvements were noted in sperm concentration (+9.02 ± 1.41 x106/ml, p<0.001), total motility (+3.97 ± 1.59%, p=0.013), progressive motility (+3.31 ± 0.79%, p<0.001), normal morphology (+1.09 ± 1.99 %, p<0.001) and SDF (-6.03 ± 1.99%, p=0.004). Patients with normalized ORP levels following treatment had better improvements in conventional semen parameters and SDF values than patients in whom the ORP level improved but remained abnormal (Table 1). These differences were statistically significant only for conventional semen parameters.

Variable	Normal ORP posttreatment (n=41)	Abnormal ORP posttreatment (n=58)	P value*
Semen Volume (ml)	-0.04±0.17	-0.27±0.18	0.572
Sperm Count (10^6/ml)	+21.52±2.51	+3.49±1.2	<0.001
Total Motility (%)	+12.54±2.56	+1.2±2.09	0.001
Progressive Motility (%)	+7.90±1.42	+1.72±0.95	<0.001
Normal Morphology (%)	+2.19±0.48	+ 0.82±0.26	0.017
SDF (%)	-8.19±2.5	-5.03±3.33	0.508

SDF: Sperm DN fragmentation **Kruskal Wallis Test*

Limitations, reasons for caution: The study lacked a placebo group which could be considered as one limitation.
Wider implications of the findings: Antioxidant supplements can reverse the seminal OS state and in turn improve semen parameters and SDF levels. There improvements are expected to hold a favorable effect on the male's fertility potential.
Trial registration number: 16351/16

P-017 Can oxidative stress testing in semen predict sperm DNA fragmentation?

A. Majzoub [1], M. Arafa[1], H. Elbardisi[1], R. Henkel[2], K. Alkubaisi[3], A. Agarwal [4], K. Al Rumaihi [3]
[1]*Hamad Medical Corporation and Weill Cornell Medicine - Qatar, Urology, Doha, Qatar*
[2]*University of the Western Cape, Medical Bioscience, Bellville, South Africa*
[3]*Hamad Medical Corporation, Urology, Doha, Qatar*
[4]*Cleveland Clinic- Center for Reproductive Medicine, Urology, Cleveland, U.S.A.*

Study question: Can seminal oxidation reduction (ORP) potential accurately predict Sperm DNA Fragmentation (SDF) and thereby serve as a surrogate marker for male infertility?
Summary answer: ORP and SDF are interrelated but they measure independent sperm functions. One test cannot predict or replace the other in the evaluation of sperm function.
What is known already: Oxidative stress (OS) is the underlying cause of sperm dysfunction in 25 to 40% of men with idiopathic male infertility and is known to correlate highly with sperm DNA fragmentation (SDF).
Study design, size, duration: This retrospective study included 1,147 patients presenting with male factor infertility to a tertiary medical center over a period of 18 months. The inclusion criteria were infertility duration of > 1year and normal female partner.

Participants/materials, setting, methods: SDF and seminal OS were recorded for all patients. SDF testing was done using the Halosperm G2 test kit (Halotech DNA SL, Madrid, Spain) with a cut-off of 30%, while ORP was determined using the MiOXSYS system (Aytu BioScience, Englewood, CO) with a cut-off of 1.36mV/10^6sperm. Statistical analysis was performed using MedCalc Statistical Software version 18.10 (MedCalc Software bvba, Ostend, Belgium) using non-parametric tests (Spearman Rank correlation, Mann-Whitney test, Fisher's Exact Test, ROC curve analysis).

Main results and the role of chance: Percentage SDF and seminal ORP correlated significantly positively (r=0.225; P<0.0001) and ORP values differed significantly (P<0.0001; Median: 1.57mV/10^6sperm vs. 2.33mV/10^6sperm) between patients with low and high SDF, respectively. Although the correlations between SDF and ORP were still significant in the individual groups (low/high SDF, low/high ORP), the association between the parameters was markedly lower (r=0.0876 to r=0.209). Fisher's Exact test indicates a significant (P<0.0001) relationship between the two classification factors ((low/high SDF, low/high ORP). However, ROC curve analysis showed that although high ORP can significantly (P<0.0001) predict high SDF with a specificity of 57.9% and a sensitivity of 62.4%, this prediction is only moderate.

Limitations, reasons for caution: The main limitation is the retrospective design of the study however this should not affect the study findings.

Wider implications of the findings: Multiple sperm function tests are still needed in order to evaluate the fertilizing ability of the human spermatozoa.

Trial registration number: n/a

P-018 The sperm chip imitating the cervical environment for high performance sperm isolation from raw semen

J. Park[1,2], Y.R. Park[2], H.J. Kwon[1], B.Y. Jeon[1], H.E. Kang[1], I.A. Na[1], E.J. Lee[1], T.E. Shin[1], E.A. Park[2], M.O. Moon[3], J.J. Ko[4], K.A. Lee[4], D.K. Kim[5,6], J.K. Choi[7], J.H. Lee[4,8]

Study question: We designed sperm selection chip which imitating the condition of female reproductive organ and cervical mucus. Can this sperm chip isolate high performance sperm from raw semen?

Summary answer: Similar structure for female reproductive track and viscous media imitating cervical mucus show high quality sperm isolation from semen without any mechanical or chemical treatment.

What is known already: Female reproductive track is known to have a naturally filtering function for selection of high quality sperm from raw semen. This process is not only safer for sperm than artificial sperm retrieval procedures and it is also more efficient for isolate high quality sperm. However, artificial sperm retrieval methods like centrifugation can damage sperm because they cause physical damage.

Study design, size, duration: The sperm chip platform which imitates the structure of the female reproductive organ, was manufactured by laser cutting the polyethylene board(WLH : 3cm X 3cm X 0.25cm). The sperm chip consists of three parts. Startion point(10ul), filtering tract(35ul), end point(10ul). And then, we designed the viscous filtering media for imitating cervical mucus using Ham's F10 and PVP(1%~3%). Normal criteria semen donated by healthy men and approved by IRB from CHA University were used for experiment.

Participants/materials, setting, methods: Sperm chip filled with PVP viscous media has been set as the treatment group. Then we set up the control group which filled with non-viscous media, Ham's F10. Liquefied semen was 10ul dropped in starting point of the platform. After 5min, 10min, 20min, and 30min time point, we collected the sperm from the end point for sperm DNA fragment and kinetics analysis. Each sample was analyzed by cell tracking plug-in ImageJ software for kinetics analysis.

Main results and the role of chance: In this study, we designed a similar female reproductive track condition as sperm chip filled PVP mucus media. It showed the isolation of highly progressive motile sperm from the debris and WBC contaminated semen. PVP filtering sperm chip has a very simple and highly cost-effective method for the motile sperm filtering. Most advanced point of the PVP chip is that there is no need for any mechanical support like the motor system. PVP sperm chip's sperm directly took action without sperm washing and there wasn't any time that was spent on sperm purification. Therefore, sperm that underwent PVP filtering shows a significantly lower number of vacuole sperms than the controlled sorting sperm.

Limitations, reasons for caution: Sperm volume loaded to starting point was very low, so retrieved sperm using the sperm chip was also low. In order for this device to be used in clinical field, the retrieved sperm concentration must be increased and stability verification for fertilization and pregnancy must precede use of this device.

Wider implications of the findings: Sperm chip sperm selection is a more natural and efficient method than the conventional sperm retrieval methods. And sperm chip can retrieve sperm at low cost and easily. In view of this, sperm chip could be used efficiently for intracellular cytoplasmic sperm injection.

Trial registration number: Not applicable.

P-019 The Mu- and Delta- opioid receptors modulate the human sperm acrosome reaction by blocking the calcium channels.

I. Urizar Arenaza [1], I. Muñoa-Hoyos [1], M. Gianzo [1], A. Exposito [2], R. Matorras [2], N. Subiran [1]

[1]*University of the Basque Country UPV/EHU, Physiology, Leioa, Spain*
[2]*Biocruces Bizkaia Health Research Institute, Reproducción Asistida, Baracaldo, Spain*

Study question: Are the Mu- and –Delta- opioid receptors involved in the regulation of human sperm capacitation and acrosome reaction?

Summary answer: Mu- and Delta- opioid receptor agonist do not regulate the human sperm capacitation but inhibit the acrosome reaction by the blocking of the calcium channels.

What is known already: Opioids exert their effect by binding to mu-, delta- and kappa- opioid receptors in human spermatozoa. As it is known, the three opioid receptors are involved in the regulation of sperm motility. Recently we have described the involvement of the kappa-opioid receptor in the inhibition of the sperm motility and acrosome reaction by blocking the calcium channels and producing phosphorylation changes in sperm-specific proteins. However, the role of mu- and delta- in the human sperm capacitation and acrosome reaction, as well the signaling pathways underlying them are largely understood.

Study design, size, duration: We used 100 human seminal samples obtained from the Cruces University Hospital. The isolated sperm cells were used for inhibitory studies of calcium signaling pathways using: Morphine: selective mu-opioid receptor agonist, DPDPE: selective delta-opioid receptor agonist, U73122: Phospolipase C inhibitor, Mibefradil high doses: a calcium channel activator, NNC55-0395: CatSper specific inhibitor. The samples were treated with the different substances for an hour, and the untreated samples (Control) were compared with the treated ones (p<0.05).

Participants/materials, setting, methods: After the treatmens, immunoblotting studies were conducted to evaluate capacitation using the anti-phosphotyrosine antibody and the results were analyzed by densidometry. Acrosome reaction was measured by Flow cytometry using the FITC-anti-CD46 antibody. The statistical analysis was performed using the SPSS Statistics 22 program.

Main results and the role of chance: Morphine and DPDPE did not change the phosphotyrosine levels in human spermatozoa following 1 hour stimulation. However, both agonists inhibited the human sperm acrosome reaction blocking the calcium channels. Morphine and DPDPE were able to blunt the acrosome reaction induced by Mibefradil (p<0.05). The inhibition of the CatSper calcium channel and the Phospholipase C by NNC55-0395 and U73122, respectively had effect on human sperm acrosome reaction, and the agonists had no statistically significant synergic effects.

Limitations, reasons for caution: Further studies are needed to describe the whole signaling pathways underlying each opioid receptor.

Wider implications of the findings: The mu- and delta- opioid receptors participate in the regulation of the acquisition of the fertile capacity in human sperm. This supports the idea that opioid system could be used as a therapeutic target in the finding of new male contraceptives.
Trial registration number: CEISH-UPV/EHU (M10/2016/254).

P-020 A pilot study to identify the level of plagiarism in the most cited andrology related articles

A. Agarwal [1], S. Baskaran [1], M.K. Panner Selvam [1], R. Henkel [1,2], D. Durairajanayagam [3], M. Ahmad [4], K. Leisegang [5], D. Singh [1]
[1]*Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland, U.S.A.*
[2]*University of the Western Cape, Department of Medical Bioscience, Bellville, South Africa*
[3]*Universiti Teknologi MARA, Physiology - Faculty of Medicine, Selangor, Malaysia*
[4]*HamadMedicalCorporation, UrologyDepartment, Doha, Qatar*
[5]*University of the Western Cape, School of Natural Medicine, Bellville, South Africa*

Study question: What is the level of plagiarism in the most cited articles published in andrology journals?
Summary answer: Evaluation of similarity index using iThenticate revealed moderate to high level of plagiarism in the most cited andrology articles.
What is known already: The act of seizing words, data, processes or even ideas from another person without acknowledging or providing appropriate credit is referred as plagiarism. It is a serious problem that could extensively jeopardize the quality of scientific publication. Though several journals have published reviews on plagiarism in scientific writing, there is no transparency on the permissible/non-permissible level of plagiarism in peer reviewed journals. In fact, there is no report on the extent of plagiarism in andrology related articles. Investigating the level of plagiarism in the published articles would provide a broader picture on the current status of plagiarism in andrology-related articles.
Study design, size, duration: Most cited articles (n=34) listed on 7 andrology journals website were analyzed for similarity index using iThenticate and Turnitin software. The articles were categorized based on year (before & after 2012) and type of publication (review vs. research article). The similarity index was compared using both softwares. Articles analyzed using iThenticate were categorized based on the level of plagiarism (low, moderate, high and very high) and incidence rate determined using arbitrary range for similarity index.
Participants/materials, setting, methods: All articles were analyzed using following inclusion and exclusion criteria:

1. Articles/cross references published before the year of analyzed article were included
2. Original source article being analyzed was excluded
3. Bibliography and all match instances below word count of 10 were excluded
4. Comparison with material available from internet sources were excluded
5. Articles/cross references published on the same year or later of the analyzed article were excluded

Main results and the role of chance: The level of plagiarism detected by iThenticate (23.56% ± 12.46) and Turnitin (19.38% ± 11.83) were comparable with a positive correlation of 0.684. Analysis based on the year of publication revealed no significant difference in plagiarism content in articles published before and after 2012 using iThenticate (26.54% ± 12.95 vs 21.72% ± 12.08, P=0.3476) as well as Turnitin (26.54 ± 11.13 vs 18.62 ± 12.45, 0.5350). Similar results were observed upon analysis based on the type of publications (reviews vs research articles) using iThenticate (22.69 ± 10.97 vs. 25.36 ± 15.55, P=0.8486) and Turnitin (18.87 ±11.53 vs. 20.45 ±12.94, P= 0.7025). The incidence rate of low, moderate, high and very high levels of plagiarism was determined to be 9%, 50%, 35%, and 6%, respectively. The above results were obtained based on an arbitrary similarity index (%) range (≤10, 11-20, 21-50, >50) using iThenticate software. Our results indicate that the level of plagiarism based on similarity index in the most cited andrology articles is moderate to high.
Limitations, reasons for caution: Analysis was performed on limited number of articles. Sample size limits the determination of clear cut-off value for the permissible/non-permissible level of plagiarism in andrology-related publications. Internet sources with similarity index (<1%) were excluded from the report.
Wider implications of the findings: Our research sheds light on the level of plagiarism in andrology related articles. Furthermore, it provides a transparency to researchers about the criteria considered in plagiarism check and helps them to be more cautious while penning their findings or ideas and improve the overall standard of scientific writing.
Trial registration number: Not applicable

P-021 Microfluidic sperm selection by the ZyMōt sperm separation device concentrates sperm with significantly less DNA damage for subsequent ART procedures.

D. Hodge [1], M. VerMilyea [2], R. O'Leary [2], S. Wittmier [1], A. Wen[1], G. Ringler [3], K. Baek [3], R. Marrs [3]
[1]*California Fertility Partners, Andrology Lab, Los Angeles, U.S.A.*
[2]*California Fertility Partners, IVF Lab, Los Angeles, U.S.A.*
[3]*California Fertility Partners, Physician, Los Angeles, U.S.A.*

Study question: Can the ZyMōt™ sperm separation device isolate fractions of sperm with less DNA denaturation from ejaculates of men with normal to abnormal thresholds of sperm chromatin fragmentation?
Summary answer: The DNA fragmentation index (DFI) of sperm retrieved from the ZyMōt™ sperm separation device post-processing was significantly lower than that in the fresh ejaculate.
What is known already: With activation of the paternal genome during embryogenesis, subsequent development of a normal embryo is dependent upon sperm DNA integrity. Studies correlate an elevated DFI with male sub-fertility and reduced probability of a successfully pregnancy. Although DFI analysis of sperm is becoming more routine for male fertility assessment, there have been minimal advancements regarding how to isolate and concentrate sperm from the ejaculate which are within the normal DFI range.
Study design, size, duration: This study was conducted between July 2018 and January 2019 at California Fertility Partners. Fresh semen specimens were voluntarily provided by patients scheduled for DNA fragmentation testing by their referring physician. Sperm from fresh semen and sperm harvested from the ZyMōt™ sperm separation device were flash frozen respectively and sent for DNA fragmentation index determination off-site. At that site sperm were then stained with acridine orange and subsequently sorted by flow cytometry.
Participants/materials, setting, methods: A total of 30 semen specimens were analyzed and a portion of the fresh ejaculate was aliquoted to cryogenic storage vials, frozen rapidly, and shipped to ReproSource for the Advanced Semen Report (ASR 2.0) ™. The remaining semen was added to the ZyMōt™ microfluidic device, incubated for 30 minutes and the harvested sperm were also aliquoted to cryogenic storage vials, frozen rapidly and submitted for DFI analysis.
Main results and the role of chance: In our controlled comparison, the study showed that sperm DNA fragmentation index was significantly different between sperm from fresh semen specimens and post processed sperm via the ZyMōt™ device ($p < 0.0001$). The sperm harvested from the ZyMōt™ sperm separation device demonstrated an average sperm DFI decrease of 20%; 95% confidence interval for a decrease between 15% to 25%.
Limitations, reasons for caution: Further validation with larger patient populations is required to definitively establish the significant difference in sperm DFI, however, our preliminary results establish a trend towards the benefit of using the ZyMōt™ microfluidic device. Additional investigation is also needed to confirm that this difference improves embryonic development and clinical outcomes.
Wider implications of the findings: The present study has indicated a compelling decrease in sperm DNA fragmentation; it is likely that the ZyMōt™ microfluidic device may be beneficial across a broad range of male infertility etiologies.
Trial registration number: Not applicable.

P-022 A pilot study to investigate the sperm zona-adhesion score (SZAS) as a predictor of successful implantation

R. Ganeva[1], M. Vasileva[2], K. Nikolova[2], M. Gospodinova[1], I. Ivanova[2], I. Rangelov[2], D. Parvanov[1], G. Stamenov[3], T. Chaushev[1]

[1]MHAT Nadezhda, Research, Sofia, Bulgaria
[2]MHAT Nadezhda, Embryology, Sofia, Bulgaria
[3]MHAT Nadezhda, Obstetrics and Gynaecology, Sofia, Bulgaria

Study question: Is it possible to predict the implantation success by evaluating the sperm zona-adhesion ability?
Summary answer: Evaluation of the sperm zona-adhesion ability is predictive for successful implantation.
What is known already: Disordered sperm-zona recognition and adhesion is one of the main causes for male infertility, but cannot be detected by the routine semen analysis. Hence, additional sperm-binding tests have been developed using whole zona pellucida or hemizona. It has been demonstrated that the hemizona binding assay (HZA) could predict the outcomes of ART. However, the existing methods have some drawbacks, such as using different zonae in each test that results in irrelevant sample comparison. In this study the predictive value of an optimized zona-adhesion assay and sperm zona-adhesion score (SZAS) for the implantation outcome was assessed.
Study design, size, duration: This cross-sectional study was carried out at Nadezhda Woman's Health Hospital (Sofia, Bulgaria) between June 2018 and August 2018. Data on implantation success and spermatozoa zona-adhesion ability were collected for 42 couples who fulfilled the inclusion criteria of male infertility factor and good quality oocytes.

The sperm zona-adhesion assessment was carried using acid solubilized zonae pellucidae that were obtained from healthy donors. All participants have signed an informed consent.
Participants/materials, setting, methods: Semen samples were assessed for routine parameters using the WHO-2010 guidelines and were processed for standard ICSI procedure.

Sperm zona-adhesion score (SZAS) was evaluated in samples of 250 000 motile spermatozoa by calculating the number of adhered spermatozoa per mm^2 of surface that was previously coated with acid-solubilised zonae-solution.

Implantation was determined by peripheral blood HCG concentration on day 14 after embryo transfer.

Statistics: Pearson correlation, t-test, receiver operating characteristic (ROC) curves, logistic regression analysis.
Main results and the role of chance: Patients were classified according to the implantation outcome as successful (n=21) and unsuccessful implantation (n=21). There was no statistical difference in the common semen parameters (sperm count, concentration, motility or morphology) between the two groups. Correlation analysis revealed no relation of the evaluated SZAS to the sperm concentration ($p>0.05$), sperm count ($p>0.05$), motility ($p>0.05$) nor morphology ($p>0.05$) among the studied patients. However, the mean SZAS in the successful implantation group was found to be significantly higher (149 ± 67) compared to the unsuccessful implantation group (84 ± 37) ($p=0.002$).

According to the ROC curve, SZAS above the evaluated cut off of 65 predicted successful implantation with sensitivity 95.2% and specificity 52.4% (AUC, 80.2%; 95% CI 0.66-0.94). In addition, SZAS was found to be a significant parameter for the prediction of implantation outcome by logistic regression analysis. The accuracy, specificity and sensitivity of the developed predictive model were 73.8%, 76.2% and 71.7%, respectively.
Limitations, reasons for caution: In this study, results are limited to the implantation stage. Data regarding live birth rates will be available before June 2019. Also increased number of participants are needed to further confirm our finding.
Wider implications of the findings: This study demonstrates the predictive value of the sperm zona-adhesion ability for successful implantation after ICSI in patients with good quality oocytes. The evaluation of SZA score could be useful tool in directing the couples with male infertility to appropriate assisted reproduction therapy.
Trial registration number: Not applicable.

P-023 CD147 deficiency in testes regulates germ cell development but not Sertoli cell-germ cell interaction during spermatogenesis

H. Chen[1], M. Ye[2], X. Wang[2]
[1]Medical School of Nantong University, Institute of Reproductive Medicine, Nantong, China
[2]Guangdong University of Technology, Institute of Biomedical and Pharmaceutical Sciences, Guangzhou, China

Study question: Global depletion of CD147 led to male infertility due to germ cell degeneration. However, whether CD147 has a role in other cell types during testis development and spermatogenesis remains elusive.
Summary answer: Through conditional knockout of CD147, we revealed that CD147 was only essential for germ cell development but not for Sertoli cells and Sertoli-germ cell interactions.
What is known already: Previous studies have demonstrated the germ cells degenerated in CD147 null mutant testis and the ectoplasmic specialization was not intactness. Our previous studies also suggested that CD147 regulated spermatocytes apoptosis but not spermatogonia.
Study design, size, duration: Laboratory-based investigation
Participants/materials, setting, methods: Floxed CD147 mice were crossbred with Amh-Cre and DDx4-Cre mice to produce offspring with the genotype of CD147 $^{-/-}$;AMH-Cre and CD147 $^{-/-}$;DDx4-Cre. Testis at various time-point were isolated for histological and western blot analyses. Primary Sertoli cells isolation from testes and western blot were performed to confirm the knockout effect of CD147 in the CD147$^{-/-}$;AMH-Cre mice.
Main results and the role of chance: In the testes of CD147 $^{-/-}$; AMH-Cre adult mice, all of the different stages of germ cells which including spermatogonia, spermatocytes, spermatids and spermatozoa were observed in the seminiferous tubules, suggesting the normal spermatogenesis occurred. The sperm concentration and sperm motility were no significant differences in all genotypes. Consistent with the results of CD147 null mutant mice and our previous studies, significant decrease of the testes weight and morphology in CD147$^{-/-}$; DDx4-Cre mice were observed compared to the testes of WT mice. Furthermore, developing germ cells were arrested at the pre-meiosis phase and apoptotic cells were observed in the CD147$^{-/-}$; DDx4-Cre testes. These results suggested CD147 deletion in Sertoli cells did not affect testis development and Sertoli cell-germ cell interactions.
Limitations, reasons for caution: The mechanism underlying the CD147 depletion induced germ cell arrest still needs further investigation.
Wider implications of the findings: Our results not only validate those from global CD147 KO studies, but also indicate that CD147 might be involved in the progression of azoospermia.
Trial registration number: No clinical trials.

P-024 Outcome of sperm selected by microfluidic technique in high DNA fragmentation index sperm samples.

G. Kant[1], K.D. Nayar[1], R. Gahlot[1], S. Gupta[1], M. Singh[1], M. Gupta[1], S. Mishra[1], K. Nayar[1]
[1]Akanksha IVF Centre, Reproductive Medicine, New Delhi, India

Study question: Does sperm selected by microfluidic sorting technique helps in improving reproductive outcome in high DNA fragmentation index (DFI) sperm samples?
Summary answer: Sperm selected by microfluidic sorting are associated with significant increase in day 3 grade A embryo development rate, clinical pregnancy rate and reduced miscarriage rate.
What is known already: DNA damage is not recognisable in living sperm prior to insemination and an increased sperm DNA fragmentation index has been associated with lower fertilization rates, impaired embryo development and reduced pregnancy rates. Standard semen processing techniques like swim up and density gradient are associated with centrifugation, which may induce reactive oxygen species and DNA damage in sperm. Microfluidic based sperm sorting allows for the selection of highly motile, morphologically normal sperm from an unprocessed specimen. Using human semen samples, it has been demonstrated that microfluidic sperm sorting technique could provide sperm with significantly reduced percentage of sperm with DNA damage.
Study design, size, duration: A prospective randomised control study was conducted from 1st August 2017 to 31st December 2018. One hundred and ninety eight patients were randomised by computer generated list and divided into 2 groups. Group A (n=100) , in which sperm were processed by microfluidic sperm sorter while in group B (n=98) sperm were processed by density gradient technique and morphologically normal motile sperm were injected by Intracytoplasmic sperm injection (ICSI) technique in all mature oocytes.

Participants/materials, setting, methods: During the study period all normozoospermic patients with high DNA fragmentation index (>25%) were included in the study, while oligospermic, asthenozoospermic samples, patients with poor ovarian reserve and advanced maternal age were excluded from the study. All A grade embryos were vitrified and transferred in frozen embryo replacement cycle. Both groups were compared on the basis of fertilisation rate, day 3 grade A embryo development rate , clinical pregnancy rate and miscarriage rate.

Main results and the role of chance: Cycle characteristics (female age, length of stimulation, gonadotrophin dose, number of oocytes and number of transferred embryos) were similar in both groups. Between the 2 groups, There was a significant increase observed in day 3 grade A embryo development rate (60% vs. 38%, p-0.003), clinical pregnancy rate (62% vs. 41%, p-0.004) while a significant decrease in miscarriage rate (12% vs. 25%, p-0.028). On the other hand there was no statistical difference observed in fertilisation rate (82% vs. 78%, p-0.48).

Limitations, reasons for caution: Larger randomised control studies are needed to strengthen these results.

Wider implications of the findings: We have demonstrated that sperm sorted by microfluidic is not only correlated with better DNA integrity but also with the reproductive outcome. Using it in routine practice can help in reducing the extraneous effect of sperm processing techniques and achieving higher pregnancy rate and sustaining it.

Trial registration number: MCDH/2017/35

P-025 Cap-Score™ accurately predicts the probability of generating pregnancy across maternal age stratifications

C. Cardona[1], G.C. Ostermeier[1], J. Schinfeld[2], F.I. Sharara[3], R. Morris[4], G.D. Palermo[5], Z. Rosenwaks[5], J.E. Nichols[6], A.J. Travis[7]

[5]*Cornell University, Reproductive Medicine, Ithaca- NY, U.S.A.*

[6]*Piedmont Reproductive Endocrinology Group, Reproductive Endocrinology, Greenville- SC, U.S.A.*

[7]*Cornell University, College of Veterinary Medicine, Ithaca- NY, U.S.A.*

Study question: Do predicted probabilities of generating pregnancy based on the Cap-Score male fertility assay differ from observed outcomes even when stratified by maternal age?

Summary answer: In women eligible for intrauterine insemination (IUI), Cap-Score remains predictive across maternal age stratifications, with predicted and observed clinical pregnancy outcomes matching closely.

What is known already: Sperm must capacitate to fertilize. Cap-Score, which quantifies capacitation status to functionally assess male fertility, was prospectively shown to predict pregnancy. Based on clinical pregnancy outcomes from IUI patients at five fertility clinics and across a wide age range, the relationship between Cap-Score and the probability of generating pregnancy (PGP) was previously defined. However, maternal age is linked with reduced fertility. The ability of Cap-Score to predict PGP across stratified maternal ages is unknown and tested here. IUI was chosen as an experimental model since the number and timing of inseminations relative to ovulation could be documented and controlled.

Study design, size, duration: Data were collected (11/2016-09/2018) from 175 couples who generated a pregnancy within, or completed, 3 rounds of IUI, and 18 couples who became pregnant through natural conception (NC). Relationships between maternal age and PGP were tested using analysis of variance (ANOVA). Differences between predicted and observed pregnancy rates, and age and outcome, were examined using Chi-Square analysis. The potential relationship between Cap-Score and delivery or miscarriage was also evaluated on a preliminary basis (t-test).

Participants/materials, setting, methods: Semen was collected as part of a standard fertility evaluation at 5 different centers. Samples having fewer than $10x10^6$ motile sperm were excluded. Fixed specimens were shipped overnight to Androvia, where the Cap-Score assay was performed. Only female fertility that would preclude attempts at IUI led to exclusion, resulting in a representative test population of patients pursuing IUI across age ranges.

Main results and the role of chance: Observations were separated into the following age groups: ≤29, 30-34, 35-39, and ≥40. There was no relationship between outcome and age group (p=0.5). The average PGP derived from the Cap-Scores (predicted, PRED) and the observed pregnancies (OP) in each group were, respectively: ≤29 (35% PRED, 26% OP, n=27); 30-34 (36% PRED, 38% OP, n=87); 35-39 (34% PRED, 38% OP, n=53); and ≥40 (39% PRED, 50% OP, n=8). There were no differences between observed and predicted pregnancy rates in any maternal age group (p=0.431, 0.626, 0.472, and 0.317, respectively). Cap-Scores and resultant PGPs reflect male fertility and did not differ across maternal age stratifications (ANOVA p=0.677).

Preliminary data from one center from 20 couples pregnant by IUI (65% live births; 35% miscarried) and 18 by NC (61% live births; 39% miscarried) were also evaluated to determine if live births were similar between high and low Cap-Scores. There was no difference in Cap-Score between miscarriages and live births in either the IUI (p=0.226) or NC groups (p=0.982). The role of chance is increased when evaluating data from a single center versus multicentric studies, and when evaluating smaller versus larger datasets.

Limitations, reasons for caution: Caution is needed when evaluating smaller datasets and those from a single center. Women over 40 had the smallest sample size and thus the greatest risk of stochastic impact. Preliminary data suggest no relationship between Cap-Score and miscarriage. More data from multiple clinics are needed to address this issue definitively.

Wider implications of the findings: Female age and fertility are indisputably linked; however, if eligible for IUI, then PGP based on Cap-Score accurately predicted outcomes even when stratified by maternal age. This likely reflects that PGPs were originally quantified based on actual clinical pregnancy outcomes collected across a representative age range.

Trial registration number: not applicable

P-026 Longitudinal analysis of patients who eventually achieved live birth after micro dissection testicular sperm extraction (micro TESE) and ICSI at a single fertility center

C. Takahashi[1], T. Morimoto[1], S. Mizuta[1], K. Yamaguchi[1], H. Matsubayashi[1], K. Kitaya[2], T. Takeuchi[1], T. Ishikawa[1]

[1]*Reproduction Clinic Tokyo, Reproductive medicine, Tokyo, Japan*

[2]*Reproduction Clinic Osaka, Reproductive medicine, Osaka, Japan*

Study question: How many attempts including embryo transfers(ET) are required to give birth to a first child in micro TESE-ICSI couples, and a there more congenital anomalies?

Summary answer: The maximum and median number of oocyte retrieval and ET cycles were 9 and 1, 10 and 2.5, respectively, and congenital defect rate was 4.0%.

What is known already: Micro TESE-ICSI provides a high therapeutic effect for non-obstructive azoospermic (NOA) couples, however the condition of retrieved testicular sperm often affects treatment efficacy. Because the background of NOA patients is various and, in many cases abnormal and/or immotile sperm are utilized, many couples who were subjected to micro TESE-ICSI feel that children from testicular sperm may have a higher birth defect rate than ejaculatory sperm.

Study design, size, duration: This retrospective study was conducted with infertile couples who underwent micro TESE, including unexplained NOA, Klinefelter's syndrome, after orchidopexy, azoospermia factor (AZF) c microdeletions, cryptozoospermia, severe oligozoospermia with successful acquisition of sperm by micro TESE, consequently obtained at least one live-born between September 2013 to December 2017. Patients were followed longitudinally during consecutive ICSI and embryo transfer cycles with testicular sperm.

Participants/materials, setting, methods: The maternal age at the time of micro TESE-ICSI was 32.8±3.1 years and their average AMH levels was 4.9±3.8 ng/ml. We assessed the maximum and median numbers for micro TESE, total oocytes used for ICSI, transplanted embryos, oocyte retrieval cycles, embryo transfer (ET) cycles, respectively. Time spent for ICSI per oocyte, total time required to find sperm were also evaluated. Finally, we examined sex, average birth weight, and congenital anomaly rate in 177 newborns.

Main results and the role of chance: The maximum and median numbers for micro TESE were 3 and 1, total oocytes for ICSI were 85 and 14, transplanted embryos were 15 and 3, oocyte retrieval cycles were 9 and 1, and ET cycles were 10 and 2.5, respectively. The maximum and median minutes of time spent for ICSI per oocyte were 76 and 8, total time to find sperm for ICSI was 1482 and 136, respectively. A case where only immotile testicular sperm were available for ICSI even after pentoxifylline treatment obtained a healthy baby. Of the 177 children including 10 cases of twins, the sex of the children was 97 males (54.8%) and 80 females (45.2%). The average weight was 2691±626g, and congenital defects were confirmed in 7 children (4.0%). These include atrial septal defect, ventricular septal defect and hydronephrosis. The incidence of the birth defects was not different from that of ejaculated sperm ICSI (2.7%). The congenital defects were not observed in cases with AZFc microdeletions. In this group of patients, the sperm searching time for ICSI was the longest among NOA cases.
Limitations, reasons for caution: Since this study is a single center retrospective observational study, large cohort study is necessary. Female factors that may be attributable for clinical outcome were not fully evaluated.
Wider implications of the findings: A very severe male factor infertility implementing such as micro TESE-ICSI can be devastating for couples who are uncertain about their ultimate prognosis. This study will help us to predict outcomes and provide information for NOA couples.
Trial registration number: N/A

P-027 Evaluate effect on sperm DNA fragmentation, semen parameters of empirical supplement in single-arm cohort study on sub-fertile male partner with primary or secondary infertility

S. Kandari [1]
[1] *Cellsure Biotech & Research Centre, Embryology, Thane, India*

Study question: Study whether sperm parameters and sperm chromatin integrity is affected post 3 month usage of empirical supplement in sub-fertile males and with any adverse outcomes.
Summary answer: DNA Fragmentation Index reduction by 57% observed in supplement cohort and no significant differences seen in sperm motility, morphology or concentration with no adverse outcomes
What is known already: Semen impairment and DNA damage in ejaculated spermatozoa has its source in testicular micro-environment, epididymal transit and seminal tract antioxidant capacity, affecting paternal genetic content adversely. Once the required reactive ion threshold is crossed in either of these checkpoints, single and double strand nicks in DNA cause irreparable damage. Current adjunct therapy of male sub-fertile patients is with empirical antioxidants with little data on its effects on fragmented sperm DNA combined with semen parameters and whether any adverse outcomes result.
Study design, size, duration: Prospective single arm cohort study was designed as single group continuous endpoint with calculated sample size (n=48) between Feb 2017- Sep 2018; over 19 months for patients opting for over the counter supplement. Considering loss to follow up, n = 58 patients were recruited who partook bi-diurnal dose of one tablet and repeat SCD and SFA was done post 3 months. Eight patients were lost to follow up and (n=50) cohort study data was analysed.
Participants/materials, setting, methods: Men aged 23- 44 years with primary or secondary infertility were analysed for sperm DNA fragmentation index (DFI) by sperm chromatin dispersion assay (SCD) and for concentration, motility & morphology by semen analysis testing (SFA) by W.H.O laboratory manual (fifth edition). Patients with >15% DFI and normal or impaired semen parameters were included. Subjects with endocrine disorders, autoimmune disease, secondary antioxidants, azoospermia, testicular cancer were excluded. Analysis of ejaculate was done according to W.H.O guideline.
Main results and the role of chance: The statistical power of the study is 80% with alpha = 0.01, beta = 0.2. DFI by SCD assay in sample before beginning regimen , termed period T_0 and post 3 months as period T_1 are statistically very significant ($p < 0.001$),by Mann-Whitney U test with Bonferri -Holm correction. DFI was lowered from median 21% +/- 8.63 (T_0) to median 9 % +/- 2.94 (T_1) post treatment showing absolute 57% reduction in DFI. There was no statistical difference in three other predetermined semen parameters, evaluated for multiple comparisons by Mann-Whitney U Test with Bonferri-Holm correction. The difference was non-significant in progressive sperm motility (p=1), sperm concentration (p=1) or morphology p=1), conducted in triplicate by two experienced andrologists in those two periods. The response rate of oral supplement was, in this cohort study was 100% with every treated patient showing reduction in DFI but we did not observe any effect on semen analysis parameters. All tests are done counting 400 spermatozoa, conducted in triplicate and with two experienced technicians.
Limitations, reasons for caution: Limitations is in being a Single Arm study, using a standard DFI threshold which is varying in different publications and use of SCD assay which suffers with non-standardization .Use of Terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate-nick end labelling or the TUNEL assay. recently acquired. shall be added in follow up studies.
Wider implications of the findings: Results show lower DFI at T_1 with no reported adverse outcomes or cases of unintentional harm to patient andrological parameters. The findings agree with the overall review of meta-analysis on effect of antioxidants on sperm DNA Fragmentation as seen in a Cochrane review of Antioxidants in Male Subfertility (2015).
Trial registration number: N/A

P-028 Tail swelling pattern in hypo-osmotic solution as a predictor for human spermatozoa with DNA fragmentation

E. Nho[1], **S.K. Kim**[1], **J.Y. Lee**[2], **B.C. Jee**[1], **S.H. Kim**[3]
[1] *Seoul National University Bundang Hospital- Seongnam- Korea, Department of Obstetrics and Gynecology, Seongnam, Korea- South*
[2] *Hamchoon Women's Clinic, Infertility- genetic testing and general Medical and health organizations, Seoul, Korea- South*
[3] *Seoul National University Hospital, Department of Obstetrics and Gynecology, Seoul, Korea- South*

Study question: Does the hypo-osmotic swelling test (HOST) have a significant correlation with sperm DNA fragmentation (SDF) level after sperm preparation?
Summary answer: SDF level was significantly lower in HOST type 'd' followed by 'g' type and 'f' type.
What is known already: HOST is a non-invasive technique to select a live single spermatozoon without DNA damage. When semen samples are incubated in a hypo-osmotic solution, the specific swelling pattern of the sperm tail can be further classified as six types. The presence of any swelling ('b' - 'g') represents healthy cell membrane function, thus considered to be viable. Sperm vitality measured by the HOST in raw semen (HOST score) has been reported to be correlated with sperm motility, percentage of normal form, and SDF level.
Study design, size, duration: A prospective study was performed from 2016 to 2017. Semen samples were obtained from 21 healthy donors. Tail swelling pattern and head halo pattern were assessed in 200 spermatozoa per slide. In each person, 10 slides were prepared thus the final counted spermatozoa was 2,000 per person.
Participants/materials, setting, methods: The semen samples were thawed and centrifuged, then processed by using the swim-up method. HOST was performed and for sperm chromatin dispersion (SCD) test, a Halo sperm kit was used. Each sperm head was counted as big halo, medium halo, small halo, no halo, or degraded. Spermatozoa with 'small halo', 'no halo' or 'degraded' were considered as spermatozoa having fragmented DNA.
Main results and the role of chance: The median HOST score was 16.7% (interquartile range: 10.4% - 20.7%) and the median SDF level was 1.40% (interquartile range: 0.65% - 2.83%). The HOST score was not related with age of male, sperm concentration, total motility, or the percentage of normal form. And the SDF level was not related with age of male, sperm concentration, or motility, but negatively correlated with the percentage of normal form (Spearman's coefficient of rank correlation r = -0.473, p=0.034).

The HOST score was not related with the SDF level, but the probability of choosing sperm without DNA fragmentation is highest in 'd' type spermatozoa (100%) followed by 'g' type (98.67%) and 'f' type (98.17%).
Limitations, reasons for caution: At the time of semen collection, Marriage or fertility status of sperm donors, their medical or surgical history, and prescribed medication were unknown. Another limitation is that we have a relatively small number of 'd' type spermatozoa.
Wider implications of the findings: The application of HOST may be a valuable tool in the routine identification and selection of viable,

DNA-intact individual spermatozoa for ICSI after further research to demonstrate its efficacy and safety.
Trial registration number: Not applicable

P-029 sperm motility, seminal l-carnitine and sperm fatty acids

M. Iliceto[1,2], T.B. Haugen[2], J.M. Andersen[2], M.H. Stensen[1], O. Witczak[2]
[1] *Fertilitetssenteret, IVF Laboratory, Oslo, Norway*
[2] *Oslo Metropolitan University, Faculty of Health Sciences, Oslo, Norway*

Study question: Do seminal L-carnitine and sperm fatty acids correlate with sperm motility?
Summary answer: Sperm fatty acids (FA) and seminal L-carnitine (LC) could be predictors for sperm motility.
What is known already: LC is a small water-soluble molecule derived from lysine. The main function of carnitine is to transfer long-chain fatty acids (FAs) to mitochondria for β-oxidation. Although a considerable amount of data is currently available on lipid metabolism and L-carnitine in somatic cells, there are few studies on LC and FAs in spermatozoa. It has been suggested that endogenous FAs of spermatozoa may represent an energy source for the cell. However, little is known about endogenous sperm FAs as a source of ATP.
Study design, size, duration: The samples had previously been obtained from men who participated in a study of semen quality related to BMI (Andersen et al., 2016). Men (n=128) aged between 22 and 61 years were included. Semen samples were collected in the period 2008-2013. Semen analysis was performed according WHO guidelines (2010). Seminal LC was analyzed in samples stored at -80 °C.
Participants/materials, setting, methods: Only semen samples produced after sexual abstinence of 2–7 days prior to sample collection were included. FA content of spermatozoa was assessed by gas chromatography while seminal LC analysis was performed on high performance liquid chromatography. FA levels are expressed as weight percentage (wt%) of the total FA, seminal LC as µg/ml and sperm progressive motility (PR) as percentage (%).
Main results and the role of chance: Associations between PR, spermatozoa FAs and seminal LC adjusted for age and sexual abstinence time were tested using Pearson correlation analysis. PR correlated positively with seminal LC ($r=0.364$; $p<0.001$), total polyunsaturated FA in spermatozoa ($r=0.448$; $p<0.001$), n-3-polyunsaturated FA (n-3-PUFA) ($r=0.463$; $p<0.001$), docosahexaenoic acid (DHA) ($r=0.462$; $p<0.001$) and palmitic acid (PA) ($r=0.251$; $p<0.05$). A stepwise multiple regression analysis was performed to predict PR based on age, days of sexual abstinence, BMI, seminal LC, DHA and PA. The total variance explained by the model for sperm motility was 40%, $F(6,90)=10.018$, $p<0.001$, thus $R^2=0.4$. Three independent variables were statistically significant: LC (unadjusted B 17.16; SE 5.9; $p<0.01$), DHA (unadjusted B 0.032; SE 5.9; $p<0.001$) and age (unadjusted B -0.643; SE 0.202; $p<0.01$).
Limitations, reasons for caution: The sample size is relatively small.
Wider implications of the findings: FAs and seminal LC could be predictors for sperm motility. The positive associations between sperm FAs, sperm motility and seminal LC indicate that FAs might be metabolic substrates for the spermatozoon, although it is not known if sperm membrane FAs, the major part of sperm FAs, contribute to energy metabolism.
Trial registration number: Not applicable.

P-030 Novel homozygous pathogenic variants in CCDC103 identified in patients with situs-inversus-totalis and absence of axoneme dynein arms: further insights on reproductive function

Study question: To study CCDC103 expression profiles in reproductive and other tissues, and genotype-phenotype correlations in *situs-inversus-totalis* patients carrying novel homozygous *CCDC103* variant
Summary answer: CCDC103 expression showed tissue-specific features, suggesting distinct tissue regulation. *CCDC103* variants led to absence of axoneme dynein arms (DA) and affected gene and protein expression.
What is known already: Primary ciliary dyskinesia (PCD) is due to genetic anomalies causing axoneme defects, being characterized by chronic respiratory infections, infertility and organ laterality defects. We previously described an infertile male patient with *situs-inversus-totalis,* absence of sperm DA and presence of a novel missense homozygous *CCDC103* variant. This gene was previously associated with the genetic aetiology of PCD and its role in DA assembly, being required for microtubule structure stabilization.
Study design, size, duration: To study CCDC103 expression profiles we collected sperm (SZ), testicular germ cells (GC), Sertoli cells (SC), oocytes and somatic cells (nasal and white blood cells), from human healthy individuals. To understand patient genotype-phenotype correlations, two patients were included in the present study, an infertile PCD male patient (Patient-1) and a female PCD patient (Patient-2), both with situs-inversus-totalis. Two different homozygous CCDC103 gene were identified, a missense change in Patient-1 and a frameshift in Patient-2.
Participants/materials, setting, methods: Quantitative PCR (qPCR), western-blot (WB) and immunofluorescence (IF) were performed in SZ, GC, SC and somatic cells. For oocytes, only qPCR was performed. Axonemes of nasal cilia of both patients were analysed by transmission electron microscopy. As previously performed for Patient 1, we also used whole-exome sequencing (WES) analysis in the Patient 2. qPCR, WB and IF were performed in both patients and compared to healthy controls. Biological samples were obtained after patient informed consent.
Main results and the role of chance: Here we firstly report that *CCDC103* is expressed at different levels in reproductive tissues and somatic cells. In controls, different mRNA expression levels were found, with the highest values detected in SZ. WB showed the presence of dimers and higher-order oligomers whose sizes are tissue-specific, suggests that *CCDC103* possibly express different mRNA transcripts in each cell type or have post-translational modifications that are tissue specific. Regarding immunolocalization, CCDC103 was restricted to the mid-piece of SZ and present in the cytoplasm of the other cells. Besides the former described missense variant in Patient-1, a *CCDC103* novel homozygous frameshift variant was found in Patient 2. Both patients evidenced absence of DA and nexin links in the axonemes, which suggests that regardless of the variant location and type, *CCDC103* pathogenic variants lead to *situs-inversus-totalis* and absence of DA. Moreover, both patients presented reduced *CCDC103* mRNA expression and reduced labelling, although more prominent in cells of Patient 2. Overall, our data provides additional evidences for the *CCDC103* involvement in PCD aetiology. Further, it suggests that CCDC103 may have different assemblies and roles in cilia and sperm flagella biology that are still unexplored.
Limitations, reasons for caution: CCDC103 possesses specific biochemical characteristics making WB experiences especially difficult. Although cases with *situs-inversus-totalis* are rare, the main limitation of our study was the reduced number of patients. Further studies on animal models are needed to better understand these genotype-phenotype correlations, namely the role of CCDC103 in human fertility.

Wider implications of the findings: Our work increases the knowledge regarding the expression and sub-cellular location of the CCDC103 protein. Such data constitutes an additional piece to the complex puzzle that constitutes the process of axonemal dyneins assembly and ultimately to understand concerning PCD pathophysiology

Trial registration number: 'not applicable'

P-031 Impact of severe male factor on cumulative live birth rates during ICSI-cycles with preimplantation genetic testing for aneuploidies.

R. Mazzilli[1], D. Cimadomo[1], A. Vaiarelli[1], L. Dovere[1], M. Giuliani[1], S. Colamaria[1], S. Bertelle[2], N. Barnocchi[3], S. Alfano[4], C. Alviggi[5], A. Conforti[5], S. Ferrero[1], M. Schimberni[6], L. Rienzi[1], F.M. Ubaldi[1]

[5]*University of Naples "Federico II", Departement of Neuroscience- Reproductive Science and Odontostomatology, Naples, Italy*
[6]*Clinica Vallie Giulia, Bioroma, Roma, Italy*

Study question: Does severe male factor (SMF) impact the cumulative live birth rate (CLBR) during ICSI-cycles with preimplantation genetic testing for aneuploidies (PGT-A)?

Summary answer: CLBR is mainly dependent on maternal age and number of inseminated oocytes, however non-obstructive azoospermia (NOA) seems to impact this outcome.

What is known already: Severe oligoasthenotheratozoospermia (OAT), obstructive azoospermia (OA) and NOA have been previously reported to significantly affect fertilization rate and oocyte developmental potential to blastocyst. However, no hard evidence of a similar impact on blastocyst euploidy rate and/or LB after euploid single embryo transfer (SET) exist. Similarly, little is known about CLBR according to SMF. In this study, we attempted to quantify the putative impact of SMF, if any, on CLBR during PGT-A cycles conducted at the blastocyst stage through comprehensive chromosome testing.

Study design, size, duration: Observational cohort study involving 2396 ICSI-cycles with qPCR-based PGT-A (April-2013 to September-2017). Vitrified-warmed euploid SETs up to April-2018 were included. The primary outcome was the CLBR per oocyte retrieval among ended cycles. A cycle was considered ended when the patient delivered or did not deliver after transferring all euploid blastocysts (if any) obtained. Main confounders were age, kind, duration and cause of infertility, PGT-A indication, sperm factor, number of oocytes, kind of incubator and media.

Participants/materials, setting, methods: Ovarian stimulation (recombinant-gonadotrophins in an antagonist protocol), blastocyst culture and biopsy, and vitrification were conducted. In case of OA or NOA, sperm were retrieved by fine-needle-aspiration (FNA) or testicular-sperm-extraction (TESE), respectively. PGT-A cycles were sub-clustered according to maternal age at retrieval (<36yr, 36-38yr, 39-41yr, and ≥42yr) and sperm factor (normozoospermia-N, moderate male factor-MMF, OAT, OA and NOA). Logistic regressions were conducted. Lastly, a decision tree was built to predict CLBR based on significant confounders.

Main results and the role of chance: Mean maternal and paternal age were 39.5±3.3yr (range:23-45) and 41.8±5.6yr (range:26-65), respectively. Maternal age in OA- and NOA-group was significantly lower than N-group (37.8±3.2, 36.5±4.6 and 39.8±3.2, respectively; p<0.01). Indeed, it biased the overall CLBR, which resulted similar among the 5 groups (27.4% (n=291/1063), 29.6% (n=222/751), 33.4% (n=120/359), 37.2% (n=16/43) and 25.0% (12/48) in N, MMF, OAT-s, OA and NOA; p=NS). If CLBR was sub-clustered according to maternal age at retrieval, it resulted significantly reduced in NOA- compared to N-group for women <36yr (n=6/19, 31.6% versus n=59/104, 56.7%; p=0.05). This was probably due to the greater effect of woman aging in women ≥36yr, which might have hindered the negative impact of NOA itself. Logistic regressions indeed outlined that the CLBR is highly dependent on maternal age (OR=0.79, 95%CI:0.77-0.82; p<0.01) and number of inseminated oocytes (OR=1.15, 95%CI:1.12-1.18; p<0.01). Among the sperm factor groups, only NOA corrected for these confounders showed a negative association with the primary outcome when compared to the N-group (OR=0.24, 95%CI:0.11-0.52; p<0.01). A decision-tree to predict CLBR in this dataset was then built based on maternal age at retrieval, number of inseminated oocytes and sperm factor group. However, to date, this last variable was disregarded from the model.

Limitations, reasons for caution: CLBRs could be higher since in 5.5%(132/2396) of the cycles a pregnancy has not been achieved yet but there is still ≥1 euploid blastocyst left. Moreover, only the first LB is accounted in the analysis. Lastly, the sample size in the groups of ICSI-cycles with surgically-retrieved sperms should be increased.

Wider implications of the findings: A multicenter study with a larger NOA population is desirable to confirm the general value of these data. NOA might represent the group of patients achieving the highest benefit in terms of CLBR per cycle due to the maximization of oocyte yield after ovarian stimulation.

Trial registration number: None

P-032 Home sperm freezing kit achieves same sperm quality after thawing.

B. Freijomil[1], B. Pujal[1], A. Munuera[1], M. Solans[1], J. Massó[1], C. Castelló[1], F. García[1], M. López-Teijón[1]

[1]*Institut Marquès, Reproductive Medicine Service, Barcelona, Spain*

Study question: Are there any differences in terms of quality of the seminal sample depending on whether it has been cryopreserved by patients or by experienced biologists?

Summary answer: Semen quality after thawing does not decrease if the sample has been frozen by the patient.

What is known already: Sperm freezing with reproductive purposes is indicated in several causes: in order to preserve fertility in oncology patients, before a vasectomy, for patients with sexual dysfunction and problems to obtain a sperm sample, and for those patients who cannot be present on the day of the In vitro fertilisation (IVF). The male is compelled to deliver the sample at an exact moment and, often, also in a determined setting, usually in a clinic. Many experience this as a stressful situation that, furthermore, obliges them to travel if they happen to live far from the IVF clinic.

Study design, size, duration: Prospective study. From November 2016 to March 2017 41 volunteers delivered a sperm sample in rooms adjacent to the laboratory. A biologist carried out a first evaluation and froze a 0.5 ml aliquot. The remaining of the sample was then given back to the volunteer with a specific freezing protocol using a kit designed by us. This kit allows the patient to freeze a sperm sample at home and be sent later to IVF centre.

Participants/materials, setting, methods: Samples frozen by volunteers(study) and aliquots frozen in parallel at the laboratory by expert biologists(control) were analysed before and after thawing. In both groups an evaluation of the following was carried out: sperm concentration and motility with Makler chamber, morphology according to Kruger criteria, vitality by using eosin-nigrosin staining, DNA sperm fragmentation with TUNEL test and bacterial growth after 24 hours of medium incubation. Wilcoxon signed-rank test was used to analyse differences among groups.

Main results and the role of chance: Regarding median progressive motility percentage recovered after thawing no significant differences between both groups were observed: 45.99% (range 2.2-119.9) versus 44.52% (range 18.2-90.9) respectively for control and study groups.

Nor significant differences among groups were found regarding median of vitality percentage: 86% (range 69-96) versus 79% (range 62-99); of morphology: 4% (range 1-7) versus 5% (range 1-9) and of DNA fragmentation rate: 9.14% (range 2.49-17.59) versus 5.18% (range 1.89- 17.16), respectively for control and study groups. After 24 hours of medium incubation, no bacterial growth in any sample was observed.

Limitations, reasons for caution:

After the shipment of the kit, it has to be delivered within 48 hours. Once frozen, the sample should reach the laboratory within 48 hours. A courier specialized in handling biological samples is required.

Wider implications of the findings: Semen cryopreservation protocols from commercial companies, when strictly followed by biologists, are so simple that could be carried out by non- experts obtaining similar results. Our freezing kit allows the patient to cryopreserve his sperm samples outside

the IVF centre in an efficient way, following a simplified cryopreservation protocol.

Trial registration number: Doesn't apply

P-033 Designing and testing a microfluidic chip for sorting spermatozoa from somatic cells to shorten the handling time of testicular biopsies for azoospermic males.

J.T.W. Berendsen[1], H.A. Meijer[1], A. Wetzels[2], L.I. Segerink[1]

[1]University of Twente, BIOS Lab-on-a-chip group, Enschede, The Netherlands
[2]Radboud University Nijmegen Medical Centre, Department of Obstetrics and Gynaecology, Nijmegen, The Netherlands

Study question: Can a microfluidic chip be used for sorting spermatozoa from erythrocytes for use in intracytoplasmic sperm injection (ICSI) after a testicular biopsy?

Summary answer: Our microfluidic device can extract 95% of the spermatozoa from a 200µl sample, while removing 90% of the erythrocytes, within a 20 minute processing time.

What is known already: Men suffering from azoospermia can father a child, by extracting spermatozoa from a testicular biopsy sample. The main complication in this procedure is the presence of an abundance of erythrocytes. While larger cells can be removed in a density gradient filter, the isolation of the few spermatozoa from the erythrocytes is manually performed due to ineffectiveness of filtering methods, making it time consuming and labor intensive. Microfluidic chips can handle small volumes of liquid and, depending on the geometry, allow for manipulation of cells without physical filters.

Study design, size, duration: The sorting of spermatozoa and erythrocytes was performed using boar spermatozoa (KI Twente) and anonymized blood samples (University of Twente). 5 different extraction settings were tested, with n=3 per setting. An initial test was performed with a biopsy sample from a bull. We then determine the Collection efficiency (CE: collected spermatozoa /total spermatozoa in sample), Extraction purity (EP: collected spermatozoa /total collected cells) and Enrichment ratio (ER: spermatozoa concentration/sample spermatozoa concentration).

Participants/materials, setting, methods: The microfluidic chip contains two inlets from the sample and buffer vials and two outlets to the waste and collection vials. The chip is operated by a pressure pump. The sample flow is 5% of total flow, and 3-3.5-4-4.5-5% of total flow is routed to waste vial. Samples are flushed through the chip, imaged and counted for data processing. Viability is assessed via live/dead staining .

Main results and the role of chance: Our system can separate spermatozoa from erythrocytes despite their similar smallest dimension (both approximately 1-2µm). The hydrodynamic forces sort the cells based on their long axis (~10µm for erythrocytes and ~50µm for spermatozoa). For a sample of 200µl, the processing time of our set-up is 15-20 minutes. For the different settings we obtained a CE of 52±0.3% and EP of 81±8% with 5% of total fluid routed to waste vial, and up to 94 ± 8% and EP of 31±9 % for 3% fluid removal. The spermatozoa retained 88±6% (n=3) viability after sorting. An initial test with two coupled chips has been performed with a biopsy sample from a bull for removal of tissue cells. This initial test had not been optimized for erythrocyte removal. CE of spermatozoa after the first step was 89% with 65.1% of the larger tissue cells removed. The second step retained 43.9% of the spermatozoa, with another 3% of the larger tissue cells removed and 86.4% of the erythrocytes removed. Further optimization of the combined system should ensure similar results for erythrocyte removal as for the first set of experiments.

Limitations, reasons for caution: Samples from animals (boar and bull) were used in this study. Furthermore, the testicular biopsy was taken post-mortem from a young bull (1.5yo) by a researcher instead of an experienced lab technician, leading to a different sample composition than a biopsy of a living human patient.

Wider implications of the findings: This microfluidic design could be used in the clinic to reduce the processing time of testicular biopsies significantly by increasing the relative concentration of spermatozoa. This could lower cost of treatment for the clinic and increase the chance of a good outcome for the patients.

Trial registration number: Not applicable

P-034 Circulating cell-free-DNA quantification and sperm quality in men exposed to an experimental testicular and epididymal mild temperature increase which drastically alters spermatogenesis: a pilot study

L. Bujan[1,2], C. Innocenti[3,4], D. Haouzi[3,4], S. Hamdi[1], R. Mieusset[1,2], S. Hamamah[3,4]

[1]Université de Toulouse- UPS- Groupe de Recherche en Fertilité Humaine EA 3694- Human Fertility Research Group, Hôpital Pauke de Viguier- CHU Toulouse, 31059 Toulouse, France
[2]Unité d'Andrologie- CECOS- Groupe d'activité de médecine de la reproduction, Hôpital Paule de Viguier- CHU Toulouse, 31059 Toulouse, France
[3]3ART-PGD department, Arnaud de Villeneuve Hospital- CHU Montpellier, 34295 Montpellier- France, France
[4]Inserm U1203- Univ Montpellier, CHU Montpellier- Hôpital Saint Eloi- IRMB, Montpellier, France

Study question: Could cell-free DNA (cfDNA) quantification in semen and serum samples become a new non-invasive biomarker of altered spermatogenesis?

Summary answer: Sera and seminal plasma cfDNA concentrations were increased during severe spermatogenesis alteration induced by mild temperature increase and were negatively correlated with sperm motility

What is known already: Studies provided evidence that a mild testicular and epididymis temperature increase have drastic effects on spermatogenesis and sperm DNA. Circulating cfDNA, presumably resulting from the release of genetic material from apoptotic/necrotic cells, has been previously reported as a diagnostic tool for female infertility, particularly in gynecological cancers and ovarian disorders. CfDNA quantification in follicular fluid has been reported as a biomarker for embryo selection during IVF. Furthermore, serum and seminal plasma cell-free mitochondrial DNA copy number was reported to be associated with human semen quality. However, circulating cfDNA quantification as a biomarker of altered spermatogenesis has not been investigated

Study design, size, duration: Five healthy fertile volunteers (age 25-35 years, having fathered at least one child) with no andrologic, medical or surgical history were recruited. An experimental mild testicular and epididymal temperature increase was induced by maintaining the testis in a suprascrotal position 15 hours daily for 120 days. The study was divided into three periods: before (baseline), during (0-120 days) and after (300 days) temperature increase. Semen and serum samples were collected before, during and after hyperthermia

Participants/materials, setting, methods: Semen samples were collected by masturbation. After liquefaction, semen volume, sperm motility (%) and total sperm concentration per ejaculate were investigated according to the WHO guidelines. Seminal plasma and serum cfDNA were measured by quantitative PCR with ALU-specific primers. Then, cfDNA quantification was normalized according to the total sperm cell concentration

Main results and the role of chance: Our results revealed an increase of seminal plasma and serum cfDNA during mild temperature increase, resulting in a significant decrease in total sperm output [sperm count Mean ± SEM: 2±1.94 million/ml at 120 days compared to 337 ± 99 (p = 0.03) and 218 ± 55 million/ml (p = 0.02) before and after hyperthermia). At baseline, seminal plasma cfDNA concentrations was 0.1 ± 0.02 ng/ml (normalised Alu-115 mean ± SEM). During temperature increase (day 120), seminal cfDNA concentration was 25.7 ± 13.1ng/ml (p = 0.087). After temperature increase (day 300) cfDNA concentration (0.16 ± 0.1 ng/ml) became similar to the baseline concentration.

In serum samples, cfDNA concentrations were 3.1 ± 1.4, 1146.5 ± 716.3 (p = 0.14) and 1.6 ± 0.4 fg/ml (p = 0.33) respectively before, during and after experimental temperature increase. Individual response per patient demonstrated a significant increase of seminal plasma and serum cfDNA during hyperthermia varying by a factor 18 to 26 000 and 54 to 2700, respectively, with highest ratio observed in azoospermia phenotype. In addition, we reported a negative correlation between motility and seminal plasma cfDNA (Pearson correlation, correlation coefficient r = - 0.64, 95% confidence interval:-0.87 to - 0.819, P-value = 0.01).

Limitations, reasons for caution: The low number of volunteers was the mainly limit of this study. These results must be validated in a large cohort of samples

Wider implications of the findings: Serum and seminal plasma cfDNA concentration were increased in severe altered spermatogenesis due to an experimental testicular and epididymal mild temperature increase. While preliminary, these results open new perspectives to identified non-invasive biomarkers of the spermatogenesis status and male infertility.

Trial registration number: not applicable

P-035 Evaluation of spermatozoa with normal and abnormal morphology using confocal Raman spectroscopy and multivariate data analysis

R. Nazarenko [1], A. Irzhak [2], A. Pomerantsev [3], O. Rodionova [3]

[1] *Zdanovskiy medical centre, Urology, Moscow, Russia C.I.S.*

[2] *Institute of Microelectronics Technology and High Purity Materials RAS, Applied Spectroscopy, Chernogolovka, Russia C.I.S.*

[3] *Semenov Institute of Chemical Physics RAS, Russian chemometric society, Moscow, Russia C.I.S.*

Study question: Can confocal Raman spectroscopy (CRS) and multivariate analysis methods ensure selection of spermatozoa with intact nuclear DNA from among the spermatozoa with normal and abnormal morphology?

Summary answer: CRS provides for differentiation between spermatozoa with intact nucleus and spermatozoa with fragmented and defective nuclear DNA only when applying multivariate analysis methods.

What is known already: Sperm morphology does not always correlate with nuclear DNA integrity. CRS is a non-invasive, non-destructive analytical method for evaluating cell nuclear DNA.

Study design, size, duration: The study took place in 2016–2018. 23 We studied 161 spermatozoa (n = 161) taken from 21 healthy donors and assembled two sets of samples: morphologically normal sperm (*N* group, 125 samples) and morphologically abnormal sperm (*A* group, 36 samples).

Participants/materials, setting, methods: Sperm morphology was evaluated according to the World Health Organization guidelines using light microscopy. The Raman spectra were collected from the sperm nucleus region. After preliminary processing of the spectra, the data were analyzed using principal component analysis (PCA) and the one-class classifier DD-SIMCA.

Main results and the role of chance: *N* Group (125 morphologically normal spermatozoa) was divided into two classes, *NN* class (normal spectra, n =102) and *NA* class (abnormal spectra, n = 23). *A* group (36 morphologically abnormal spermatozoa) contained *AA* class (morphologically and spectrally anomalous spermatozoa, n = 19) and *AN* class (morphologically abnormal but spectrally normal spermatozoa, n = 17). It was concluded that the *NN* class is a uniform class and includes the *AN* class, which allowed the samples in these classes to be classified as normal, i.e. having intact nuclear DNA. Normal and abnormal spectra were present in both groups; however, normal spectra prevailed (82%) in the *N* group and the frequency of abnormal spectra was equal to that of normal in the *A* group.

Limitations, reasons for caution: The influence of laser radiation on living cells has not been investigated in full, which might limit the method application in clinical practice.

Wider implications of the findings: CRS along with multivariate analysis may serve as the method for investigating a single living sperm without damaging it before using that sperm for fertilization in IVF/ICSI.

Trial registration number: not applicable

P-036 Transfer of vitrified-thawed sperm from a patient with cryptozoospermia using hollow-core agarose capsules resulted in birth of a healthy infant

Y. Matsui[1], Y. Kaneko[1], S. Tsuchiya[1], K. Itakura[1], A. Wada[1], A. Iizumi[1], K. Nishimura[1], T. Ozaki[1], Y. Araki[2], Y. Araki[2,3], M. Nishimura[1]

[1] *Nishimura Women's Clinic, Private Clinic, Hamamatsu, Japan*

[2] *The Institute for Advanced Reproductive Medical Technology, Labo, Gunma, Japan*

[3] *Gunma Paz College, School of Medical Technology, Gunma, Japan*

Study question: Can a healthy baby be generated after embryo transfer with a few vitrified thawed sperm (cryptozoospermia) using agarose capsules and intracytoplasmic sperm injection?

Summary answer: Sperm was vitrified in hollow agarose capsules and thawed. A cultured vitrified blastocyst was thawed, and a transferred embryo resulted in pregnancy and childbirth.

What is known already: Small samples of spermatozoa from a patient with oligozoospermia or testicular sperm extraction (TESE) should be reliably recovered while maintaining survival after thawing. Small numbers of spermatozoa have been frozen in mouse and human zona pellucidae, and as small drops on CryoTop sheets. However, obtaining zona pellucidae from humans is difficult and recovering all of the thawed spermatozoa using the CryoTop procedure is laborious. Recently, a new method for freezing spermatozoa in agarose capsules has been reported.

Study design, size, duration: Repeated semen analysis of a man aged 25 years did not confirm any sperm. A single sperm was revealed in sediment. The man and his 22-year-old wife were referred to the Department of Urology, which resulted in a recommendation for TESE-intracytoplasmic sperm injection (TESE-ICSI). However, the patient wanted to use ejaculated sperm. In the first round of oocyte retrieval, sperm was frozen conventionally on two previous occasions before ICSI, but did not lead to pregnancy.

Participants/materials, setting, methods: We obtained written, informed consent to use agarose capsules and then finally vitrified 15 sperm from four ejaculations. As with ICSI, capsules were fixed using manipulators, and one or two spermatozoa were injected into one capsule. The capsules were transferred into a drop of cryoprotectant solution, and then placed on a CryoTop sheet, kept under liquid nitrogen (LN_2) vapor for 30 seconds, and placed in LN_2.

Main results and the role of chance: Vitrified-thawed frozen spermatozoa were injected into five of nine metaphase II oocytes (MII) and fresh spermatozoa were injected into four more. Of seven thawed spermatozoa, six were motile. The fertilization rate using frozen spermatozoa-ICSI was 80% (4/5), the blastocyst formation rate was 75% (3/4), the fertilization rate of fresh sperm-ICSI was 50% (2/4) and the blastocyst formation rate was 50% (1/2). All blastocysts were vitrified. After thawing, a single embryo produced using vitrified-thawed sperm was transferred to the wife of the patient during a hormone replacement cycle. A healthy boy weighing 3,120g was born at 40 weeks and 6 days of gestation by cesarean section.

Limitations, reasons for caution: This is the first reported instance of a healthy baby resulting from vitrified spermatozoa using agarose capsules in a background of cryptozoospermia. We will confirm the effectiveness and safety of agarose capsules, proceed with clinical trials, and apply this procedure to patients with TESE.

Wider implications of the findings: Conventional freezing of few sperm can result in a loss of sperm during transfer between containers or centrifugal washing during the procedure. On the other hand, freezing using agarose capsules allows immediate confirmation of spermatozoa status after thawing, which reduces the burden on the embryologist at the time of ICSI.

Trial registration number: Not applicable.

P-037 Effect of adipose tissue-derived mesenchymal stem cells conditioned medium on stressed and non-stressed human sperm: in vitro study

R. Bader[1], J.N. Ibrahim[2], M. Moussa[3], A. Mourad[4], J. Azoury[5], J. Azoury[1], N. Alaaeddine[6]

[1] *Mount lebanon Hospital, Azoury IVF Clinic, Beirut, Lebanon*

[2] *Lebanese University, Faculty of Public Health II, Beirut, Lebanon*

[3] *Saint-Joseph University, Faculty of Medicine- Regenerative Medicine and Inflammation laboratory, Beirut, Lebanon*

[4] *American University of Beirut Medical Center, Department of Obstetrics and Gynecology, Beirut, Lebanon*

[5] *Inova Fairfax Hospital, Department of Obstetrics and Gynecology, Falls Church-Virginia, U.S.A.*

[6] *University Hospital of Montreal, Faculty of Medicine- Cellular and Molecular Immunology Laboratory, Montreal, Canada*

Study question: Does adipose tissue-derived mesenchymal stem cells conditioned medium (AT-MSCs-CM) have an effect on human sperm parameters in the presence and absence of oxidative stress (OS)?

Summary answer: AT-MSCs-CM improves sperm vacuolization and DNA fragmentation while keeping other parameters stable, in stressed and non-stressed sperm.

What is known already: Male factor, is a major contributor to infertility, being responsible for approximately 50% of cases. OS results in sperm damage and reduction of IVF rates, thus it is identified as an important factor of male infertility; the present treatment options for it are either invasive or not cost-effective. AT-MSCs are known to have immune-modulatory and anti-oxidant effects through their secretions, hence raising the idea of their potential benefit to improve sperm parameters.

Study design, size, duration: A total of 30 men, in their fourth decade, with a normal sperm analysis, attending Azoury IVF clinic, between December 2017 and September 2018, were enrolled in the study. After obtaining a written informed consent from all patients, a questionnaire about age, previous diseases and habits was filled, and sperm samples were obtained.

Participants/materials, setting, methods: Sperm were divided into two groups: non-stressed and H_2O_2-stressed. Isolated AT-MSCs from healthy donors undergoing liposuction were seeded until 75% confluence and CM were collected at 24, 48 and 72 hours. The two groups were cultured with the indicated CM and a time course was performed followed by an evaluation for sperm motility, morphology, vacuolization, viability, DNA fragmentation and OS levels using light microscopy, Spermoscan kit, eosin-nigrosine staining, halosperm kit and nitroblue tetrazolium test, respectively.

Main results and the role of chance: The incubation of non-stressed and stressed sperm samples with AT-MSCs-CM for 24 hours was found to have the best impact on sperm vacuolization, DNA fragmentation and OS levels while preserving their motility, viability and morphology. Incubation with CM improved all sperm parameters except morphology in comparison to the non-treated group, with the best effect noted with CM collected at 24 hours for sperm vacuolization ($p<0.0001$) and DNA fragmentation ($p<0.0001$). When compared to fresh semen parameters (T0), samples cultured with CM 24h showed a significant decrease in sperm vacuolization ($p<0.0001$ and $p<0.001$ respectively) and DNA fragmentation ($p<0.0001$) while keeping other parameters stable.

Limitations, reasons for caution: Results were obtained from a relatively limited number of human sperm samples. It was also not possible to evaluate additional parameters due to the restricted number of sperm cells in the samples.

Wider implications of the findings: Findings from the present study contribute to the understanding of sperm physiology and would have relevance in the diagnosis and/or treatment of infertile patients, and hence can be regarded as an interesting strategy to improve IVF outcomes.

Trial registration number: N/A.

P-038 Sperm DNA fragmentation index (DFI) and alpha-glucosidase are good predictors for prognosis of sperm motility in oligoasthenozzospermic men, treated with carnitine and essential nutrients

S. Micic[1], N. Lalaic[2], D. Djordjevic[3], N. Bojanic[3], G.M. Busetto[4], A. Virmani[5], A. Agarwal[6]

[1] *Uromedica Polyclinic, Andrology department, Belgrade, Serbia*
[2] *Uromedica Polyclinic, Andrology lab, Belgrade, Serbia*
[3] *Clinical Center of Serbia, Clinic of Urology, Belgrade, Serbia*
[4] *University La Sapienza, Department of Urology, Rome, Italy*
[5] *Sigma-tau Health Science, Innovation- Research-Development, Utercht, The Netherlands*
[6] *American Center for Reproductive medicine, Andrology Center, Cleveland, U.S.A.*

Study question: This study wanted to correlate DFI, seminal alpha-glucosidase and progressive sperm motility in a group of 175 oligoasthenozoospermic men treated with special test formulation

Summary answer: This study showed that increase of seminal alpha glucosidase and decrease of DFI positively impacts on progressive sperm motility, after the treatment with test combination.

What is known already: L-carnitine is concentrated in high energy demanding tissues and it plays an important role in transferring long-chain fatty acids into the mitochondria for beta-oxidation, producing energy. In addition, it modulates acyl-CoA /CoA ratio, stores energy as acetylcarnitine and reduces ROS. DNA damage, such as fragmentation and denaturation, can have adverse effects on fertilization and embryo development. Infertile men have a greater extent of sperm DNA damage and poor sperm DNA integrity than fertile men. Alpha-glucosidase is a normal constituent of human semen and produced mainly in the epididymis and it is also considered a marker of functional epididymis.

Study design, size, duration: This study was randomized, double blind, placebo controlled (DBPC) and examined the effect of combination (Proxeed Plus), containing L-C 2g and ALC 1g, as well as antioxidants, vitamins and minerals, in men with idiopathic oligo-asthenozoospermia (age group 18-50 years). The protocol was 2 months wash-out and 6 months treatment (T0, T3, T6), with test combination (125 patients) or placebo (50 patients).

Participants/materials, setting, methods: Men (age group 18-50 years) with idiopathic oligoasthenozoospermia, and history of difficulty conceiving >12 months were randomized to receive treatment or placebo in a double blind protocol. Analysis of ejaculate was done according to WHO 5th guideline. Progressive sperm motility (rapid, progressive) was done manually. DFI was evaluated by Halosperm kit (Halotech DNA, S.L, Madrid) and seminal alpha glucosidase was measured by a biochemistry analyzer (Contec Bc 300, Beijing, China).

Main results and the role of chance: The parameter values were: DFI (%): T0=38,50 (32,00-48,75), T3=35,50 (25.50-44,00) and T6= 31,00 (25,00-41,00); seminal activity of alpha-glucosidase (U/L) :T0 =2 5,40 (20.00-42.88) and T6 = 32.50 (23.00-42.83); the progressive sperm motility (%): T0 28,00(12,00-38,00), T3= 30,00%(25,50-44,00) and T6= 31,00%(20,00-41,00); these parameters showed significance of $p<0.001$ (DFI and motility) and $p<0.002$ (glucosidase) done by Wilcoxon rank test. Further the Spearman's rank-order correlation test showed that the increase of seminal alpha glucosidase ($R=0.246$; $p < 0.046$) levels influenced the progressive sperm motility. Thus the correlation of seminal plasma alpha glucosidase (AUC= 0.752) and progressive sperm motility showed that in man an increase of seminal alpha glucosidase of 12%, after six months therapy, would impact progressive sperm motility >10% with borderline significance (AUC= 0.726; $p<0.0048$). Whereas, if DFI drops by more than 3% (cut-off), after 6 months of therapy, it can be expected, with moderate accuracy, that men have sperm motility greater than 10% (AUC=0.793; $p<0.001$). In placebo group there was no significant difference in sperm motility, seminal aplha-glucosidase and DFI, between T0 and T6

Limitations, reasons for caution: None

Wider implications of the findings: This study demonstrated, after six months therapy, that increase of seminal alpha glucosidase positively impacted upon the patient progressive sperm motility. Further the decrease of DFI after therapy can be used as an independent predictor of progressive sperm motility higher than 10%

Trial registration number: PXB-001/B24

P-039 Comprehensive study of sperm head vacuoles from morphology to assisted reproductive outcomes

M.H. Bahadori [1]

[1] *Guilan University of Medical Sciences, Anatomy-, Rasht, Iran*

Study question: Is it necessary to use other morphological examination that may be more relevant in regard to the promotion of assisted reproduction outcomes?

Summary answer: The sperm head vacuole reflect different sperm abnormalities declined viability and acrosome integrity. Therefore, intracytoplasmic sperm injection outcomes will be different in the semen samples

What is known already: Nowadays, the assessment of sperm parameters is performed according to standard sperm analysis. The current morphological examination does not provide any information about abnormalities in nuclei and genomic quality. Therefore, Vacuolization are formed from unnecessary organelles and cytoplasm which have not been removed during spermatogenesis. In the ICSI cycles, the use of such sperms have been associated to poor embryo and pregnancy outcomes. Moreover, the aim of this study was to assess whether the examination of sperm vacuole characteristics and its association with other parameters included DNA conformation and integrity, acrosome integrity, viability, and protamination status can predict ICSI outcomes.

Study design, size, duration: Semen samples were obtained from 98 men who visited Alzahra Educational and Remedial Center between October 2017 to February 2018. Infertile couples with male factor infertility (teratozoospermia) who were undergoing ICSI treatment were included. All semen samples had vacuolated spermatozoa. The classification of each semen sample was performed based on Vanderzwalmen's criteria as follows: grade I, no vacuoles; grade II, ≤2 small vacuoles; grade III, ≥1 large vacuole; grade IV, large vacuole with other abnormalities.

Participants/materials, setting, methods: To accurately measure the size and location of vacuole, the frequency, size, high magnification and scanning electron microscope methods were used for each patient. The chromatin integrity and condensation were assessed using toluidine blue and aniline blue staining, respectively. Viability and acrosome integrity was evaluated using triple staining. The protamine status was evaluated with chromomycin A3 staining. The assisted reproduction outcomes such as rates of fertilization, embryo development, biochemical pregnancy, and miscarriage were followed.

Main results and the role of chance: There are significant association between vacuole size and status of sperm chromatin condensation and packaging. So that, the results show a significant correlation between the vacuole size (large vacuole) and abnormal chromatin condensation of sperms ($p<0.05$). also, the presence of bright yellow fluorescence (CMA3-positive) was more frequently observed in spermatozoa with grades of III and IV than other groups ($p<0.05$), reflecting a higher percentage of abnormal chromatin packaging in these groups. These results were also investigated in the sperms with large nuclear vacuole.

However, a significant correlation was investigated between the frequency of vacuole and acrosome integrity and sperm viability. So that, the percentage of reacted acrosomes (blue/white) was significantly higher in spermatozoa with grades II-IV in comparison to normal group ($p< 0.05$). the viability of sperms was also declined in these groups ($p<0.05$).

The examination of sperm head vacuole was not significantly associated with fertilization rate ($p >0.05$) and embryo development rate ($p >0.05$). Whiles this association was significantly observed on biochemical pregnancy rate in the grade III and IV ($P <0.05$). Also, the odds ratio for miscarriage percentage was significantly higher (3.3: 1.1-9.6; $p=0.024$) in these groups in comparison with other groups.

Limitations, reasons for caution: The lack of evaluation of the gene expression involved in the protamination of the vacuolated sperms, which is closely associated with sperm quality and the small sample size are the limitations of this study.

Wider implications of the findings: The results of our study highlight the importance of follow up of more sperm parameters such as sperm head vacuole characteristics, because may reflect DNA damage and protamination defects.

Trial registration number: The results of this study indicated that our projects in Guilan University of medical sciences with No: 97320107 and .

P-040 Relationship between occupational exposures and seminal parameters: a prospective cohort study.

R. Lafuente[1], M.Á. Checa[2], K. Lattes[3], D. García[4], D. Mataró[3], R. Vasenna[4], B. Jacquemin[5,6,7,8]

[5]ISGlobal, ISGlobal, Barcelona, Spain
[6]Inserm U1168, VIMA Aging and Chronic Diseases: Epidemiological and Public Health Approaches, Villejuif, France
[7]CIBER, Epidemiología y Salud Pública CIBERESP, Barcelona, Spain
[8]Universitat Pompeu Fabra, Universitat Pompeu Fabra, Barcelona, Spain

Study question: Is there an association between occupational exposures and semen quality in men of subfertile couples undergoing assisted reproductive procedures?

Summary answer: Occupational exposures appear to reduce semen quality, specifically, decreasing concentration and sperm motility.

What is known already: Seminal parameters have been declining over time worldwide. This decline is likely multifactorial, and a variety of lifestyle factors, environmental and occupational exposures has been proposed to influence spermatogenesis and reproductive function, either positively or negatively. Occupational hazards are by far the best documented in reproductive epidemiological research. Generally, occupational exposures have been divided into physical exposures (heat, radiation), chemical exposures (solvents, pesticides), psychological exposures (distress), exposure to metals, and welding. It is important to know the effect of occupational exposures and to know what type they are in order to adequately inform patients.

Study design, size, duration: This prospective cohort study included 224 male patients undergoing conventional semen analysis for infertility investigation from January/2014 to December/2017, contributing with 840 seminograms (3.8 in average per patient). The study was approved by the institutional ethics committee and subjects were consented prior to participation.

Participants/materials, setting, methods: Semen analysis (3-5 days of abstinence) of conventional parameters (volume, sperm concentration, progressive motility and morphology) was carried out through computer-assisted semen analysis (CASA), and sperm DNA fragmentation (SCSA) was evaluated as a sperm function parameter. Exposures were assessed through questionnaires and were defined as being exposed to chemical (i.e. solvent, paints) or physical (i.e. extreme temperatures) or outdoor air exposures (i.e. particles) within the occupational framework. ANOVA/t-test measures were used to determine significant differences.

Main results and the role of chance: We observed that 20.1% of patients were exposed to any occupational exposures. The most frequent exposures were: chemical and outdoor air exposures (40.0%), only chemical (37.8%) and physical such as extreme temperatures (22.2%). We found statistically significant differences in means of sperm concentration according to the exposure: in not exposed, 62.7 mill/mL; exposed to chemicals and outdoor air pollutants, 55.8 mill/mL; exposed only to chemicals, 36.7 mill/mL and exposed to extreme temperatures, 13.6 mill/mL ($p = 0.040$). Also, we found statistically significant differences in progressive motility according to the exposure: in not exposed, 40.8 mill/mL; exposed to chemicals and outdoor air, 41.7 mill/mL; exposed only to chemicals, 30.5 mill/mL and exposed extreme temperatures, 31.7 mill/mL ($p = 0.043$). Volume, morphology and sperm DNA fragmentation were not significantly influenced by occupational exposures.

Limitations, reasons for caution: These analyses are crude and are not adjusted by potential confounders. Also, we considered exposure at any time during work life without taking into account duration or when the exposure occurred.

Wider implications of the findings: Occupational exposures are linked to decreased sperm quality but the mechanisms of action of exposure and the repercussion on reproductive physiology are yet to be understood. Our results open the way to better understand which parameters are more affected by different kinds of occupational exposure in a susceptible population.

P-041 Optimizing sperm selection by magnetic activated cell sorting (MACS) for couples with idiopathic failed implantation

S.T. Mathew[1], K. Matravadi[2], D.G. Rao[3]

[1]Oasis Centre For Reproductive Medicine, Embryology, Visakhapatnam, India
[2]Oasis centre For Reproductive Medicine, Embryology, Hyderabad, India
[3]Oasis Centre For Reproductive medicine, Medicine, Hyderabad, India

Study question: Will sperm selection by magnetic cell sorting (MACS) optimize the reproductive outcomes for women with previous idiopathic failed implantation?

Summary answer: MACS seems like a beneficial intervention to optimize sperm selection and reproductive outcomes for women with previous idiopathic failed implantations.

What is known already: Reasons for Implantation failure are still elusive. Sperm selection criterion at Intra-Cytoplasmic Sperm Injection (ICSI) is shown to influence reproductive outcomes. In-spite of decades of research we have not found the best method to optimize sperm selection. MACS technique has shown to sort sperms with relatively normal sperm DNA fragmentation Index and there by improve the reproductive outcomes.

Study design, size, duration: This is a retrospective study of couples that underwent fertility treatments at our center in the year 2018. Patients with advanced maternal age, uterine anomalies, endometriosis and severe male factor infertility were excluded from this study. Women with previous failed idiopathic implantation were offered MACS and recruited in this study (n=52).
Participants/materials, setting, methods: Women with history of unexplained failed implantation were only included in this study (n=52). All women were under the age of 35 years and underwent controlled ovarian stimulation. Semen sample on the day of oocyte retrieval was subjected to MACS and oocytes were injected by ICSI. Embryos were cultured till blastocyst stage and vitrified. In a frozen embryo transfer (FET) cycle two blastocysts were transferred. Implantation rates, Clinical Pregnancy rates and Miscarriage rates were calculated.
Main results and the role of chance: This group of women had a failed implantation in the previous cycle and in this cycle with usage of MACS at ICSI showed a CPR of 77%, IR of 65% and MR of 11%. MACS seems like a beneficial intervention to optimize sperm selection at ICSI and in-turn ensuring an optimal reproductive outcome in couples with history of idiopathic failed implantations.
Limitations, reasons for caution: Retrospective data, Small sample size
Wider implications of the findings: MACS seems to be an active intervention for optimizing sperm selection criterion in specific defined groups and its role in routine use of MACS for all couples undergoing fertility treatments needs further evaluation.
Trial registration number: -

P-042 The potential of sperm retrieved by micro-TESE in fertilizing vitrified and warmed oocytes

J. Fedder[1], J. Pedersen[1], E. Jessen[1], A.M. Milton[1], K. Blach[1]
[1]*Odense University Hospital, Centre of Andrology & Fertility Clinic, Odense, Denmark*

Study question: Do sperm retrieved by micro-TESE from men with reduced spermatogenesis have a potential to fertilize vitrified/warmed oocytes equally to donor sperm?
Summary answer: A trend for increased fertilization, cleavage and pregnancy rates were obtained using donor sperm compared to sperm retrieved by micro-TESE from men with reduced spermatogenesis.
What is known already: It is well documented that fertilization, cleavage, implantation and pregnancy rates using vitrified/warmed oocytes are equal to results obtained using fresh oocytes not exposed to cryopreservation. Testicular sperm retrieved by micro-TESE can be used fresh for fertilization of fresh, aspirated oocytes. However, such sperm often are cryopreserved and later on thawed for fertilization of fresh oocytes since it may be difficult to coordinate oocyte aspiration and micro-TESE. By micro-TESE testicular sperm are often obtained in a low number, and their potential to give rise to pregnancy might be reduced.
Study design, size, duration: Historical prospective study comparing fertilization, cleavage and pregnancy rates using testicular sperm obtained by micro-TESE or (when it was not possible to find testicular sperm) donor sperm. Forty consecutive couples undergoing micro-TESE during 2016-2018 due to Klinefelter's syndrome, maturation stop in the spermatogenesis, or failed sperm retrieval by conventional techniques with needle or TruCut were included.

Results obtained with cryopreserved, excess testicular sperm from the included patients were not analyzed.
Participants/materials, setting, methods: Three hundred and sixty two oocytes from 30 women were vitrified, and after warming 283 oocytes survived.

The women were stimulated with FSH in GnRH-agonist protocols and the aspirated oocytes vitrified using the Cryotech or Vitrolife techniques. The oocytes were warmed at the day of micro-TESE.

Fertilization and cleavage rates using sperm from the patients versus donor sperm were compared using the $\chi 2$-test, and pregnancy rates were compared using Fishers exact test.
Main results and the role of chance: Seventeen couples having 184 oocytes warmed and injected with own sperm obtained a fertilization rate (FR) of 64% and a cleavage rate (CR) of 53%. In comparison 13 couples having 99 oocytes warmed and exposed to donor sperm (control group) obtained a fertilization rate of 71% (NS) and a cleavage rate of 68% (p=0.019). No significant differences could be detected for subgroups with Klinefelter's syndrome (N=3; FR=62%, CR=57%), a history of cryptorchidism (N=4; FR=68%, CR=53%), or other reasons of non-obstructive azoospermia (N=10; FR=62%, CR=53%) compared to the control group.

A non-significant trend for an increased pregnancy rate was observed with donor sperm compared to own sperm [positive hCG in 69% (9 of 13) versus 35% (6 of 17) and clinical pregnancy in 46% (6 of 13) versus 35% (6 of 17)].

No differences could be observed by using the "vitrolife technique" for vitrification of oocytes compared to using the "cryotech technique". Excess blastocysts (10 fertilized with donor sperm and 7 fertilized with own semen) are still cryopreserved.
Limitations, reasons for caution: The study has not sufficient power for comparison of biochemical and clinical pregnancy rates between the groups. Furthermore, the subgroups with Klinefelter's syndrome, a history of cryptorchidism, or other pathologies are yet too small to make clear conclusions about differences between the respective subgroups and the control Group.
Wider implications of the findings: The study will be extended, and a new prospective study analyzing fertilization, cleavage and pregnancy rates using different combinations of cryopreserved and fresh testicular sperm, retrieved by micro-TESE, and fresh and cryopreserved oocytes will be designed.
Trial registration number: NCT 03809026

P-043 A low total motile sperm count in donor sperm obtained from commercial banks does not affect pregnancy rates after intrauterine insemination.

J. Ruiter-Ligeti[1], G. Shrem[1], M.M. Dahan[1], W. Buckett[1]
[1]*McGill University, Reproduction, Montreal, Canada*

Study question: Does the total motile sperm count of donor sperm obtained from commercial banks affect pregnancy rates after intrauterine insemination?
Summary answer: The absolute total motile sperm count found in thawed donor sperm on the day of insemination does not affect pregnancy rates after IUI.
What is known already: There is no consensus on the optimal sperm count for insemination with cryopreserved sperm. Samples sold by commercial banks typically represent just a portion of an ejaculate produced by donor who meets the banks standards for age, health and minimum sperm quality. Data from Denmark show that increasing the TMSC to greater than 19 million increased the likelihood of achieving pregnancy [1]. Another study found that frozen ejaculates with at least 20 million sperm yielded pregnancy rates similar to fresh samples containing more sperm [2].
Study design, size, duration: We performed a retrospective cohort study of single women and women in same sex relationships undergoing IUI at a single academic fertility center between January 2011 and March 2018.
Participants/materials, setting, methods: Our primary outcome is pregnancy rates per IUI, stratified by post washed TMSC. The data was analyzed in three groups: samples with less than 5 million, 5 to 10 million and greater than 10 million TMSC. Pregnancies are defined by a serum Beta HCG of greater than 5 mIU/ml. Chi-squared analyses and correlation coefficients were performed. IRB approval was obtained.
Main results and the role of chance: Of 9341 IUIs performed during the study period, 1080 IUIs were performed for single women and women in a same sex relationship using commercially available donor sperm. We found that there were no differences in the pregnancy rates per insemination based on TMSC. The pregnancy rates per cycle were 15/114(13.3%) for the group with less than 5 million, 34/351(9.5%) with 5 to 10 million and 61/609(10.0%) for samples with greater than 10 million TMSC, (p=0.52). We found no significant correlation (r= -0.072) between donor sperm TMSC and pregnancy after IUI (p= 0.46). Further, a reassuring beta-HCG level (>100IU/L) drawn 14 days after IUI was unrelated to TMSC (r= 0.0071, p=0.94).
Limitations, reasons for caution: A major limitation of our study design is that variables such medical history, BMI, and conception history were unavailable, thus our study represents all comers in an unselected sample using cryopreserved donor sperm.
Wider implications of the findings: Our data shows that the absolute total motile sperm count found in donor sperm on the day of insemination does not affect pregnancy rates after IUI. This result is useful in reassuring patients when freshly thawed donor sperm is found to have a lower TMSC.
Trial registration number: IRB approval MUHC NAGANO 2019-5254

P-044 Controversy Over The Use of Fresh Versus Frozen-Thawed Testicular Sperm In Men With Non-Obstructive Azoospermia Undergoing ICSI

S. Anis Hebisha[1], S.S. Gaafar[1], M.E. Eldeeb[2], S. Galal[3]
[1]*Faculty of Medicine-Alexandria University, OBGYN, Alexandria, Egypt*
[2]*Faculty of Medicine-Alexandria University, Andrology, Alexandria, Egypt*
[3]*Faculty of Medicine-Alexandria University, Physiology, Alexandria, Egypt*

Study question: Does testicular sperm cryopreservation in non-obstructive azoospermia affect fertilization and pregnancy rates in ICSI cycles? And does sperm motility play role in the outcome?
Summary answer: No discernible differences in fertilization and pregnancy rates were found when using fresh versus frozen-thawed testicular spermatozoa, and sperm motility is a major determinant.
What is known already: Azoospermia is found in 10-15% of infertile men (1). Non-obstructive azoospermia (NOA) is one of the most challenging subsets, which is caused by dysfunction in the process of spermatogenesis (2). With the introduction of sperm retrieval techniques, such as testicular sperm extraction (TESE) and microsurgical testicular sperm extraction (mTESE), those infertile men were able to have children of their own (3). Integration of cryopreservation techniques in the TESE-ICSI procedures reduced the need for repetition of the TESE procedure in future attempts (4), as well as the need of synchronisation between the male and female cycle for oocyte retrieval (5,6)
Study design, size, duration: Retrospective analysis of consecutive ICSI cycles.

A total of 226 cycles of TESE-ICSI were performed from October 2017 until August 2018.

They included 63 fresh TESE sperm and 163 frozen-thawed TESE sperm .
Participants/materials, setting, methods: 226 male patients with NOA in whom testicular sperm was found after testicular sperm extraction. Study was conducted in the IVF Unit at Elshatby University hospital, Egypt

A testicular tissue was excised from the male participants for TESE under general anesthesia. All subjects under went this procedure for the first time. Samples were either directly used for ICSI or cryopreserved. ICSI was performed with at least one mature oocyte (MII) injected with testicular sperm.
Main results and the role of chance: A total of 226 cycles of TESE-ICSI were performed. They included 63 fresh TESE sperm and 163 frozen-thawed TESE sperm. P value less than 0.05% was considered significant. The fertilization rates were comparable between fresh and frozen TESE (67% and 55% respectively, p=0.101) as well as the pregnancy rates (42.6% and 39% respectively, p= 0.647). Afterwards, the sperm were categorized according to their motility which was found to positively affect the fertilization and the clinical pregnancy rates; fertilization rates of fresh TESE sperm using motile versus immotile sperm were (70% and 46% respectively, p=0.029) and of frozen TESE sperm using motile versus immotile sperm were (60% and 40% respectively, p<0.001).

Clinical pregnancy rates of frozen TESE sperm when using motile versus immotile sperm were (52.7% and 14% respectively, p<0.001).

However, the rates of fertilization and clinical pregnancy were comparable when using fresh motile versus frozen motile sperm (p=0.151 and 0.233 respectively).

Thus, the motility of the sperm is a main determinant of the fertilization and clinical pregnancy rates of TESE-ICSI procedures regardless the use of a fresh or frozen TESE.
Limitations, reasons for caution: The retrospective design of the study was a limiting factor as the presence of residual unknown bias could not be ruled out.
Wider implications of the findings:

Using cryopreservation in TESE procedures is an effective method to treat infertility in patient with NOA without minimizing neither the fertilization nor the clinical pregnancy rates. Selection of sperm should be based on their motility.This would spare the female an unnecessary ovarian stimulation and the male an avoidable TESE repetition

Trial registration number: Alexandria University , faculty of Medicine research committee

P-045 Roles for osteocalcin in proliferation and differentiation of spermatogonial cells cocultured with somatic cells

T. Rastegar[1], S. Dr, Solhjoo[2], H. Dr, Toolee[3]
[1]*Tehran University of Medical Sciences, Anatomy, tehran, Iran*
[2]*Kerman University of Medical Sciences, Anatomy, Kerman, Iran*
[3]*Shahroud University of Medical Sciences, Anatomy, Shahroud, Iran*

Study question: Do osteocalcin affect in proliferation and differentiation of spermatogonial cells?
Summary answer: Osteocalcin improved proliferation and differentiation of spermatogonial cells.
What is known already: Osteocalcin can improved male fertility by Pancreas, bone testis axis.
Study design, size, duration: SCs and Leydig cells were isolated from neonate NMRI offspring mice and adult NMRI mice, respectively.
Participants/materials, setting, methods: SCs population were then enriched in a differential attachment technique and assessed for morphological features and identity. Then, SCs were cocultured with Leydig cells and incubated with osteocalcin for 4 weeks. Evaluation of proliferation and differentiation-related factors were surveyed using immunocytochemistry (ICC), Western blot, and quantitative real-time polymerase chain reaction (PCR). Finally, the rate of testosterone release to the culture media was measured at the end of 4th week.
Main results and the role of chance: Morphological and flow cytometry results showed that the SCs were the population of cells able to form colonies and to express ID4, α6-, and β1-integrin markers, respectively. Leydig cells were also able to express Gprc6α as a specific marker for the cells. Incubation of SCs/Leydig coculture with osteocalcin has resulted in an increase in the rate of expressions for differentiation-related markers. Levels of testosterone in the culture media of SCs/Leydig was positively influenced by osteocalcin. It could be concluded that osteocalcin acts as a positive inducer of SCs in coculture with Leydig cells probably through stimulation of testosterone release from Leydig cells and associated signaling.
Limitations, reasons for caution: this research should be done in human Sc.
Wider implications of the findings: Previously some researchers did in vivo study about Osteocalcin but we did in vitro and also in vivo in other studies.
Trial registration number: 123

P-046 Chemokines Alter Fallopian Tube Responses to DNA-Fragmented-Sperm by PCR Array

S.O. Mousavi[1], R. Mohammadi[2], F. Amjadi[3], S. Aghajanpour[2], M. Eslami[1], R. Aflatoonian[2]
[1]*Faculty of Advanced Science and Technology- Tehran Medical Sciences- Islamic Azad University- Tehran- Iran., Department of Genetics, Tehran, Iran*
[2]*Royan institute for Reproductive Biomedicine, Department of Endocrinology and Female infertility- Reproductive Biomedicine Research Center-, Tehran, Iran*
[3]*Iran University of Medical Science, Department of Anatomical Science, Tehran, Iran*

Study question: Can DNA-fragmented-sperm make changes in chemotactic response of fallopian tube during reproductive process?
Summary answer: Data suggested that sperm DFI is an important factor which can alter the fallopian tube reaction in reproductive events.
What is known already: Normal physiological homeostasis in the female reproductive tract needs Pro-inflammatory chemokines that attract immune cells. Chemokines are one of the major compartments of immune system. Sperm and fallopian tube interaction in the female reproductive tract has an important role in fertilization, early embryo development, implantation and pregnancy. It was shown that the chemokines including CCLs and CXCLs have relevance in ovulation, sperm capacitation and fertilization. Studies also showed that seminal fluid presented at intercourse provokes expression of chemokines, appears to initiate adaptations in the female immune response that promote fertility.
Study design, size, duration: Semen samples with normal features from 30 patients who considered unexplained infertile were collected. After washing sperms, they were categorized to two groups according to their DNA fragmentation by TUNEL assay.

Fallopian tube epithelial cell was also cultured into the tissue culture flasks containing DMEM/F12 with 10%FBS medium up to 70% of confluence.

Participants/materials, setting, methods: Fallopian tube epithelial cells were co-incubated with sperms for 24h. Afterwards, cells were washed and RNA extraction was performed followed by cDNA synthetized. The control group was fallopian tube epithelial cells without sperm co-incubation. Finally, the mRNA expression level of chemokines was evaluated by PCR Array and compared between 3 groups (control, normal DFI, abnormal DFI, n=2×10).

Main results and the role of chance: Our findings are compatible with previous studies which show that chemokines play fundamental role in the interaction between sperm and female reproductive tract. Generally, CCLs and CXCLs had lower expression than the control group. However, the expression of CXCL13 and PPBP was higher in sperm groups than control. Moreover, the considerable point is that CXCL13 had higher expression in abnormal DFI group than in normal DFI group, similar to CX3CL1 ($P<0.05$). Unlike mentioned genes, CXCL10 and CXCL11 which have the same pattern of expression between different groups, had lower expression in abnormal DFI group than in normal DFI group.

Limitations, reasons for caution: Obtaining semen samples due to ethical and logistical issues was the major limitation of this study. Furthermore, *in vitro* co-incubation of fallopian tube epithelial cells with sperms may not directly represent the *in vivo* interaction.

Wider implications of the findings: Our results showed that abnormal sperm DFI seems to be established as a pathogen in female reproductive tract and significantly alter the chemokines in fallopian tube which prevent fertilization events in advance to other reproductive process.

Trial registration number: Not applicable.

P-047 Sperm DFI changes cytokines influences in fallopian tube using PCR array

R. Mohammadi[1], S.O. Mousavi[2], M. Sabbaghian[3], S. Aghajanpour[1], Z. Zandieh[4], T. Maadani[1], R. Aflatoonian[1]

[1]Royan institute for Reproductive Biomedicine., Department of Endocrinology and Female infertility- Reproductive Biomedicine Research Center-, Tehran, Iran

[2]Faculty of Advanced Science and Technology- Tehran Medical Sciences- Islamic Azad University-, Department of Genetics-, Tehran, Iran

[3]Royan institute for Reproductive Biomedicine, Department of Andrology- Reproductive Biomedicine Research Center-, Tehran, Iran

[4]Iran University of Medical sciences, Department of Anatomical science-, Tehran, Iran

Study question: Can DNA fragmentation of sperm induce significant changes in immunological response of fallopian tube?

Summary answer: Sperm DNA fragmentation can change immunological response of fallopian tube.

What is known already: The interaction between the male and female gametes and embryos in the female reproductive system plays an important role in fertility, embryonic development, and implantation. Active immune systems throughout the female genitalia are against viral pathogens and bacterial agents which cause sexually transmitted diseases. Cytokines are one of the most important variables of immune cells that provide effective host protection. During fertilization sperms carry proteins which are allogenic to the female immune system. Therefore, cytokines play and important role in the fallopian tube specially in the presence of sperm.

Study design, size, duration: Fallopian tube epithelial cells were cultured into the tissue culture flasks containing DMEM/F12 with 10% FBS medium. Sperm samples from 20 donors with normal features were collected. The extent of sperm DNA fragmentation was measured by the TUNEL assay. Afterward, samples classified to two groups of normal and abnormal DFI. The third group was fallopian tube cells without sperm.

Participants/materials, setting, methods: Different sperms were co-incubated with fallopian tube cells for 24h. RNA extraction from cells was down fallowed by cDNA synthetized. Finally, PCR array was performed to evaluate of cytokine genes expression profiling. In addition, this data was validated by q-PCR.

Main results and the role of chance: The results of the data analysis indicated that the expression of some cytokines in the vicinity of sperm significantly changes. Sperm DFI is also effective in expressing cytokines, and the results has shown that the expression of cytokines in cells exposed to abnormal-DFI sperm compared to the cells exposed to sperm with normal DFI significantly changes.The present study on the effect of spermatozoa on cytokine production from the fallopian tube epithelial cells revealed that the expression of cytokines altered between different groups. Anti-inflammatory cytokines including IL4, IL6 and IL11 has the lowest expression in abnormal DFI group. However, other cytokines like IL18, IL23A and IL17F had different pattern of expression between the groups.

Limitations, reasons for caution: The major limitation of this study was obtaining semen samples due to ethical and logistical issues. On the other hand, *in vitro* culture system may not directly mimic of *in vivo* environment.

Wider implications of the findings: This study indicate that abnormal DFI can change the expression of cytokines which have essential roles in sperm preservation and fertilization. Therefore, this promising novel outcome might be true that alteration in immunological responses of fallopian tube can disrupt fertilization events.

Trial registration number: Not applicable.

P-048 AZFc-gr/gr Partial Deletion and Related DAZ/CDY1 Copy Number Change is Associated with Azoospermia in Iranian Men

Z. Samiei[1,2], M.A. Sadighi Gilani[3], M.R. Zamanian[1]

[1]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Genetics, Tehran, Iran

[2]University of Science and Culture- ACECR-, Faculty of Basic Sciences and Advanced Technologies in Biology, Tehran, Iran

[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR-, Department of Andrology, Tehran, Iran

Study question: Is there any association between AZFc subdeletions and related *DAZ* and *CDY1* gene copies with Azoospermia among Iranian men?

Summary answer: AZFc-gr/gr partial deletions and two copy of *DAZ* with one copy of *CDY1* deletions are a risk factor for Azoospermia in the Iranian population.

What is known already: Microdeletions in the azoospermia factor (AZF) regions of the Y chromosome are well-known genetic causes of male infertility, resulting in impairment of spermatogenesis. However, the importance of partial deletions of AZFc region is controversial. This region harbors genes of multi-copy that are expressed in the testicular tissue. In the last decade, much research has focused on deletion frequencies and types of *DAZ* and *CDY* family members and their relationship to male infertility.

Study design, size, duration: 204 azoospermic and 200 fertile men were included in the study as case and control groups while subjects with abnormal karyotype, Yq microdeletions, obstructive azoospermia, hypogonadism, hypoandrogenism, chronic diseases or those reported to be heavy smokers and/or with alcohol intake were excluded from the study. The study was approved by the Royan institute Ethics Committee. Written informed consent was obtained from all study participants.

Participants/materials, setting, methods: Study subjects were evaluated for the presence of AZFc partial deletion (gr/gr, b1/b3 and b2/b3) using seven sequence tagged site (STS) markers through Multiplex PCR. *DAZ* and *CDY1* copy number status were determined using sequence family variant analysis through PCR-RFLP.

Main results and the role of chance: Amongst the three AZFc partial deletions, the frequency of gr/gr was significantly higher (6.4%; 13/204) in azoospermic group compared to control (1.5%; 3/200) ($P = 0.012$). Therefore, gr/gr deletion can be considered as a risk factor for male infertility in Iranian population. All gr/gr partial deletions were accompanied with loss of two of four *DAZ* and one of two *CDY1* copies. Among 13 cases with azoospermia and gr/gr deletions, 11 were of *DAZ1+DAZ2/CDY1a* or *CDY1b* copy deletions (84.6%) and 2 of *DAZ3+DAZ4/CDY1b* copy deletion (15.4%). All 3 fertile men with gr/gr deletions were of *DAZ3+DAZ4/CDY1a* or *CDY1b* deletion (100%). In conclusion, AZFc-gr/gr deletions are a risk factor for male infertility in the Iranian population, where accompanying *DAZ1+DAZ2* copy number deletions are more frequent among azoospermic men compared to *DAZ3+DAZ4*.

Limitations, reasons for caution: The researchers had not access to the spermograms of all members of fertile group (56/200). Assessment of

oligospermic men (moderate and severe cases) will help in showing the importance of findings. A larger sample size will enable us to statistically compare between the *DAZ/CDY1* copy number groups.
Wider implications of the findings: AZFc partial deletions are prone to be vertically transmitted to the male offspring and even expanded in size through ART. So, genetic counseling is recommended and offering PGD may prevent the condition in affected men. Present study implies that AZFc partial deletion screening needs to be considered in routine practice.
Trial registration number: -

P-049 Oxidation-reduction potential levels are not influenced by the presence of leukocytospermia

H. Elbardisi[1], A. Majzoub[1], K. AlRumaihi[1], K. AlKubaisi[1], S. AlSaid[1], A. Agarwal[2], R. Henkel[3], M. Arafa[1]
[1]*Hamad Medical Corporation, Urology, Doha, Qatar*
[2]*Cleveland Clinic, American Center for Reproductive Medicine, Cleveland- Ohio, U.S.A.*
[3]*Department of Medical Bioscience, University of the Western Cape, Bellville, South Africa*

Study question: Does leukocytospemia affect the level of seminal oxidation reduction (ORP) potential?
Summary answer: ORP levels are not influenced by the presence of leukocytospermia
What is known already: Oxidative stress (OS) is a major contributor to male infertility. It is caused by an imbalance between reactive oxygen species (ROS) and reductants in favor of ROS, negatively affecting sperm functions. OS can be directly measured through ORP using the MiOXSYS system which has been shown to predict male infertility. In semen, ROS are produced by sperm and leukocytes. It is not clear as to what is the extent of leukocytic contribution to ROS production in semen as this could influence the ORP result.
Study design, size, duration: This was a retrospective study. It included 3,968 patients presenting with male factor infertility to a tertiary medical center over a period of 18 months. The inclusion criteria were infertility > 1year in duration and normal fertility assessment of the female partner.
Participants/materials, setting, methods: ORP was determined using the MiOXSYS system (Aytu BioScience, Englewood, CO) which has a cut-off of 1.36mV/106 sperm (3,968 patients) while SDF testing was done using the Halosperm G2test kit (Halotech DNA SL, Madrid, Spain) with a cut-off of 30% (1147patients). Leukocytospermia was detected by means of the Endtz test in 241men. Statistical analysis was performed using MedCalc Statistical Software version 18.10 using non-parametric tests (Spearman Rank correlation, Mann-Whitney test, Fisher's Exact Test, ROC curve).
Main results and the role of chance: SDF showed positive correlation with ORP ($r=0.225$, $P<0.0001$) and negative correlation with the number of leukocytes ($r=-0.262$, $P=0.0383$). However, no significant correlation was detected between ORP and leukocyte count ($r=0.0195$, $P=0.7665$). While Fisher's Exact test was significant ($P=0.0408$) for leukocytospermia and SDF, no relationship was found for leukocytospermia and ORP ($P=0.1369$). ROC curve analysis showed that neither ORP could predict leukocytospermia, nor could the leukocyte count predict high (≥1.36mV/106 sperm/mL)/low (<1.36mV/106 sperm/mL) ORP levels.
Limitations, reasons for caution: The main limitations are the retrospective design of the study.
Wider implications of the findings: More studies are needed to verify the effect of ROS source on sperm function.
Trial registration number: NA

P-050 The use of phospholipase C zeta (PLCζ) analysis to identify candidates for artificial oocyte activation (AOA): a series of clinical pregnancies and proposed management algorithm

X. Meng[1], P. Melo[2], C. Jones[1], C. Ross[3], G. Mounce[1], K. Turner[1,3], T. Child[1,3], K. Coward[1]
[1]*University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom*
[2]*Oxford University Hospitals NHS Foundation Trust, The Women's Centre, Oxford, United Kingdom*
[3]*Oxford Fertility, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom*

Study question: Does PLCζ analysis constitute an efficient diagnostic and prognostic tool to inform clinical decisions when considering AOA treatment in patients with male-factor infertility?
Summary answer: PLCζ analysis is a helpful diagnostic and prognostic test to determine patient eligibility for AOA treatment and predict the likelihood of subsequent clinical pregnancy.
What is known already: PLCζ is a key sperm protein that triggers oocyte activation in successful fertilisation. In couples with male-factor infertility undergoing intracytoplasmic sperm injection (ICSI) there is a 1-3% rate of total fertilisation failure (TFF). TFF results from oocyte activation deficiency (OAD), where the abnormal expression of PLCζ in sperm alters calcium oscillations within the oocyte leading to fertilisation failure. AOA is the only known treatment for OAD using chemical stimuli to artificially reproduce calcium release and successfully trigger oocyte activation. Nevertheless, evidence on the diagnostic applicability of PLCζ analysis and pregnancy outcomes following AOA in couples with TFF remains scarce.
Study design, size, duration: This prospective study was conducted between October 2016 and March 2018 at Oxford Fertility, UK. We recruited 27 couples with known male-factor infertility due to either globozoospermia; previous total fertilisation failure of ≥8 mature oocytes; or a history of fertilisation failure caused by suspected impaired oocyte activation. Eight fertile controls with proven fertility were also recruited. Women whose partners were diagnosed with PLCζ deficiency underwent ICSI-AOA using protocols with added calcimycin to induce oocyte activation.
Participants/materials, setting, methods: Immunofluorescence staining and quantitative analyses of PLCζ in participants' sperm were performed. The relative fluorescence (RF) of PLCζ in sperm from infertile males was compared with those of randomly matched fertile controls. Comparisons of PLCζ expression between the two groups were established. Clinical outcomes following ICSI-AOA were recorded, including fertilisation rate and rates of biochemical/clinical pregnancy and live birth. Using Youden index analyses, cut-off values of PLCζ associated with successful ICSI-AOA outcomes were determined.
Main results and the role of chance: No significant age difference was identified between infertile patients (35.4 ± 5.2 years, mean ± SD, n=27) and controls (38.0 ± 2.8 years, n=8) ($p=0.36$). Overall, the proportion of sperm expressing PLCζ was lower in the infertile group ($78.16\pm3.54\%$, n=27) than in the controls ($91.65\pm1.00\%$, n=8) ($p<0.001$). Moreover, the mean total level of PLCζ in sperm from the infertile males was lower ($p<0.001$) than that of the fertile controls (RF 17.21 ± 1.45 and 24.61 ± 1.29 arbitrary units [a.u.], respectively). Among the 27 infertile males, immunofluorescence analysis identified 7 with PLCζ deficiency (significant reduction in percentage of sperm expressing PLCζ and in mean PLCζ fluorescence level). Of these, 5 opted to undergo ICSI-AOA treatment. Following ICSI-AOA, successful fertilisation was recorded in all 5 couples (fertilisation rate 56.8%) with a total of 1 biochemical pregnancy, 3 ongoing clinical pregnancies (>12 weeks' gestation) and 1 live birth at term gestation. Overall, we report a clinical pregnancy rate of 80% in couples whose oocytes were successfully fertilised using AOA. Following Youden index analysis of the PLCζ data from all infertile males, the cut-offs below which oocyte activation was likely to benefit from AOA were 71% for proportion of sperm expressing PLCζ, and 15.57 a.u. for mean PLCζ per sperm.
Limitations, reasons for caution: PLCζ immunofluorescence analysis does not use real-time assays, thus precluding the assessment of PLCζ levels in individual sperm cells chosen for ICSI-AOA. Moreover, AOA treatment was not used in infertile patients with similar PLCζ levels to fertile controls, limiting evaluation of the PLCζ analysis as a predictor of AOA outcomes.
Wider implications of the findings: This study demonstrates the applicability of PLCζ quantification to inform clinical decisions when considering AOA treatment for couples with OAD. Larger comparative studies are required to provide further evidence of the effectiveness of AOA. In addition, developing a recombinant PLCζ protein would circumvent the need for calcimycin in AOA.
Trial registration number: National Research Ethics Committee (REC) Reference Number: 10/H0606/65

P-051 Clinical outcome of ICSI cycles in a series of 112 patients with severe asthenozoospermia and ultrastructural flagellar defects: a 17-year experience

V. Mitchell[1,2], A.L. Barbotin[1,2], A. Loyens[3], C. Decanter[2,4], G. Robin[2,4], N. Ramdane[5], N. Rives[6,7]

[3]*Inserm, Umr-s 1172, Lille, France*
[4]*Lille University Hospital, Endocrine Gynaecology and Reproductive Medicine, Lille, France*
[5]*Lille University Hospital, Biostatistics, Lille, France*
[6]*Rouen University Hospital, Biology of Reproduction Unit, Rouen, France*
[7]*Rouen University, EA4308: "Gametogenesis and Gamete Quality", Rouen, France*

Study question: Does the flagellar ultrastructural phenotype in patients with severe asthenozoospermia influence the outcome of ICSI ?
Summary answer: Reproductive outcomes, in terms of fertilization, implantation, embryo quality, miscarriage, pregnancy and live births are similar regardless the flagellar phenotypes.
What is known already: There are two main forms of flagellar pathologies: non-specific flagellar anomalies (NSFA) and homogeneous, suspected genetic, disorders as primary flagellar diskinesia (PFD) and dysplasia of fibrous sheath (DFS). In the literature, there is still a debate on the impact of the flagellar abnormalities on the ICSI outcomes that may be influenced by the nature of flagellar defect. However, the number of cases is still small for drawing conclusions.
Study design, size, duration: A large retrospective cohort analysis was performed on 112 severe asthenozoospermic patients using spermogram and sperm ultrastructural data from 2001 and 2017 in the reproductive units of Lille and Rouen University Hospitals.
Participants/materials, setting, methods: The 112 patients were classified as three groups according to the ultrastructural flagellar phenotype: NSFA n=67, PFD n=18, DFS n=27. In ICSI, 169 cycles were evaluated (NSFA n=114; PFD n=27; DFS n=28). Comparisons in outcomes were done using generalized liner mixed model included women as random effect and women age and ICSI rank as covariates. Semen parameters were compared between groups using Kruskall-Willis. P values<0.05 were considered significant.
Main results and the role of chance: Statistically significant lower motility, vitality and normal forms were associated with PFD and DFS defects respectively compared to NSFA group. The overall fertilization, pregnancy and delivery rates were of 57.6%, 31.7% and 25.5%, respectively. Fertilization rate was 58.4% in the NSFA, 52.6% in PFD, 61.7% in DFS. There were no statistically significant differences between the NFSA, PFD and DFS in terms of fertilization, implantation, pregnancy and delivery rates. Embryo quality, expressed as mean number of grade A defined as 4 cells on Day 2, ≥8 cells on Day 3, <10%fragmentation and equally sized mononucleated blastomeres, was 21.6% (NSFA), 16.7 (PFD) and 32.6% (DFS), respectively. Thus a trend in reducing the good quality embryos in PFD was observed but without significant statistical differences among the 3 groups (p= 0.44).
Limitations, reasons for caution: Although a large cohort of patients was enrolled, the study is retrospective. Further studies could consider a cohort of transferts in embryo development as blastocysts.
Wider implications of the findings: ICSI offers a valuable treatment for asthenozoospermic patients who desire biological offspring. Outcomes derived from this series study demonstrated that the use of ejaculated spermatozoa with entirely different flagellar ultrastructural defects (homogenous and heterogenous) has similar likelihood of success in ICSI. It is reassuring for the patients and clinical staff.
Trial registration number: Not applicable.

P-052 Protamine 1 (P1) as a prognostic indicator for human sperm quality and ICSI outcome

A. Zeyad[1], H. Amor[2], B. Abdulkareem[3], M. Alhudhud[3], M. Hammadeh[2]

[1]*HMG- Alrayan Hospital, IVF, Al-Riyadh, Saudi Arabia*
[2]*University of Saarland, - Obstetrics and Gynaecology, - Homburg/Saar, Germany*
[3]*HMG- Alrayan Hospital, IVF Department, Al-Riyadh, Saudi Arabia*

Study question: Could Protamine 1 (P1) be used as a prognosis indicator for human sperm quality and ICSI output?
Summary answer: Protamine 1 revealed correlations with sperm parameters and pregnancy rate after ICSI treatment and therefore, it could be used for assessment of sperm quality.
What is known already: Abnormal protamination during the spermatogenesis increases the abnormality of human spermatozoa (Utsuno *et al*., 2014) and decreases the chromatin condensation (Aoki *et al*., 2005).

Protamine 1 considered as a main nuclear protein in mammals, it packages sperm DNA. In some mammalian species, the sperm contains only P1 (Balhorn, 2007). It acts as the main protector for sperm DNA, hence any defect in the P1 may increase the sperm DNA fragmentation and subsequently decrease the sperm quality and eventually impair the ICSI outcomes.
Study design, size, duration: This is a prospectively designed study which was carried out at the Department of Obstetrics and Gynecology, University of Saarland, Germany in 2018. One hundred twenty semen samples were collected from unselected male partners of couples consulting for infertility treatment and were included in this study. 84 of them underwent an intra-cytoplasmic sperm injection (ICSI).
Participants/materials, setting, methods: Semen samples were assessed and prepared according to WHO guideline 2010. Sperm nuclear protamine was extracted and analyzed using acid-urea –PAGE. Chromatin condensation and DNA fragmentation were evaluated by Chromomycin (CMA_3) and TUNEL assay respectively.
Main results and the role of chance: The mean and standard deviation of the analyzed parameters were as a follow:

Sperm concentration (58.61 ± 47.481 $X10^6$/ml); sperm motility (42.90 ± 20.272%); progressive motility (17.01 ± 13.014); morphologically abnormal spermatozoa (91.05 ± 6.597%); sperm DNA fragmentation (14.83 ± 9.430%); sperm protamine deficiency (34.81 ± 17.586%); protamine P1(466.03 ± 154.979 (ng/10^6 sperms) and P2(451.43 ± 148.827 (ng/10^6 sperms).

Protamine 1 showed significant positive correlations with sperm concentration and total motility (r= 0.320, p<0.01; r= 0.195, p<0.05; respectively) and correlate negatively with morphologically abnormal spermatozoa and sperm protamine deficiency (CMA_3) (; r= -0.193, p<0.05; r= -0.242, p<0.01; respectively). But, no significant relationship between P1 and other sperm parameters was found**.**

In addition, P1 concentration found to be significantly higher in the sperm of male partners of patients with negative pregnancy test (498.28 ± 152.46, ng/10^6sperm) in comparison to the sperm of the male partners of patients who did get pregnant (425.03 ± 151.43, ng/10^6sperm) (p<0.05).
Limitations, reasons for caution: The sample size.
Wider implications of the findings: The findings indicated that the P1 could be used as a prognostic factor for sperm quality. However, more studies with large sample size are needed.
Trial registration number: Basic Science.

P-053 Selection of vacuole free spermatozoa with the assistance of the hyaluronic acid-binding assay.

N. Sayme[1] , T. Krebs[2], M. Kljajic [3]

[1]*Team Kinderwunsch, Gynecology, Hannover, Germany*
[2]*Team Kinderwunsch, IVF Laboratory, Hannover, Germany*
[3]*University Hospital Homburg, IVF Laboratory, Homburg, Germany*

Study question: Does the hyaluronic acid-binding assay has a positive effect on the selection of vacuole free human spermatozoa, comparison to the standard morphologically selected sperm method?
Summary answer: Hyaluronic-acid-binding assay selection is a good method to select spermatozoa in regard to the presence of vacuoles, especially for spermatozoa with more than two vacuoles.
What is known already: The selection of normal spermatozoa during ICSI does not enable the detection of nuclear defects. Sperm head nuclear abnormalities were identified earlier as vacuoles by motile-sperm organelle-morphology examination (MSOME). In terms of the links between the presence of vacuoles and embryo development, it was shown that the injection of morphometrically normal spermatozoa with no vacuoles was associated with significantly higher blastocyst rate, a smaller proportion of arrested embryos and higher pregnancy rates. According to previously obtained data

in assisted reproduction, it is of importance to reliably select vacuole-free spermatozoa.

Study design, size, duration: This is prospective and blinded observational study. Hyaluronic acid (HA) bound, standard morphologically (SM) selected (200x) and unselected sperm (control) were collected by different persons. The evaluation of vacuoles was performed by Nomarski high-power differential interference contrast (Nomarski/DIC) optics (600x up to 7.200x). The number of vacuoles in each sperm head was determined as an: absence of vacuoles, the presence of one vacuole, the presence of two vacuoles, the presence of more than 2 vacuoles.

Participants/materials, setting, methods: Fifteen human semen samples were prepared by 80% density gradient. From each sample, a minimum of 20 spermatozoa per method (HA, SM selection) were collected in separated PVP droplets. Additionally, 20 unselected sperm were collected from each sample designated as controls. All samples were blind-observed by the same person. Statistical significance was defined as $P<0.05$ One way analysis of variance and post-hoc Tukey-Test were performed. All statistical evaluations were carried out using SigmaStat Version 3.5.

Main results and the role of chance: After complete statistical analysis, the number of spermatozoa without vacuoles found in Hyaluronic acid bound selected ($p<0.001$) and standard morphologically selected ($p<0.01$) were significantly higher compared to the unselected spermatozoa. The number of sperm with 1 ($p<0.05$) or 2 vacuoles ($p<0.01$) and more than 2 vacuoles ($p<0.001$) was significantly higher in the unselected spermatozoa. Furthermore, in Hyaluronic acid bound selected spermatozoa the appearance of 2 and more than 2 vacuoles was significant lower compared to the standard morphologically selected spermatozoa ($p<0.05$).

Limitations, reasons for caution: The time necessary for the isolation of individual spermatozoa from each sample was one of the limiting factors. Therefore, only 20 spermatozoa per sample were collected. However, obtained results are encouraging and in order to obtain more concrete results, future research should be performed on a larger numbers of samples.

Wider implications of the findings: Both selection methods provide spermatozoa which containing less number of vacuoles, compare to the unselected samples, especially in the group with more than two vacuoles. Therefore, HA selection may be an effective method to identify spermatozoa with a higher fertilization potential in order to improve results in ART procedures.

Trial registration number: not applicable

P-054 The assessment of microdissection testicular sperm extraction (micro TESE) and intracytoplasmic sperm injection (ICSI) in couples with Klinefelter syndrome (KS)

T. Ishikawa[1], S. Mizuta[1], K. Yamaguchi[1], T. Takeuchi[2], K. Kitaya[1], H. Matsubayashi[1]

[1]Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan
[2]Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan

Study question: What are sperm retrieval rate (SRR) by micro TESE, fertilization rate, and pre- and post- implantation development in KS couples?

Summary answer: In KS patients with successful sperm retrieved, age was younger than failure group and their embryonic development using motile sperm was comparable to unexplained NOA.

What is known already: Micro TESE, in combination with ICSI, is presently used to treat infertility in cases of NOA including KS, which is the most common sex-chromosome disorder among infertile males, with a prevalence of 1 in 660 men and is a frequent cause of hypogonadism and infertility. There were few reports regarding ICSI outcome in the couples of KS and the aim of this study is to assess the prevalence and the significance including SRR by micro TESE and ICSI outcomes with embryonic development in KS couples.

Study design, size, duration: A retrospective study was conducted in 131 patients with KS and 649 NOA patients with 46, XY without past history (unexplained NOA; not including after orchidopexy, KS, cryptozoospermia, mumps orchitis, etc) who underwent micro TESE and ICSI for their wives between September 2013 to December 2018.

Participants/materials, setting, methods: A total of 1186 azoospermic patients were examined chromosomal analysis on cultured lymphocytes from peripheral blood. We evaluated SRR of micro TESE, two pronuclei (2PN) oocyte rates, blastocyst development rates, good-quality blastocyst (Grade 3BB and above on day 5 by the Gardner scoring) rates, and clinical pregnancy rates per embryo transfer (ET). We did not undergo preoperative hormonal therapy for KS patients. Statistical analysis was performed using unpaired t-tests and chi-squared tests.

Main results and the role of chance: We identified 131 KS out of 1186 azoospermic patients (11.0%). SRR of first attempt micro TESE in KS (55/102=53.9%) was higher than unexplained NOA (102/482=21.2%) ($p<0.01$). Spermatozoa were successfully retrieved in 5 of 29 (17.2%) KS and 19 of 167 (11.4%) unexplained NOA who had previously undergone micro TESE with no sperm found. No correlation was found between serum FSH, LH, and T level and testicular volume with the success of sperm retrieval. Patient age in successful micro-TESE for cases of KS is significantly younger (32.1± 4.8 years) than that in failed cases (35.2±5.5 years) ($p<0.05$) in first attempt micro TESE. 2PN oocytes, blastocysts development, and good-quality blastocysts rates were 54.2%, 40.7%, and 15.1% in KS and 53.9%, 45.1%, and 18.7% in unexplained NOA, respectively (no significant differences). Clinical pregnancy rates per ET were 33.6% in KS and 29.7% in unexplained NOA. Eighty-eight out of 100 (88.0%) cycles could be performed ICSI using motile sperm. With respect to motility of retrieved sperm, 2PN oocytes (56.9%), blastocysts development (43.7%), and good-quality blastocysts rates (16.1%) using motile sperm was significantly higher than that of using immotile sperm even after pentoxifyllin administration (41.0%, 6.7%, and 3.3%, respectively) ($p<0.005$) from KS couples.

Limitations, reasons for caution: We did not show the data using ejaculated sperm with KS. The natal outcome and development of these children has not been fully investigated. We need long-term follow-up of babies of the KS couples.

Wider implications of the findings: Micro TESE is particularly helpful for successful sperm retrieval in KS cases, however, a salvage micro TESE offers a less chance of finding sperm. In KS, the motile sperm retrieval from testicular tissue in micro-TESE is a critical key to succeed and rationale for good embryonic development and clinical pregnancy.

Trial registration number: Not applicable.

P-055 Perinatal outcomes using ejaculate versus surgical sperm retrieval in patients undergoing intra cytoplasmic sperm injection for male infertility – A retrospective analysis of 628 patients

K. Mogili[1], M. Kamath[1], T. Aleyamma[1], R. Karuppusami[2], S. Thomas[1], A. Chandy[1]

[1]Christian Medical College- Vellore- India, Reproductive medicine, Vellore, India
[2]Christian Medical College- Vellore- India, Biostatistics, Vellore, India

Study question: Does surgical sperm retrieval in patients with azoospermia influence the perinatal outcomes when compared to ejaculate in patients with non-azoospermic male infertility

Summary answer: There was no increased risk of preterm birth (PTB), low-birth weight (LBW) or congenital anomalies when surgically retrieved sperm was used compared to ejaculate

What is known already: Surgical sperm retrieval (SSR) followed by intracytoplasmic sperm injection (ICSI) is the main line of treatment for couples with azoospermia desiring a biological child. Various studies have reported either a decrease or no difference in pregnancy and live birth rates following ICSI with testicular sperm compared to epididymal sperm and ejaculate. However, perinatal and neonatal outcomes with ICSI using surgically retrieved sperm in azoospermic men and ejaculate in non -azoospermic infertile men are not well established

Study design, size, duration: 628 couples undergoing ICSI for male infertility between 2011- 2015 were included in this retrospective cohort study. The ejaculate group had 478 couples and the SSR group had 150 couples

Participants/materials, setting, methods: Data from all couples who underwent ICSI for male infertility using ejaculate or surgically retrieved sperm during the study period were analysed to compare the pregnancy outcomes (miscarriage, multiple gestation, preterm birth, live birth, mode of delivery and congenital anomalies). Logistic regression analysis was performed for perinatal

outcomes like PTB, LBW following singleton live births. A subgroup analysis for perinatal outcomes was conducted between testicular and epididymal sperms

Main results and the role of chance: The clinical pregnancy rate per embryo transfer was 212/465 (45.6%) in the ejaculate group and 74/146 (50.6%) in the SSR group (p value=0.15). The live birth rate per embryo transfer was 163/465 (35.05%) in the ejaculate group and 51/146 (34.9%) in the SSR group (p value=0.97). The mean gestational age at delivery was lower in ejaculate group (36.3 ± 2.3 weeks) compared to SSR group (37.29 ± 1.3). There was no difference in miscarriage rate, mode of delivery and congenital anomaly rates between the two groups (p value of 0.5, 0.16 and 0.16 respectively).

Logistic regression analysis for singletons showed no difference in PTB (epididymal sperm vs ejaculate OR 0.21, 95% CI 0.02- 1.66) (testicular sperm vs ejaculate OR 0.46, 95% CI 0.12- 1.65) or LBW (epididymal sperm vs ejaculate OR 0.42, 95% CI 0.09- 1.9) (testicular sperm vs ejaculate OR 0.80, 95% CI 0.27-2.3)

Subgroup analysis between epididymal and testicular sperm also showed no difference in PTB (OR 2.18, 95% CI 0.20- 22.94) or LBW (OR 1.87, 95% CI 0.31-11.02) for singletons.

Limitations, reasons for caution: The main limitation is that it is a retrospective study. An adjusted logistic regression analysis for perinatal outcomes could not be performed because of the small number of patients .Also,data was not available for male FSH, LH and karyotype.

Wider implications of the findings: No major differences were noted in perinatal or neonatal outcomes when ejaculate or surgically retrieved sperm was used. This helps in counseling couples prior to ICSI regarding the outcomes

Trial registration number: N/A

P-056 Post-wash total motile sperm count as the most accurate predictor for live birth after intrauterine insemination

M.J. Soriano [1,2], L.M. Castillo [1,3], V. Lozoya [4], I. Molina [5], C. Díaz-García [6]

[1] *IVI foundation, Innovation, Valencia, Spain*
[2] *Instituto de Investigación Sanitaria La Fe, Medicina Reproductiva, Valencia, Spain*
[3] *University of Valencia, Department of Pediatric-Obstetrics and Gynecology, Valencia, Spain*
[4] *IVI Foundation, Research Support and Management Unit, Valencia, Spain*
[5] *Hospital Universitari i Politècnic La Fe, Reproducción Humana Asistida, Valencia, Spain*
[6] *IVI-RMA London, Reproductive Medicine, London, United Kingdom*

Study question: Is it possible to predict the success of a homologous or donor intrauterine insemination (IUI) cycle according to the male infertility?

Summary answer: The post-wash total motile sperm count (PTMSC) has more precise predictive value over standard WHO criteria at the time of homologous and donor IUI.

What is known already: The effectiveness of IUI depends on several factors. One of the most important is the sperm quality. World Health Organization (WHO) defined cut-off values to distinguished between normal and abnormal semen samples. Although this criteria classification has been widely used, there is a controversy among clinicians. Some of them claim that the most influential variable in the IUI is only the sperm motility. Others consider that pregnancy rates are influenced by concentration too. This lack of standardization could be solved with the PTMSC, a parameter that represents the exact number of progressive motile sperm that are available for the insemination.

Study design, size, duration: A retrospective cohort study. A total of 7435 subfertile couples undergoing IUI in the last 15 years were analysed. 5390 couples underwent IUI with homologous semen (IUI-H) and 2045 couples underwent IUI with frozen donor semen (IUI-D).

Participants/materials, setting, methods: All the infertile couples that underwent IUI. Three prediction models of pregnancy and livebirth were compared according to the WHO parameters, the sperm count and the PTMSC, calculated by multiplying the sperm concentration by progressive motile spermatozoa and the volume used in the insemination procedure. Logistic regression analysis and AUC-ROC curve processed by R package were used to evaluate the association between the three parameters and the likelihood of pregnancy and live birth in IUI.

Main results and the role of chance: The overall pregnancy rate (PR) per IUI-H cycle was 10.4 and 20.8% after IUI-D. The multiple PR was 5.4% in IUI-H and 7.8% in IUI-D, and the overall live birth rate (LBR) was 80.5% and 85.6%, respectively. Logistic regression analysis showed that the PR and LBR were not influenced by WHO criteria in none of the IUI procedures. Sperm count and PTMSC were significantly correlated with a positive clinical outcome in terms of PR after both IUI ($p<0.01$). AUC-ROC curves showed that PTMSC has a significantly greater predictive capacity of livebirth. The final predictive model had an AUC of 0.51 ($p<0.05$) in case of total sperm, and an AUC of 0.55 ($p<0.01$) in reference to PTMSC in IUI-H. The same trend was observed after IUI-D ($p<0.01$). The probability of achieving a live birth after IUI-H was higher when PTMSC was over 10 million (OR=0.85, 95% CI: 0.67 to 1.08). The mean value of PTMSC was significantly higher in IUI-H (13.85±9.28 vs 6.59±4.19, $p<0.05$). Patients with a PTMSC less than 5 million had a greater challenge in getting a live birth after IUI-D (OR=0.37, CI: 0.24 to 1.18).

Limitations, reasons for caution: A prospective design study is necessary to further confirm the correlation between PTMSC parameter and clinical outcome in IUI.

Wider implications of the findings: Due to PTMSC has shown to be better correlated with the PR and LBR than the WHO 2010 classification criteria, we should reconsider using the PTMSC parameter as the best prognostic tool to achieve a live birth after IUI-H or IUI-D.

Trial registration number: This is not a clinical trial.

P-057 Oxidation-reduction potential in semen correlates with semen parameters and DNA fragmentation but not necessarily with lifestyle in men visiting a fertility clinic

I. Goovaerts[1], U. Punjabi[1], J. Luyckx[2], B. Missault[2], K. Peeters[1], D. De Neubourg[1]

[1] *Antwerp University Hospital, Centre for Reproductive Medicine, Edegem, Belgium*
[2] *University of Antwerp, Faculty of Medicine and Health Sciences, Edegem, Belgium*

Study question: Does lifestyle influence the redox potential in semen affecting semen quality via sperm parameters and DNA fragmentation in the total and vital fraction?

Summary answer: Oxidation-reduction potential correlates with semen motility, morphology and vital sperm DNA fragmentation, but not with physical activity, BMI, smoking, drug or alcohol abuse.

What is known already: A disbalance between reactive oxygen species and the antioxidant capacity can lead to oxidative stress (OS) in semen. A MiOXSYS™ analyser assesses easily the static oxidation-reduction potential (sORP). A bad lifestyle is hypothesized as being a major cause of OS, thereby inducing DNA fragmentation, membrane oxidation and apoptosis. Investigating lifestyle is mostly performed by self-reporting surveys. For physical activity, a validated Baecke questionnaire (Baecke et al.,1982) which coded three categories: occupation, sports, and leisure time, is frequently applied. Lifestyle adjustment in men with inferior semen quality, might reduce the need for more advanced assisted reproductive technologies.

Study design, size, duration: This cross-sectional study comprised a cohort of 225 patients between January 2017 and March 2018. Only complete semen samples were included with a minimum of 2 days of abstinence. The study was approved by the institutional ethical committee and written informed consent was obtained from each participant.

Participants/materials, setting, methods: In 206 men (18-65 years) semen parameters were evaluated according to WHO 2010 guidelines, OS was measured by MiOSYS™ (n=198) and DNA fragmentation was assessed on fresh semen by TUNEL assay in the total and the vital fraction using flow cytometry (n=179). A clinical male fertility diagnosis questionnaire (n=206) and the Baecke survey (n=95) were filled out. Spearman correlation and Mann-Whitney test were used to compare groups.

Main results and the role of chance: Significant negative correlations were found between the sORP and progressive motility (r= -0.24; p=0.0005), total motility (r= -0.23; p=0.0010) and morphology (r= -0.18; p=0.0112). While sperm concentration, total sperm count and semen leukocyte concentration showed no significant correlations. Moreover, sORP was significantly higher

(p=0.0001) in patients with one or more subnormal sperm parameter (4.23 mV/sperm concentration) than in normozoospermic men (0.77 mV/sperm concentration). Sperm DNA fragmentation in the vital fraction, and not in the total population, was significantly correlated with sORP (r=0.19; p=0.01). As far as lifestyle is concerned, no significant correlations could be found between sORP (M ± SD; 2.50±6.22 mV/sperm concentration) and body mass index (BMI; 25.3±3.96), physical activity (8.1±1.4), or mean age (34.8±8.26 years). Moreover, none of the other lifestyle factors (smoking, alcohol, drug abuse), had a significant influence on the oxidation-reduction potential in semen.

Limitations, reasons for caution: The study was limited by the limited number of participants who filled out the Baecke questionnaire. Self-reporting surveys can be subjective. Moreover, the type of diet was not included in the study.

Wider implications of the findings: Measurement of sORP can serve as an adjunct to routine semen analysis as a supplementary test to link oxidative stress and poor semen quality, identifying altered functional status of the sperm and thereby directing those men to appropriate therapeutic management.

Trial registration number: N/A

P-058 Relationship between oxidative stress in semen and the fertilizing capacity of the sperm - evidence from the conventional IVF model in couples with unexplained infertility

H.N. Sallam[1], N. Sallam[2], A. Farrag[2], D. El-Kaffash[3], F. Ezzeldin[2], M. Abdelbaqy[4]

[1]Alexandria University Faculty of Medicine, Dept of Obstetrics and Gynaecology, Alexandria, Egypt

[2]Alexandria Fertility and IVF Center, IVF Unit, Alexandria, Egypt

[3]Alexandria University Faculty of Medicine, Dept of Clinical Pathology, Alexandria, Egypt

[4]Alexandria Regional Center for Women's Health and Development, Epidemiology and Biostatistics, Alexandria, Egypt

Study question: Is there a relationship between oxidative stress in the native semen and the fertilizing capacity of the spermatozoa?

Summary answer: Oxidative stress in the native semen is negatively and significantly related to the fertilizing capacity of the spermatozoa.

What is known already: Oxidative stress (OS) is thought to affect the fertilizing capacity of the sperm. This is based on indirect evidence such as the association of OS with sperm parameters in normo and oligo-asthenospermia as well as the relationship between OS and the clinical outcome of ICSI. However, the relationship between OS in semen and the fertilizing capacity of the sperm should ideally be tested in the IVF model taking the fertilization rate (FR) in relation to OS as the primary outcome measure, preferably in couples with unexplained infertility where the fertilizing capacity of the sperm is in question.

Study design, size, duration: This prospective cohort study was conducted between September 2017 and December 2018. Couples with unexplained infertility were treated for one cycle of combined IVF/ICSI if 12 oocytes or more were retrieved. If good embryos resulted from IVF, 2 were transferred. If no fertilization occurred from IVF, 2 embryos resulting from ICSI were transferred. All remaining embryos were frozen. A total of 108 couples were enrolled but only 25 fulfilled the criteria and completed the study.

Participants/materials, setting, methods: A total of 575 oocytes were retrieved from the 25 patients attending our IVF Unit (mean ± SD = 20.5 ± 5.6 oocyte/cycle). In each patient, 3 to 5 oocytes were inseminated by conventional IVF procedure and the rest were treated with ICSI. Oxidative stress was determined in the native semen samples by measuring the oxidative reduction potential (ORP) using the MiOXYS system and the results correlated with the fertilization rate of the IVF-fertilized oocytes.

Main results and the role of chance: Out of the 575 oocytes retrieved, 108 were inseminated with conventional IVF (mean ± SD = 4.2 ± 1.4 oocytes per cycle) resulting in 36 embryos from 14 patients (FR = 33.3%), of whom 3 became pregnant (pregnancy rate = 21.4%). There was a negative correlation between the ORP in the native semen and the FR. The mean (± SD) ORP in the native semen in couples with =>50% IVF fertilization was 1.02 ± 0.1 mV/10^6 sperm/mL which is significantly lower than in couples with <50% fertilization (2.05 ± 0.7 mV/10^6 sperm/mL) (P<0.02). The sensitivity, specificity, PPV, NPV, +LR and –LR of the ORP assay in predicting =>50% fertilization were 70.0%, 60.0%, 53.8% , 75.0%, 80.0% and 20% respectively with a cut-off point at =<1.5692 mV/10^6 sperm/mL. In the other 11 patients where no fertilization occurred by IVF, embryos resulting from ICSI were transferred, resulting in 7 pregnancies (pregnancy rate = 63.6%). The mean (±SD) ORP in the native semen in patients pregnant with IVF-fertilized oocytes was also significantly lower than in patients pregnant with ICSI-fertilized oocytes (0.99 ± 0.1 mV/10^6 sperm/mL versus 2.68 ± 0.7 mV/10^6 sperm/mL; P <0.05).

Limitations, reasons for caution: The small sample size of this study can be considered a limitation but these early results can be further confirmed by larger prospective studies involving couples with various causes of infertility, although the criteria required for the recruitment of these couples are not easy to fulfill.

Wider implications of the findings: These results confirm the negative effect of OS in native semen on the fertilizing capacity of the sperm. Measuring ORP in native semen can be used in couples with unexplained or male factor infertility to help determine whether anti-oxidant therapy, IUI, IVF or ICSI is the best management option.

Trial registration number: Not applicable.

P-059 An evaluation of sperm parameters based on age; an analysis of almost 18 000 specimens.

G. Shrem[1], J. Balayla[2], N. Steiner[1], A. Lasry[3], A. Volodarsky-Perel[1], W.Y. Son[1], M.H. Dahan[1]

[1]McGill University, MUHC Reproductive Center, Montreal, Canada

[2]McGill University, OB & Gyn, Montreal, Canada

[3]McGill University, Faculty of Medicine, Montreal, Canada

Study question: Is there an age influence on mean sperm parameters?

Summary answer: Age affects the semen volume, sperm concentration and motility in a non-linear fashion with the best sperm parameters available between the ages of 30-40 years.

What is known already: Normal ranges of sperm parameters in a man's ejaculate, were defined previously but do not take age into consideration (Cooper *et al.* 2009, Check *et al.* 1992). A negative correlation was found between age and routine semen parameters when using 40 years as a cut-off value (Verón *et al.* 2018). But to the best of our knowledge, no age-normograms of semen analysis results have been published.

Study design, size, duration: This is a retrospective study that includes 17,777 semen analysis from the MUHC reproductive center produced from 2004 to 2018. Mean data is presented with standard error bars. Data was analyzed as nonlinear polynomial regression analysis and p-values.

Participants/materials, setting, methods: Males who were referred to MUHC reproductive centre, for any clinical reason, and produced sperm for diagnosis. Sampled were produced by masturbation in the clinic and handed to the Andrology laboratory for CASA.

Main results and the role of chance: Analysis of the 17,777 computer-assisted and technician verified semen analyses (CASA) demonstrated that (graph): the volume, motility, count, progressive count, rapid motility and concentration increase to a maximum level between the ages of 30 to 40 after which they decrease again (P value < 0.0001; R^2>0.90 in all cases). Interestingly Krugger Tyberg % strict normal forms almost follow a linear relationship increasing as males age (P value < 0.0001; R^2=0.89). To test whether these results were a function of patients who presented to fertility centers and did not represent the general population we plotted only values with normal results based on the 2010 WHO parameters (not shown). Again a similar pattern was seen with the CASA results increasing until about 30 years of age. Remaining best until 40 years of age and then subsequently decreasing. This pattern among the normal results confirms the nonlinear relationship of sperm parameters and age.

Limitations, reasons for caution: This is a retrospective study, hence has inherent bias. However, being almost 18,000 specimens, likely the results reflect the general population. None were lost to follow up, since all could be extracted from our sperm database where they all specimens were maintained at initial calculation of results and entered prospectively.

Wider implications of the findings: Unlike female fertility which peaks in the 20s, as an evolutionary theory males could best protect based on strength, knowledge and status in their 30s. Best sperm at 30-40, allows males an advantage when multiple copulations are occurring with different individuals, as occur with chimpanzees, or possibly did with pre-humans.

Trial registration number: n/a

P-060 The correlation of sperm DNA fragmentation with Blastocyst grading and it's implantation potential

M. Hozain[1], E. Hassanen[1], Y. Azzouz[1], H. El Khedr[1], H. Zaki[2]
[1] *Ganin Fertility Center, IVF Laboratory, cairo, Egypt*
[2] *Ganin Fertility Center, gynecology, cairo, Egypt*

Study question: Is sperm DNA fragmentation (SDF) has a correlation with Blastocyst's trophectoderm (TE) and Inner cell mass (ICM) grading, or with the implantation rate?
Summary answer: There is no correlation between SDF and blastocyst grading. Although there is an inverse correlation between abnormal SDF and the implantation rate in ICSI patients.
What is known already: Achieving pregnancy depends on sperm and oocyte quality. Sperm DNA integrity is a crucial parameter representing sperm quality. Abnormal SDF has a negative impact on pre and post implantation embryo development. Published studies focused on the correlation between SDF and Blastocyst formation with its morphological grading, based on the fact that embryonic genome activation starts between 4-8 cells stage of development.
Study design, size, duration: Retrospective cohort study included 189 couples, assigned to normal SDF group (121 cases), and abnormal SDF group (68 cases). Semen in both groups was processed by double layer density gradient (DG). All included cases underwent ICSI in Ganin Fertility Center from January 2018 to September 2018.
Participants/materials, setting, methods: All cases in this study reached the blastocyst stage with female age $\leq$37 years old and male sperm count $\geq$ 5 million. SDF test was done by TUNEL assay using benchtop flow cytometer with cutoff value 20%. Blastocyst morphological assessment was carried out by experienced embryologists according to Gardner's criteria. The data were collected and analyzed using IBM SPSS version 22 for Microsoft Windows. The difference is considered significant if the *p*-value is $\leq$ 0.05.
Main results and the role of chance: There were no significant differences in male age, female age or number of MII oocytes between the two groups. There was a significant difference between SDF values for normal and abnormal SDF groups (14.3% vs. 28.6%) ($p < 0.005$). The fertilization rate was (78.44% vs. 76.67%) ($p > 0.05$) for normal and abnormal SDF groups respectively. The blastulation rate was (65.52% vs. 58.71%) ($p < 0.05$) for normal and abnormal SDF groups respectively. On comparing the blastocysts grading we found that the good TE was (18.91% vs. 21.45%) ($p > 0.05$), Fair TE was (33.94% vs. 35.02%) ($p > 0.05$), Poor TE was (7.54% vs. 7.54%) ($p > 0.05$), Good ICM was (32.34% vs. 35.18%) ($p > 0.05$), Fair ICM was (26.73% vs.27.65%) ($p > 0.05$) and poor ICM was (1.59% vs. 1.74%) ($p > 0.05$) for normal and abnormal SDF groups respectively. Pregnancy rate was (66.3% vs. 51.6%) ($p > 0.05$) for normal and abnormal SDF groups respectively. However, the implantation rate was (47.96% vs. 33.20%) ($p < 0.05$) for normal and abnormal SDF groups respectively So, the abnormal SDF levels would affect the implantation potential without reflection on the blastocyst morphological grading.
Limitations, reasons for caution: This study is retrospective and the blastocysts assessment would have been better if done through PGT-A not only the morphological grading of TE and ICM.
Wider implications of the findings: If these findings are confirmed with larger prospective randomized control trials so, the usage of sperm selection techniques may improve the negative impact of abnormal SDF on the reproductive outcomes.
Trial registration number: not applicable

P-061 Unraveling the origin of azoospermia in male cystinosis patients.

A. Reda[1], K. Veys[1], P. Kadam[2], C. Camps[1], A. Taranta[3], L.R. Rega[3], D. Cyr[4], F. Emma[3], L. Van den Heuvel[1], E. Goossens[2], E. Levtchenko[1]
[1] *KU Leuven, Organ system, Leuven, Belgium*
[2] *Vrije Universiteit Brussel, Biology of the testis BITE, Brussels, Belgium*
[3] *Bambino Gesù Children's Hospital, IRCCS- Laboratory of Nephrology, Rome, Italy*
[4] *Centre INRS-Institut Armand-Frappier, Centre INRS-Institut Armand-Frappier, Quebec, Canada*

Study question: Is azoospermia in male cystinosis patients obstructive or non-obstructive in origin?
Summary answer: Azoospermia in male cystinosis patients is obstructive in origin.
What is known already: Cystinosis is a rare autosomal recessive metabolic disorder caused by mutations in the lysosomal membrane protein cystinosin (CTNS), which leads to intracellular lysosomal cystine accumulation. Depending on the disease severity, three forms are distinguished: infantile (most severe), juvenile (intermediate), and ocular (benign) form. The main clinical presentation in infantile cystinosis is the renal Fanconi syndrome, leading to end stage renal disease (ESRD) by the age of ten, if the patient is left untreated. Cysteamine, a cystine-depleting agent, beside renal replacement therapy, has improved the life expectancy of cystinosis patients. In contrast to females, male infantile cystinosis patients suffer from infertility.
Study design, size, duration: Three groups were included in a prospective case control study; adult cystinosis patients (three infantile, two juvenile, and one ocular male patients), control group (seven adult fertile male subjects), and a positive control group for obstructive azoospermia (ten adult vasectomized males who underwent vasectomy 4-8 weeks prior to enrollment). In addition, clinical data and testicular sections for five adult infantile male cystinosis patients were retrospectively included in the study (in total, eight infantile cystinosis patients).
Participants/materials, setting, methods: Scrotal ultrasound for screening for soft biomarkers of obstruction and semen analysis were performed in all prospectively included subjects, while sexual hormonal levels were evaluated only in the cystinosis patients. In addition, clinical data, semen analysis results, percutaneous epididymal sperm aspiration (PESA) results, sexual hormonal profile, and testicular sections from the retrospectively included cystinosis patients were analyzed. For the testicular sections, morphological evaluation and immunohistochemistry were performed.
Main results and the role of chance: All testicular sections taken from three infantile cystinosis patients (3/3) showed the presence of testicular sperm and normal spermatogenesis, with a Johnsen's score of 7 to 9. Besides, epididymal sperm was present in two other infantile cystinosis patients (2/2), obtained by PESA procedure, which was only performed in those two patients. Hence, all of the five investigated infantile cystinosis patients showed either testicular or epididymal sperm (5/5 or 100%), indicating that testicular function was preserved in those patients. In contrast, seven out of the total eight infantile cystinosis patients underwent semen analysis, and they all presented with azoospermia (7/7 or 100%), including four out of the five patients that showed testicular or epididymal sperm, while a semen sample from one infantile patient, who underwent testicular biopsy, could not be retrieved. Meanwhile, the two juvenile cystinosis patients (2/2) showed a reduced sperm count (15.9 and 6.4 million/ml), and the ocular cystinosis patient (1/1) showed normal sperm count (71.6 million/ml). Remarkably, the scrotal ultrasound results revealed a significant higher epididymis caput diameter (normalized to the testis volume) in infantile cystinosis group compared with healthy controls (1.63 ± 0.66 mm/cm^3 for infantile cystinosis vs 0.50 ± 0.18 mm/cm^3 for controls, $p<0.001$).
Limitations, reasons for caution: The study is performed in a small group of patients; however, the rarity of the disease makes it challenging to recruit more male cystinosis patients. Moreover, we could not investigate the presence of testicular or epididymal sperm in all included cystinosis patients due to ethical reasons.
Wider implications of the findings: The results obtained in the study further unravel the origin of the observed azoospermia in male infantile-type cystinosis patient by suggesting an obstructive cause. In addition, our research might provide a better age-dependent treatment to circumvent infertility in these patients.
Trial registration number: Not applicable

P-062 Male ageing negatively affects the chances of live birth in IVF/ICSI cycles for idiopathic infertility.

F. Horta[1], B. Vollenhoven[1,2,3], M. Healey[2,4,5], L. Busija[6], S. Catt[1], P. Temple-Smith[1]
[1] *Monash University, Obstetrics and Gynaecology, Melbourne, Australia*

[2]Monash IVF, Reproductive Medicine, Melbourne, Australia
[3]Monash Health, Obstetrics and Gynecology, Melbourne, Australia
[4]University of Melbourne, Obstetrics and Gynecology, Melbourne, Australia
[5]Royal Women's Hospital, Obstetrics and Gynecology, Melbourne, Australia
[6]Monash University, School of Public Health and Preventive Medicine, Melbourne, Australia

Study question: Does male age have an effect on the clinical outcomes of IVF/ICSI cycles adjusted by female age in idiopathic infertility?
Summary answer: Male ageing negatively affects clinical IVF/ICSI outcomes in women independent of female age in idiopathic infertility couples.
What is known already: The effect of male age (MA) on the outcomes of infertility treatments is controversial and poorly explored. In contrast, fertility declines significantly with female age (FA) beyond the mid-thirties and reduced oocyte quality plays an important role. The negative effect of male age on sperm quality is largely associated with an increasing susceptibility to sperm DNA damage which has a negative predictive factor for clinical outcomes. Although increasing maternal/oocyte age may diminish the efficiency of DNA repair, studies disregard the need to control for female age/infertility making it difficult to clearly define the role of male ageing in infertile couples.
Study design, size, duration: This cohort study analyzed records from 24,411 IVF/ICSI cycles performed at Monash IVF in Australia between 1992-2017. Separate analyses were performed for (1) 2,425 cycles of couples with idiopathic infertility (IIG) and (2) the general study group (GG). The primary outcome was live birth and secondary outcomes were clinical pregnancy and miscarriage. Male and female age were examined as continuous and categorical (MA: <40, 40-44, 45-49, 50-54, ≥55; FA:<30, 30-34, 35-39, ≥40) predictors.
Participants/materials, setting, methods: Couples with primary/secondary infertility who underwent IVF/ICSI cycles with male partners classified as normozoospermic were selected. Women with moderate to severe endometriosis, tubal factors, polycystic ovarian syndrome, ovarian hyperstimulation syndrome, poor responders (≤3 mature oocytes retrieved) and women with more than 15 cumulus oocytes complexes retrieved or who used cryopreserved gametes were excluded. Binary logistic multilevel modelling was used to identify the effect of MA and FA on clinical outcomes after controlling for cofounding factors.
Main results and the role of chance: For the idiopathic infertility subgroup, there was a negative effect of MA and FA on live birth (LB) [MA-OR: 0.959 (0.941-0.978); FA-odds ratio (OR): 0.904 (0.880-0.928) *p<0.0001*]. Possible confounding factors such as number of embryos transferred, type of treatment (IVF/ICSI) and embryo transfer day (Day3/Day5), and the interaction between male and female age were not statistically significant (p>0.05). The GG analysis (n=22,670 cycles) revealed a negative effect of both MA [0.971 (0.966-0.976) *p<0.0001*] and FA [0.922 (0.914-0.929)*p<0.0001*] on LB. Secondary outcomes in IIG showed significant reduction in the odds of clinical pregnancy (CP) [MA-OR: 0.972 (0.955-0.989); FA-OR: 0.919 (0.897-0.942) *p<0.0001*] and increase in the odds of miscarriage with older age: MA [OR: 1.045 (1.009-1.083); *p=0.002*]; FA [OR: 1.113 (1.048-1.182); *p<0.001*]. The interaction between MA and FA was not significant (*p>0.05*). Worse outcomes were associated with more cycles [CP-OR: 0.964 (0.932-0.996) *p=0.03*; LB-OR: 0.956 (0.919-0.994) p=*0.023*] while more inseminated oocytes were associated with better outcomes [CP-OR: 1.063 (1.031-1.065) *p<0001*; LB-OR: 1.070 (1.035-1.105) *p<0.0001*].Analyses for age categories showed that a negative effect of MA on all outcomes was observed only when the female partners were ≥30 years (*p<0.05*) with no effect of MA in women younger than 30 years (*p>0.05*).
Limitations, reasons for caution: Due to the nature of this study, selection bias may have been introduced, including limited information in confounding factors. The study may also be limited in its generalisability due the strict selection criteria. Age as category could potentially result in residual confounding due to categorizing a continuous variable.
Wider implications of the findings: These findings provide evidence of an effect of male age on fertility outcomes, independent of female age. By adjusting for female age/infertility etiology, we have more clearly defined the role of male ageing in the infertile couple. This study provides information for counseling of couples with idiopathic infertility.
Trial registration number: not applicable

P-063 Impact of obesity and type 2 diabetes on male infertility: relevance to seminal oxidative stress

S. Abbasihormozi[1], A. Shahverdi[2], A. Kouhkan, Kouhkan[3], V. Babapour[4], Z. Zolfaghary[5], A. Parhizkar[6]
[1]university of tehran, basic science, Tehran, Iran
[2]Reproductive Biomedicine Research Center- Royan Institute for Reproductive, Embryology, Tehran, Iran
[3]Reproductive Biomedicine Research Center- Royan Institute for Reproductive, Endocrinology and Female Infertility, Tehran, Iran
[4]Faculty of Veterinary Medicine- University Of Tehran, Basic Science, Tehran, Iran
[5]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Epidemiology, Tehran, Iran
[6]Reproductive Biomedicine Research Center- Royan Institute for Reproductive Biomedicine- ACECR, Andrology, Tehran, Iran

Study question: This study investigates the possible effect mechanism of reactive oxygen species induced by obesity and diabetes on sperm parameters in obese and diabetic's subfertile male.
Summary answer: We observed elevated ROS levels in semen samples of type 2 diabetic and obese subjects compared with normal donors
What is known already: Increased amount of ROS levels in men affected by either diabetes or obesity could be considered prognostic factors in subfertile patients, by affecting the hypothalamus-pituitary-gonadal (HPG) axis, hypothalamic–pituitary–adrenal (HPA) axis and DNA fragmentation, Following the generation of ROS the HPA axis becomes activated and releases cortisol in response to stress and the cross-talk between the HPG and HPA axes, negatively affect testosterone secretion from Leydig cells to produce enough testosterone
Study design, size, duration: A case-control study was conducted in men (n = 150) attending the Infertility Center of Royan Institute between December 2016 and February 2017. Participants were categorized into four groups; normal weight (BMI<25 kg/m2) and non-type-2 diabetic (Control=40), obese and non- type-2 diabetic (Obese=40), non-obese and type-2 diabetic (Nob-DM=35), and obese and type-2 diabetic (Ob-DM=35).
Participants/materials, setting, methods: The semen analysis was performed according to the World Health Organization criteria. Oxidative stress, DNA fragmentation, sperm apoptosis, and total antioxidant capacity (TAC) were evaluated in semen samples of men. Serum glucose, HbA1c, cortisol, and testosterone levels were determined using the ELISA method.
Main results and the role of chance: Compared with the control group, sperm motility, progressive motility, and normal morphology were significantly decreased in the obese, Nob-DM, and Ob-DM groups (P<0.01). The obese, Nob-DM, and Ob-DM groups showed significantly lower levels of TAC and higher amounts of oxidative stress, early apoptotic sperm, and the percentage of DNA fragmentation as compared with the control group (P < 0.05). Testosterone concentration was decreased in the obese, Nob-DM, and Ob-DM groups when compared with healthy individuals (P < 0.05), whereas the cortisol level was significantly increased in the Nob-DM and Ob-DM groups in comparison to the obese and control group (P < 0.01).
Limitations, reasons for caution: The main limitation of this study was the lack of our knowledge about the patient's lifestyle (especially for physical activity). Although we tried to age-matched our studied groups, it was not possible even with adjusting the age between experimental groups.
Wider implications of the findings: hormonal regulators of male reproductive functions can be affected by the disruption of the balance between ROS production and the antioxidant defence mechanism in the male reproductive
Trial registration number: no

P-064 IGF2 and IGF1R mRNAs are detectable in human spermatozoa

R. Cannarella[1], F. Mancuso[2], R.A. Condorelli[1], I. Arato[2], S. La Vignera[1], G. Luca[2], A.E. Calogero[1]
[1]University of Catania, Department of Clinical and Experimental Medicine, Catania, Italy
[2]University of Perugia, Department of Experimental Medicine, Perugia, Italy

Study question: Are *IGF2* and *IGF1R* genes expressed in human spermatozoa? If so, are their levels related with sperm concentration and total sperm count?

Summary answer: *IGF2* and *IGF1R*genes are expressed in human spermatozoa. The levels of their transcripts correlated positively with the sperm concentration and total sperm count.

What is known already: *IGF2* and *H19* are two imprinted genes; the former is paternally expressed, whereas the latter is maternally expressed. In mammals, *h19* and *Igf2* have been shown to influence the embryo-placental development:*H19* inhibits its growth through the inhibition of the *Igf1r* transcription, *Igf2* stimulates it. Infertile patients with oligozoospermia have lower *H19* DMR methylation rate compared with fertile normozoospermic men. This may possibly impact on sperm *IGF2* and *IGF1R* expression. However, no study has evaluated whetherthese genes are expressed in human spermatozoa so far.

Study design, size, duration: This was a cross sectional study. Twenty-two semen samples from Caucasian patients attending the Division of Andrology, University Teaching Hospital "G. Rodolico", University of Catania, for semen analysis were consecutively recruited, from January 2018 to March 2018. No exclusion criterion was adopted.

Participants/materials, setting, methods: Spermatozoa were subjected to reverse transcription quantitative PCR (RTpPCR) using specific primers for the detection of IGF2 and IGF1R mRNA levels. They were then correlated with patient conventional sperm parameters using the Spearman (τ) and Kendall (rho)'s ranks, as appropriated for not normally-distributed variables. The Student-*t* test was adopted to assess differences of expression in oligozoospermic patients compared to those with a normal sperm count. A p value <0.05 was considered as statistically significant.

Main results and the role of chance: The patients enrolled in this study were 32.1±9.3 (15-54) years old. They underwent to sperm analysis for the following reasons: andrological control (n=14), varicocele (n=6), premature ejaculation (n=1), infertility (n=1). Most of the patients were not interested to fertility at the time of counseling. IGF2 and IGF1R mRNA were both detectable at the sperm level. A statistically significant positive correlation was found between IGF2 mRNA levels and sperm concentration (τ=0.403, p< 0.01; rho=0.587, p<0.005) and total sperm count (τ=0.347, p<0.024; rho=0.509, p<0.015). IGF1R mRNA levels correlated positively with sperm concentration (τ=0.595, p<0.001; rho=0.774, p<0.001) and total sperm count (τ=0.547, p<0.001; rho=0.701, p<0.001). No additional correlations were found between the levels of these transcripts and the other conventional sperm parameters. Among the entire cohort, on the basis of total sperm count, two groups could be identified: Group 1 (n=5; age: 29.6±8.2 years), made up of patients with a total sperm count <39 million/ejaculate and Group 2 (n=17; age: 32.9±9.7 years), made up of those with a total sperm count ≥39 million/ejaculate. Both IGF2 (1.7±0.9 vs. 3.6±1.5, p<0.05) and IGF1R (1.8±0.6 vs 3.3±1.2, p<0.05) mRNA levels were significantly lower in Group 1 compared to Group 2.

Limitations, reasons for caution: Although our data showed that sperm IGF2 and IGF1R mRNA levels significantly correlated with sperm concentration and total sperm count, larger sample size will be needed to confirm these results.

Wider implications of the findings: Due to the paternally-imprinting of the *IGF2* gene which makes spermatozoa the only source of IGF2 in the early phase of fertilization, sperm *IGF2* and *IGF1R*mRNA may be translated in the oocyte and influence fertility and embryo-placental development. *Ad hoc* studies are needed to evaluate this hypothesis in humans.

Trial registration number: Not applicable.

P-065 Proliferation and differentiation of fresh and frozen-thawed pre-pubertal mouse spermatogonial stem cells in a sequential organotypic culture.

A. Rives[1], L. Dumont[2], A. Oblette[2], M. Delessard[2], J. Saulnier[2], N. Rives[1], C. Rondanino[2]

[1]Reproductive Biology Laboratory-CECOS- Rouen Normandie University Hospital, Normandie, Rouen, France

[2]EA 4308 "Gametogenesis and Gamete Quality"- IRIB, Normandie, Rouen, France

Study question: To assess the impact of a sequential organotypic culture on the ability of fresh and frozen-thawed pre-pubertal mouse spermatogonial stem cells (SSCs) to proliferate and differentiate in vitro.

Summary answer: Organotypic culture in a sequential medium didn't promote the in vitro progression of spermatogenesis beyond the round spermatid stage and maintained the balance between proliferation/apoptosis.

What is known already: Each year, approximately 2550 new cases of cancer are diagnosed in children and adolescents. The recent advances in oncology have drastically improved the survival rates (up to 80%). Cancer treatment have several adverse side effects, particularly on SSCs.In prepubertal boys, fertility preservation should be considered by testicular tissue freezing. In order to restore fertility in infertile cancer survivors, in vitro maturation of frozen SSCs seems to be a possible option. However, the spermatogenic yield remains actually very low even in mouse model.

Study design, size, duration: Fresh and frozen-thawed testicular tissues from 6.5 days post-partum (*dpp*) CD-1 male mice were cultured using an organotypic culture system. Two type of culture media were compared : (i) a two-step culture, 21 days in a StemPro-34 SFM medium supplemented with EGF, bFGF, GDNF, LIF, Kit-Ligand and CSF, then 30 days in the basal medium containing α-MEM, 10% KSR supplemented with retinol (10^{-6}M), (ii) a one-step culture using the basal medium during 30 days.

Participants/materials, setting, methods: Histological analyses were used for the distinct experimental conditions tested as well as for in vivo control mouse testes, to identify the in vitro differentiation stage of germ cells. Cell proliferation (PCNA/Ki67), germ cell apoptosis (TUNEL assay/cleaved caspase 3), immature germ cells (TRA98), round spermatids (CREM/acrosin) and spermatozoa (acrosin and α-tubulin) will be evaluated by immunohistochemistry or immunofluorescence.

Main results and the role of chance: The sequential culture condition did not alter the structural integrity of testicular tissue and the balance between germ cell proliferation/apoptosis. However, this protocol did not allow the in vitro progression of spermatogenesis beyond the round spermatid stage. Surprisingly, the proliferation phase before differentiation did not allow the spermatogonial cell line enrichment, but promoted their entry into meiosis. In addition, our data show that the use of the vitrification protocol seems to be more favorable to the progression of in vitro spermatogenesis than controlled slow freezing.

Limitations, reasons for caution: Our data on in vitro spermatogenesis using organotypic culture was only obtained in a mice model of pre-pubertal testicular tissue maturation. These experimental conditions should be tested to human pre-pubertal testicular tissue.

Wider implications of the findings: The enrichment of the spermatogonial cell line wasn't obtained after culture in the presence of GDNF, EGF, bFGF, LIF, CSF-1 and Kit-Ligand and the sequential culture protocol tested didn't promote the complete in vitro spermatogenesis.

Trial registration number: not applicable

P-066 Prospective analysis of dietary pattern influence on sperm quality on male partners of couples undergoing IVF/ICSI

M. Arque[1], S. Peon[2], M. Alvarez[3], J. Espinós[4]

[1]Fertty International, Reproductive Medicine, Barcelona, Spain

[2]Hospital de la Santa Creu i Sant Pau, Reproductive Medicine, Barcelona, Spain

[3]Institut Universitari Dexeus, Reproductive Medicine, Barcelona, Spain

[4]Fertty, Reproductive Medicine, Barcelona, Spain

Study question: Does following the European Dietary Recommendations influence the sperm quality in men of subfertile couples attempting IVF/ICSI?

Summary answer: Adequate kilocalorie, total fat, saturated fat and vitamin B9 intake are correlated with better sperm quality.

What is known already: Some dietary pattern studies have concluded that diets characterized by high intakes of fruits, vegetables, whole grains, fish and low intake of meat are associated with better semen quality. Yet, whether following the European DRV (Dietary Reference Values) of specific nutrients is associated with semen parameters remains largely unexplored.

Study design, size, duration: This was a multicentric prospective cross-sectional study of 144 men from couples attending 3 fertility clinics in Spain. The study was designed to evaluate the influence of habitual dietary pattern and lifestyle on fertility outcomes.

Participants/materials, setting, methods: Men aged 25-49 years, 51.3% overweight or obese, 35.9% smokers, with complete dietary and lifestyle data

were analyzed. Diet was assessed via a food-frequency validated questionnaire. Semen quality was evaluated according to World Health Organization 2010 guidelines. Multiple logistic regression analysis was used to evaluate associations between consumption of each nutrient and the likelihood of having abnormal semen parameters, after adjusting for potential confounders.

Main results and the role of chance: Men who have an adequate kilocalorie intake have a higher percentage of sperm with mobility grade a than men with an inadequate kcal intake (11.2 ± 11.3 versus 7.8 ± 6.98 respectively,p = 0.010). Men who have an adequate intake of total fats have a total concentration of sperm higher than those with an inadequate fat intake (156 ± 142 million vs. 115.9 ± 93 million sperm respectively, p = 0.011). Those who have an adequate intake of saturated fats have a higher total concentration of sperm (182 ± 183 vs. 123 ± 95 million sperm respectively, p= 0.011) and a higher percentage of sperm with mobility grade a (13.6 ± 13.8 vs. 8.7 ± 8.1 respectively, p = 0.01). Men who have an adequate vitamin B9 intake exhibit a higher percentage of sperm with mobility grade a than men with an inadequate intake (12.1 ± 12 versus 7.7 ± 6.6 respectively, p = 0.01). No statistically significant relationship was observed for any of the other parameters analyzed.

Limitations, reasons for caution: The main limitation of the study stems from its cross-sectional nature, limiting our ability to determine causality.

Wider implications of the findings: Male adherence to a healthy diet could improve semen quality. Following the European Dietary Recommendations shows a positive correlation with semen parameters. Since observational studies may prove associations but not causation, the associations summarized in the present study need to be confirmed with well-designed RCTs.

Trial registration number: N/A

P-067 New medium from green tea extract, glutathione and vitamin C (GGC) for activation of human spermatozoa in vitro

A.H. Zwamel[1], **N.K. Kadhim**[1]

[1] *University of Baghdad, College of Science\Dept. Biology, Baghdad, Iraq*

Study question: Are the antioxidants: green tea, glutathione and vitamin C have an effect on human sperm parameters during *in vitro* activation (IVA)?

Summary answer: Green tea, glutathione and vitamin C used together in a new culture medium (GGC) and they observed synergism effect to improve sperm motility during IVA.

What is known already: Several factors obstruct sperm motility such as high viscosity and lipid peroxidation in sperm membrane, so that the uses of *in vitro* media with aqueous nature and antioxidant content lead to decrease the viscosity and reduce the lipid peroxidation, allowing sperms move more freely. Polyphenols in the green tea extract are proved to be of the most powerful antioxidants. Glutathione and vitamin C are also antioxidants known to fight free radicals and reduce the oxidative damage. To date, the effect of these three antioxidants together on the outcomes of the *in vitro* sperm activation has not been evaluated.

Study design, size, duration: The study was conducted on 250 semen samples from patients with asthenozoospermia, diagnosed by seminal fluid analysis according to World Health Organization (WHO) 2010 standard criteria, their age between (21-45) years, they attended the infertility outpatient clinic of High Institute of Infertility Diagnosis and Assisted Reproductive Technologies, Al-Nahrain University in Baghdad form September 2017 to June 2018.

Participants/materials, setting, methods: Each semen sample divided to three groups: (G1) activated with ferticult flushing medium, (G2) activated with GGC medium using (10 *mM/ml* of Green tea extract, 10 *mM/ml* of Glutathione, 60 *μM/ml* of Vitamin C, sodium pyruvate 0.01*g/L* and 10% human serum albumin added to 1*L* Ringer solution), and (G3) activated with GGC medium (with double concentrations of Green tee extract, glutathione and vitamin C). All samples activated by swimming up technique.

Main results and the role of chance: Sperm motility, progressive sperm motility and normal sperm morphology were significantly (P<0.01) increased in G1 which were (85.22±0.86) (60.12±1.02) (56.39±1.33) respectively and in G2 which were (97.18±1.28) (93.49±1.34) (77.06±1.24) respectively, while significantly (p<0.01) decreased in G3 which were (24.59±0.66) (20.55±0.54) (22.10±0.83) respectively as compared with pre-activation which were (36.18±0.91) (29.95±0.1.07) (38.46±0.85) respectively. Sperm concentration was significantly (P<0.01) decreased in activated groups (G1=21.96±1.59, G2=22.91±1.63 and G3=19.91±0.66) as compared with pre-activation (40.05±2.06). Among the activated groups, G2 was demonstrate significant (P<0.01) increased in sperm motility, progressive sperm motility and normal sperm morphology as compared with (G1 and G3), While G3 observed significant (P<0.01) decreases in these three parameters as compared with (G1 and G2).

Limitations, reasons for caution: This study was to evaluate the sperm parameter after *in vitro* activation. Further studies are required to evaluate the effect of GGC medium on successful rate of intrauterine insemination (IUI) and *in vitro* fertilization (IVF).

Wider implications of the findings: The new GGC medium was appropriate to improve sperm motility and morphology of asthenozoospermic patients by *in vitro* sperm activation using direct swimming up technique. The increased concentrations of green tea extract, Glutathione and Vitamin C gave opposite effect on the sperm parameters post activation.

Trial registration number: not applicable.

P-068 Does dual ovulation trigger offer any advantage over single ovulation trigger in IUI cycles – An open label RCT

V. DAS[1], **A. Rawat**[2], **S. Agrawal**[2], **A. Agarwal**[3], **A. Pandey**[2], **N. Kumar**[2]

[1] *King george's Medical University- Lucknow- India, Obstetrics & Gynecology, LUCKNOW, India*

[2] *K G's Medical University, Obstetrics & Gynecology, Lucknow, India*

[3] *K G's Medical University, Obstetrics & Gynecology, - Lucknow, India*

Study question: Whether co-administration of hCG and GnRH enhances the pregnancy rate in intra uterine insemination cycles

Summary answer: No significant difference was observed in pregnancy/patient or pregnancy /cycle in hCG and GnRH agonist group vs hCG alone for ovulation trigger in IUI cycle

What is known already: IUI increases the number of oocytes and sperms available for fertilization. hCG is the standard drug used to trigger final oocyte maturation and ovulation. Prolonged LH like action of HCG leads to the development of OHSS. GnRH trigger is used for final oocyte maturation in patients with high risk of OHSS. Recently concept of dual trigger with single bolus of GnRH agonist with reduced hCG dose for trigger has been investigated in IVF high responders and have demonstrated significant improvements in ongoing pregnancy and live birth rates. But its use in IUI cycle has not been studied.

Study design, size, duration: Open label randomized control trial, conducted over a period of one year from August 2017 to August 2018 after ethical approval in a teaching hospital India. Block randomization (2:2) was done according to computer generated random table into control (hCG trigger) and study group (hCG and GnRH trigger) Allocation concealment was done by sequentially numbered opaque sealed envelopes. Total women enrolled were 399, randomization done in 92. 70 IUI cycles done in both the groups

Participants/materials, setting, methods: Infertile women planned for IUI enrolled after consent. Bilateral tubal block, vaginal infection, ovarian cyst, AUB, primary ovarian failure, uncontrolled thyroid and adrenal dysfunction excluded. Follicular monitoring done by TVS. Injection HCG 10000 IU or 5000 IU IMI with GnRH agonist 1 mg sc administered at 17-18 mm follicle. IUI done 36- 40 hours after trigger. Failed ovulation labelled if follicle not ruptured 48 hours after trigger. Luteal support given, reviewed after fortnight for pregnancy

Main results and the role of chance: Demographic factors between two groups were similar. HCG alone group had 59 women while dual trigger group had 57 women. 85% women in both group belonged to urban area. Unexplained infertility was the most prevalent in 42.86% IUI cycles. In 74.29% clomiphene citrate and in 25.71% cycles letrozole was used for ovulation induction. Follicle ruptured in 90% IUI cycles in both the groups. Single IUI done in both the groups in 92.8% cycles. There was no significant difference in the distribution of women on the basis of endometrial thickness in both the groups. Pregnancy/patient was seen in 10.16% cases in HCG alone group vs 8.7% in Dual trigger group (p= 0.797). Pregnancy/cycle was seen in 8.57% in cases of HCG group vs 7.14% in dual trigger group (p= 0.753). Present study did not show any advantage of dual trigger over single ovulation trigger in IUI cycle. There were no side effects observed in either of two groups

Limitations, reasons for caution: Small sample size is its limitation. Determinants of success in IUI cycles are multiple including duration of infertility, drugs used for ovulation induction, endometrial thickness,

sperm preparation techniques, follicle and Oocyte quality and number of times IUI done in one cycle etc. and do not depend only on ovulation trigger.

Wider implications of the findings: Study has generated enough interest and future research potential. It is proposed for further multi-centric randomized trials with simultaneous study for other determinants of IUI success with bigger sample size

Trial registration number: Ref/2017/10/15731

P-069 Soluble CD147 triggers differential calcium mobilization and sperm functions in human sperm

E. Fok[1], H. Chen[2], J. Jin[1], H.C. Chan[3]

[1]*The Chinese University of Hong Kong, School of Biomedical Sciences, Hong Kong, Hong Kong*

[2]*Nantong University, Institute of Reproductive Medicine, Nantong, China*

[3]*The Chinese University of Hong Kong, Epithelial Cell Biology Research Centre, Hong Kong, Hong Kong*

Study question: How did CD147 regulate different sperm functions in male and female reproductive tract?

Summary answer: We revealed the differential localization of membrane-bound CD147 and the differential calcium mobilization elicited by soluble CD147 before and after capacitation for sperm functions.

What is known already: CD147 is expressed as membrane-bound and soluble form and is required for male and female fertility. In male mice, the membrane-bound CD147 shuttles from the principal piece to the mid-piece of sperm during epididymal maturation. In female mice, CD147 null cumulus-oocyte complexes show a significant decrease in the fertilization rate. In human, we showed the presence of CD147 in seminal fluid and follicular fluid. Further, we showed that the decreased level of CD147 is associated with the decreased sperm motility and defective acrosome reaction in asthenozoospermia patients. However, the mechanism underlying the effect of CD147 on sperm functions remain elusive.

Study design, size, duration: We collected sperm samples from normal donors and evaluated the localization of CD147 and the effect of soluble CD147 on sperm functions and calcium mobilization with or without capacitation.

Participants/materials, setting, methods: The localization of CD147 on sperm before and after capacitation was assessed by immunofluorescence staining. Effect of CD147 on sperm functions was examined by treating sperm samples with CD147 neutralizing antibody or with soluble CD147 (recombinant protein or conditioned media containing soluble CD147). Sperm motility and hyperactivated motility were measured by computer-assisted sperm analysis (CASA), acrosome reaction was evaluated by fluorescein-Pisum sativum agglutinin (FITC-PSA) assay. Calcium mobilization was recorded by calcium imaging.

Main results and the role of chance: In ejaculates, the localization of CD147 was observed in the mid-piece. The localization of CD147 shifted from the mid-piece to the head region upon capacitation. Immunodepletion of CD147 in non-capacitated sperm significantly reduced sperm motility. Soluble CD147 treatment in non-capacitated sperm did not trigger hyperactivation. Intriguingly, upon capacitation, soluble CD147 induced a 3-fold increase in the percentage of acrosome-reacted sperm. The degree of acrosome reaction induction was comparable to that induced by progesterone, a well-established acrosome reaction inducer. Soluble CD147 elicits calcium mobilization in both non-capacitated sperm and capacitated sperm but the magnitude of mobilization was 2-fold higher in capacitated sperm. These results suggest that the shuttling of membrane-bound CD147 and the differential calcium mobilization triggered by soluble CD147 may underlie the differential regulation of sperm motility and acrosome reaction by CD147.

Limitations, reasons for caution: The mechanism underlying the CD147-induced calcium mobilization await further investigation.

Wider implications of the findings: CD147 triggers calcium mobilization and regulates sperm functions. CD147 is a potential diagnostic marker for defective sperm motility and acrosome reaction in male infertility.

Trial registration number: Not applicable

P-070 Sperm motility factor using CASA is related to PGS outcome.

J.I. Baek[1], Y.E. Lee[1], H.R. Lee[1], K.H. Choi[1], B. Jeon[2], J.W. Park[1], M. Kim[3], H. Lee[4], Y.B. Lee[5], Y.S. Kim[5], T.K. Yoon[5], J.H. Lee[1,6]

[1]*CHA fertility center, Embryology, Seoul, Korea- South*

[2]*CHA fertility center, Andrology, Seoul, Korea- South*

[3]*CHA fertility center, Genetics, Seoul, Korea- South*

[4]*CHA fertility center, Department of Nursing, Seoul, Korea- South*

[5]*CHA Fertility Center Seoul Station, Department of Ob/Gyn, Seoul, Korea- South*

[6]*CHA university, Department of Biomedical Science- College of Life Science, Pochen, Korea- South*

Study question: Is there an involvement between embryo aneuploidy and sperm motility factor using CASA?

Summary answer: Even if the sperm morphology is normal, motility related-factors affect the chromosome abnormality of the embryo.

What is known already: General semen analysis is subjective technique depending on the laboratory. Because, detailed description of sperm motility is not possible without use of special equipment. As an attempting to assess sperm quality accurately, computer-assisted semen analysis (CASA) has been developed. Using the CASA system, the several parameters for sperm motility are quantified and detailed.

Many previous studies reported that the sperm morphology affects the chromosome abnormality of the embryo. However, there is a lack of research on sperm motility and embryo aneuploidy. Therefore, in this study, we identified the effect of sperm motility analysis using CASA system on the PGS outcome.

Study design, size, duration: This is a retrospective study included 38 PGS cases between January 1, 2016 and August 31, 2018.

Participants/materials, setting, methods: The subject of study is the patient who needs PGS at the doctor's discretion with normal sperm. We analyzed sperm motility of raw semen by CASA system and carried out aCGH to determine chromosomal abnormalities of embryos. Patients are divided to two groups, Group I (with all abnormal embryos) and Group II (with one or more normal embryos). Then, we compared CASA parameters between 2 groups. The data are statistically analyzed by T-test using SPSS.

Main results and the role of chance: Among 8 sperm motility parameters (STR, LIN, WOB, ALH, VCL, VAP, VSL and BCF), the average of STR (straightness), LIN (linearity), WOB (wobble) and ALH (lateral head amplitude) showed similar pattern between 2 groups ($p>0.05$). However, VCL(curvilinear velocity), VAP(average path velocity), VSL(straight line velocity), and BCF (beat cross frequency) are significantly lower in group I, than group II (28.75 ± 6.90 vs. 37.84 ± 6.28, 19.08 ± 5.22 vs. 25.59 ± 3.60, 13.80 ± 5.08 vs. 19.71 ± 3.62, 4.05 ± 0.95 vs. 5.07 ± 0.86, $p<0.05$).

Therefore, 4 parameters from CASA (VCL, VAP, VSL and BCF) are related to the aneuploidy ratios of IVF embryos.

Limitations, reasons for caution: More subdivided patients are required for further study.

Wider implications of the findings: In addition to sperm morphology, sperm motility of raw semen might also be related to the PGS outcome.

Trial registration number: N/A

P-071 Antioxidants for male subfertility: a systematic review and meta-analysis

R. Smits[1], R. Mackenzie-Proctor[2], A. Yazdani[3], M. Stankiewicz[4], R. Hart[5], V. Jordan[6], M. Showell[6]

[6]*University of Auckland, Department of Obstetrics and Gynaecology, Auckland, New Zealand*

Study question: Do oral antioxidants improve the live birth rate when taken by subfertile men of a couple attending a reproductive clinic?

Summary answer: This review shows that antioxidant supplementation in subfertile men may improve live birth rates for couples, however the quality of the available evidence is low.

What is known already: The inability to have children affects 10-15% of couples worldwide. A male factor is estimated to account for up to half of the infertility cases with between 25% to 87% of male subfertility considered to be due to the effect of oxidative stress. Oral supplementation with antioxidants is thought to improve sperm quality by reducing oxidative damage. Antioxidants are widely available and inexpensive when compared to other fertility treatments, however most antioxidants are uncontrolled by regulation and the evidence for their effectiveness is uncertain. We compared the benefits and risks of different antioxidants used for male subfertility.

Study design, size, duration: For the update of this Cochrane systematic review we conducted a search according to the Cochrane Gynaecology and Fertility search strategy for randomised controlled trials (RCTs) from inception to February 2018. After thorough literature search and review, 61 studies were included and 44 were found to be eligible for quantitative meta-analysis including 6264 subfertile men. Two review authors independently selected trials and extracted data for meta-analysis.

Participants/materials, setting, methods: Randomised controlled trials (RCTs) were included that compared any type, dose or combination of oral antioxidant supplement with placebo, no treatment or treatment with another antioxidant. We excluded studies comparing antioxidants with fertility drugs alone and studies that included fertile men attending a fertility clinic because of female partner infertility. Statistical analysis was performed in accordance with the Cochrane Gynaecology and subfertility Group guidelines.

Main results and the role of chance: Antioxidants may improve both, live birth rate (OR 1.79, 95% CI 1.20-2.67) and clinical pregnancy rate (OR 2.97, 95% CI 1.91-4.63). However, the quality of the evidence is low and the live birth result was based on only 124 live births from 750 couples in seven relatively small studies. When studies at high risk of bias were removed from the analysis, there was no evidence of increased live birth (OR 1.38, 95% CI 0.89-2.16). Adverse events were often not reported. We were uncertain whether antioxidants made a difference to miscarriage rates, (OR 1.74, 95% CI 0.40-7.60), as only three studies reported on this outcome and the quality of the evidence was 'very low'. Eleven studies reported on mild gastrointestinal upsets, (OR 2.51, 95% CI 1.25-5.03). The quality of this evidence was rated as 'very low quality', therefore we were uncertain whether the use of antioxidants made a difference to this outcome). We were unable to draw any conclusions from the antioxidant versus antioxidant comparison as insufficient studies compared the same interventions.

Limitations, reasons for caution: The quality of the evidence ranged from low to very low quality due to poor reporting of methods of randomisation, failure to report on live birth rate and clinical pregnancy, often unclear or even high attrition, and also imprecision due to often low event rates and small overall sample sizes.

Wider implications of the findings: Subfertile couples should be advised that overall the current evidence is inconclusive based on the above mentioned limitations and more studies are needed to investigate this further.

Trial registration number: Not applicable.

P-072 TRIM42 interacted with TRIM27, is required for spermatogenesis and testicular tumor

X.J. Zhuang[1], P. Liu[1], J. Qiao[1]

[1]*Reproductive Medicine Center, Department of Obstetrics and Gynecology- Peking University Third Hospital, Beijing, China*

Study question: Is there an association between the expression of Tripartite motif protein 42 (TRIM42) in human spermatogenesis and testicular tumor?

Summary answer: TRIM42 as an E3 ubiquitin ligase, interacted with TRIM27 could play multiple roles in the regulation of spermatogenesis and testicular tumor.

What is known already: Male infertility and testicular tumor are a common disease in young adults and these incidences have risen dramatically over the past several decades in many countries. Tripartite motif (TRIM) family proteins are involved in various biological and cellular functions including differentiation, development, proliferation, apoptosis, oncogenesis, innate immunity and viral autophagy. TRIM27, a known cancer-associated protein, associated with prostate cancer, endometrial cancer, ovarian carcinoma, breast carcinoma and spermatogenesis in testis. The expression and precise underlying mechanisms of Trim42 have not been clearly in human testis during spermatogenesis and risk of testicular tumor.

Study design, size, duration: A total of 126 individuals with azoospermia or oligozoospermia , 35 testicular tumor cases and 56 healthy controls were recruited to this study at the Reproductive Medical Center of Peking University Third Hospital between January 2016 and June 2018.

Participants/materials, setting, methods: TRIM42 were analyzed with blood and testicular biopsy samples from non-obstructive azoospermia and testicular tumor patients. Trim42 mRNA and protein levels in human testes were investigated using RT-PCR,Q-PCR and western blotting, respectively. Immunofluorescent analysis was performed on testis sections by TRIM42 antibodies during the development of spermatogenesis. And its interacted with a variety of functionally proteins was explored by co-immunoprecipitation and immuno-colocalization *in vitro*.

Main results and the role of chance: Trim42 mRNA and protein were abundantly transcribed in male germ cells in human. Immunohistochemical results revealed TRIM42 was abundant in the nuclei and cytoplasm of spermatogonia and primary spermatocytes. Moreover, TRIM42 was diffusely localized in the cytoplasm of spermatids and round spermatids, and functions as an E3 ubiquitin ligase collaborating with an E2 ubiquitin conjugating enzyme UbcH6 *in vitro*. In addition, TRIM42 interacted with TRIM27 and shared a similar distribution pattern *in vitro*. Furthermore, TRIM42 and TRIM27 expression levels were significantly changed during the normal group, azoospermia group and the testicular tumor patients group.

Limitations, reasons for caution: Protein analysis was performed in testicular biopsy samples from only a small number of patients and controls. In future investigations, a larger sample size should be used and the role of the other genes involved in the azoospermatism should be analyzed.

Wider implications of the findings: TRIM42 was an E3 ubiquitin ligase and interacted with TRIM27 could play multiple roles in the regulation of spermatogenesis and testicular tumor in human. TRIM42 connecting with TRIM27 could be a predictive marker for chemoresistance in testicular tumor patients and also a candidate for a molecular-targeted agent.

Trial registration number: N/A.

P-073 The Impact of Four Sperm Preparation Techniques on Sperm DNA Fragmentation, Motility and Concentration: A Prospective Study

G. Raad[1], L. Mouchantaf[1], J. Azoury[1], J. Azoury[2], J. Azoury[1], H. Bakos[3]

[1]*Azoury IVF clinic, ivf, Beirut, Lebanon*

[2]*Inova Fairfax Hospital, ob-gyn department, Virginia, U.S.A.*

[3]*Monash IVF Group- Sydney- NSW- Australia and University of Sydney- Sydney- NSW- Australia, ivf, Sydney, Australia*

Study question: Is there a difference in sperm DNA fragmentation rate when the same semen sample is processed by four sperm preparation techniques?

Summary answer: Both direct and indirect swim-up were more effective at selecting lower percentages of spermatozoa with fragmented DNA compared to the density gradient technique.

What is known already: In assisted reproductive technology (ART), different sperm preparation techniques are used to select a motile spermatozoa population from semen. However, it has been shown that motility may not reflect the molecular composition of the spermatozoon. Specifically, the DNA integrity of the motile sperm has been identified as important factor for fertilization, pregnancy and offspring health. Moreover, sperm preparation techniques could have differential effects on the DNA fragmentation rate of motile sperm. Therefore, several studies attempted to compare the outcomes of these techniques in terms of sperm motility, morphology, and DNA integrity without reaching a firm consensus.

Study design, size, duration: A prospective auto-controlled study was conducted on 33 semen samples from 33 participants attending the Azoury IVF clinic. After liquefaction, sperm concentration, motility and DNA integrity were assessed. Each sample was then divided into four aliquots and each aliquot processed by one of the following techniques: direct swim-up, indirect swim-up, density gradient or density gradient followed by a swim-up. At the end of each experiment, sperm concentration, motility and DNA integrity were assessed.

Participants/materials, setting, methods: In order to perform the four different sperm preparation techniques on the same sample, only fresh semen samples with a minimum volume of 1.5 ml, a sperm concentration of $\geq$ 20 x 10^6/ml, and sperm motility of $\geq$ 30% were included. Before and after processing, sperm concentration and motility were assessed according to the World Health Organization guidelines (2010) and sperm DNA integrity was assessed using Sperm Chromatin Dispersion (SCD) test.

Main results and the role of chance: In this prospective study, the mean age of the participants was 39.10 years ± 8.47, the median of sexual abstinence days was 3.0 days, and the mean of infertility duration was 5.68 years ±3.12. After semen processing, lower sperm concentrations, higher percentages of motile sperm, and lower percentages of spermatozoa with fragmented DNA were detected in the 4 sperm preparation techniques compared to the unprocessed semen. Lower sperm concentrations were obtained after direct swim-up ($p<0.001$), indirect swim-up ($p<0.001$), and density gradient followed by swim-up ($p<0.001$) compared to the density gradient technique. Further, a higher percentage of motile sperm were recovered after direct swim-up ($p<0.001$), indirect swim-up ($p<0.001$) and density gradient followed by swim-up ($p<0.001$) compared to density gradient. In addition, lower percentages of spermatozoa with fragmented DNA were collected after direct swim-up ($p<0.01$) and after indirect swim-up ($p<0.001$), when compared to the density gradient technique. Interestingly, significant positive correlations were found between the percentage of sperm with fragmented DNA in the fresh semen and the percentages of sperm with fragmented DNA after direct swim-up ($R=0.91$, $p<0.001$), indirect swim-up ($R=0.81$, $p<0.001$), density gradient ($R=0.77$, $p<0.001$), and density gradient followed by swim-up ($R=0.76$, $p<0.001$).

Limitations, reasons for caution: Further studies are required to determine if these effects will ultimately affect patient outcomes in an ART setting including fertilisation rates, embryo development and pregnancy outcomes. Furthermore, additional experiments are needed to elucidate the molecular mechanisms underlying the outcomes of these sperm preparation techniques.

Wider implications of the findings: The two swim-up methods (direct and indirect) were less time-consuming, cost less, and resulted in lower sperm DNA fragmentation compared with the density gradient technique. Thus, using direct or indirect swim-up techniques could be beneficial for infertile men especially those with high DNA fragmentation.

Trial registration number: not applicable

P-074 Sperm quality and male fertility on chronic carriers of hepatitis B virus

M. Ben Jemaa[1], S. Daoud[1], N. Chakroun[1], M. Ben Amor[2], T. Rebai[2], A. Sellami[1]

[1] *Histology-Embryology Laboratory and Research Unit, Medical School of Sfax, Sfax, Tunisia*

[2] *Histology-Embryology Laboratory and Research Unit, Medical School of Sfax-, Sfax, Tunisia*

Study question: Is there a negative impact of chronic Hepatitis B virus (HBV) infection on sperm quality and male human reproductive potential in vivo and in vitro?

Summary answer: Hepatitis B surface antigen significantly affects sperm mobility and vitality. However, no significant impact was observed on male fertility both in vivo and in vitro.

What is known already: Chronic HBV infection leads to an adverse impact on sperm parameters and male fertility. The ability of HBV to integrate into human germ cells and sperm genome has been confirmed by cytogenetic and molecular studies suggesting the possibility of vertical transmission of HBV to offspring.

Study design, size, duration: This is a case-control retrospective study including 57 ejaculates of patients investigated for couple's infertility, over a period of 10 years.

Participants/materials, setting, methods: Semen analysis was carried out according to WHO method. Studied samples were divided in two groups : G1 (HBs Ag positive patients ; n=31) and G2 control group (HBs negative patients, n=26). We excluded from our study population all azoospermic patients or patients with any factor that may alter sperm parameters.

Main results and the role of chance: The mean values of sperm mobility and vitality were significantly lower than those in G2 ($p=0.01$, $p=0.04$; respectively) . These perturbations could be related to the process of apoptosis in SPZ induced by HBs antigen with structural and molecular sperm modifications. A history of paternity following spontaneous pregnancy was noted in 32.2% of G1 patients against 38.4% in G2 patients ($p = 0.4$). We didn't notice any significant differences in the outcome of assisted reproduction techniques (ART) between the 2 groups ($p = 0.3$). However, HBV replication within embryos conceived from HBV-contaminated SPZ may occur during the fertilization period with a risk of vertical father-child transmission.

Limitations, reasons for caution: A potential limitation for this study is its retrospective design. Moreover, patients come from different geographical regions with different HBV genotypes.

Wider implications of the findings: DNA viral integration into the sperm genome could interfere with male reproduction and offspring health. It would be important to deepen this work by conducting a molecular study in average and high endemicity areas where chronic hepatitis B constitutes a public health problem.

Trial registration number: No trial registration number

P-075 DNA methylation profile of spermatozoa varies regarding to the method of sperm preparation (MACS selection vs. DGC)

M. Stimpfel[1], C. Otto[2], N. Jancar[1], E. Vrtacnik-Bokal[1], I. Virant-Klun[1]

[1] *Univerzitetni Klinicni Center Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia*

[2] *ecSeq Bioinformatics GmbH, ecSeq Bioinformatics GmbH, Leipzig, Germany*

Study question: How does magnetic-activated cell sorting (MACS) of non-apoptotic spermatozoa change the DNA-methylation profile of spermatozoa compared to spermatozoa prepared only by density gradient centrifugation (DGC)?

Summary answer: Reduced Representation Bisulfite Sequencing revealed 99 differentially methylated regions (DMRs) and 800 differentially methylated positions (DMPs) between MACS selected and DGC-only prepared spermatozoa.

What is known already: MACS procedure enables the selection of non-apoptotic spermatozoa with improved quality, especially in term of DNA fragmentation. Studies have shown that using such spermatozoa in ICSI/IVF procedures can improve fertilization rate, embryo/blastocyst quality (especially in women aged over 30 years) and pregnancy rate. Despite known positive effect for selection of spermatozoa with lower DNA fragmentation other influences of MACS on sperm genetic/epigenetic status are not known. Epigenetic status (especially methylation) becomes recently an important subject of interest, because it was shown that also epigenetic information can be transmitted transgenerational without changing the information on DNA level.

Study design, size, duration: Our prospective sibling-oocyte study included 19 couples who were treated in 2018 with ICSI due to male infertility, more precisely due to teratozoospermia (defined by strict Kruger criteria). The women in the couple included in the study were not older than 36 years and were required to have at least 6 mature MII oocytes after controlled ovarian hyperstimulation. Half of MII oocytes were fertilized using spermatozoa prepared only with DGC and half with MACS.

Participants/materials, setting, methods: MACS was performed after DGC using MACS® ART Annexin V System (Miltenyi). The remaining spermatozoa that were not used for ICSI, were evaluated for morphology, DNA fragmentation (HaloSperm) and stored in liquid nitrogen for epigenetic status in term of methylation using Reduced Representation Bisulfite Sequencing (RRBS). To detect differentially methylated regions (DMRs) and positions (DMPs) between DGC and MACS samples a two-dimensional Kolmogorov-Smirnov test (for DMRs) and Mann-Whitney U test (for DMPs) were used.

Main results and the role of chance: Of all stored samples, samples from 7 patients were used for RRBS analysis, of which 5 were successfully analysed. The comparison of MACS-selected and DGC-only prepared spermatozoa of these 5 patients showed that the percentage of morphologically normal spermatozoa (14.0±10.8 vs. 13.2±10.0;P=0.335) and of spermatozoa with fragmented DNA (39.4±14.8 vs. 47.3±22.8;P=0.183) were similar between the groups, although both of DNA-fragmentation indexes were abnormal. Fertilization rate and the quality of embryos was not significantly different, although there was a trend towards higher blastocyst rate in MACS-group (25.0% vs. 52.6%;P=0.097). The RRBS analysis identified 99 DMRs and 800

DMPs. 43 DMRs and 392 DMPs were hypermethylated in DGC-group, while 56 DMRs and 408 DMPs were hypomethylated. When DMRs were annotated to genes, 8.8% of them were annotated to promoters, 11.8% to exons, 33.0% to introns and 46.4% to intergenic regions. In case of DMPs, 5.3% were annotated to promoters, 5.4% to exons, 39.3% to introns and the rest to intergenic regions. When DMRs were annotated to CpGs, 16.1% were annotated to CpG islands, 6.5% to CpG shores and 5.0% to CpG shelves, while in case of DMPs, 5.3% were annotated to CpG islands, 18.0% to CpG shores and 7.1% to CpG shelves.
Limitations, reasons for caution: Due to protamine the DNA in spermatozoa is highly condensed, which makes RRBS analysis difficult and can negatively influence the quality of obtained sequencing data. Higher number of samples should be analysed to confirm obtained results.
Wider implications of the findings: The sperm DNA methylation profile could be used as additional test to assess the quality of spermatozoa. It could be also correlated to quality of embryos/blastocysts and could serve as prognostic predictor for laboratory outcome of IVF/ICSI cycles.
Trial registration number: 'not applicable

P-076 Targeted methylation of MAEL promoter leads to double-strand breaks and activation of transposable elements in human hypospermatogenesis

Y. Cheng[1], S.K. Wee[1], Y.M. Lin[1]

[1]National Cheng Kung University Hospital- College of Medicine- National Cheng Kung University, Department of Urology, Tainan City, Taiwan R.O.C.

Study question: Does the targeted methylation of MAEL promoter have a direct impact on human genome instability?
Summary answer: Targeted methylation of the specific MAEL promoter region (-188 to +294) might induce DNA instability by de-repressing transposable elements.
What is known already: The mouse *Maelstrom (Mael)* localizes in perinuclear nuage and participates in the piRNA-mediated defense system to protect the germ line from retrotransposons. The male MAEL knockout mice are sterile with phenotype presenting small testicles and intra-testicular meiotic arrest. With high throughput analysis in human testes, we have identified significantly higher methylation levels of 26 consecutive CpGs in the MAEL promoter in patients with hypospermatogenesis(HS) and non-obstructive azoospermia(NOA), compared to patients with normal spermatogenesis(NS). Our previous report has shown that aberrant methylation of MAEL promoter is associated with de-repression of LINE-1.
Study design, size, duration: The targeted DNA methylation system (TDM) has been created to study the consequences after methylating the MAEL promoter region(from -188 to +294) in human NCI-H358 cells. We use germ cell-enriched testicular cells from HS patients versus NS group to study the transcript levels of MAEL and LINE-1.
Participants/materials, setting, methods: MAEL and LINE-1 expression levels in TDM cells were determined by quantitative real-time RT-PCR and compared with un-methylated cells. We checked the double-strand breaks (DSBs) by immunofluorescence with histone γ-H2AX in TDM cells compared with un-methylated cells. The quantification of γ-H2AX foci number is calculated and analyzed. In patients with hypospermatogenesis and non-obstructive azoospermia, the mRNA transcript levels of testicular tissue were determined by quantitative real-time RT-PCR compared to normal spermatogenesis.
Main results and the role of chance: After target methylation of MAEL promoter region, MAEL expression levels of TDM cells declined dramatically compared to un-methylated cells ($P < 0.01$). Inversely, LINE-1 transcripts were significantly higher in TDM cells compared to un-methylated cells ($P < 0.01$). Similar results were found in the human testicles. The MAEL transcript levels were significantly lower in HS patients than the NS group($P < 0.05$). Otherwise, the increasing LINE-1 transcript levels were determined in the HS group versus the NS group ($P < 0.05$). Back to in vitro TDM model, there were significantly more γ-H2AX foci numbers detected in TDM cells than in un-methylated cells ($P < 0.05$).
Limitations, reasons for caution: It is difficult and ineffective to use human intra-testicular germ cells to study the epigenetic regulation of spermatogenesis. Therefore, we conducted the targeted DNA methylation system of MAEL promoter in human NCI-H358 cells to explore the direct impact of MAEL methylation on DNA integrity.
Wider implications of the findings: Our report has extended the knowledge of epigenetic regulation of MAEL promoter in human hypospermatogenesis and provide clues for future treatment of male infertility.
Trial registration number: not applicable

P-077 Adaptation of four Sperm DNA Fragmentation techniques to study ICSI-selected sperm shows a bias between this subpopulation and the whole ejaculate

S. Lara-Cerrillo[1], J. Benet-Catala[2], T. Lacruz-Ruiz[1], J. Ribas-Maynou[1], A. Garcia-Peiro[1]

[1]CIMAB Barcelona Male Infertility Centre, Research & Development, Sant Quirze del Vallés Barcelona, Spain
[2]Universitat Autònoma de Barcelona, Departament de Biologia Cel·lular- Fisiologia i Immunologia. Facultat de Medicina, Bellaterra Barcelona, Spain

Study question: Is it possible to adapt current techniques to detect if ICSI-selected sperms are different from the whole ejaculate in terms of Sperm DNA Fragmentation (SDF)?
Summary answer: Adaptation of SDF detection techniques to study ICSI-S is possible and shows that this subpopulation has differences in SDF compared to the whole ejaculate.
What is known already: During ICSI procedures sperm cells are selected according to morphology and motility. Multiple authors suggest that ICSI-selected sperm (ICSI-S) may represent a subpopulation of the ejaculate with different chromatin integrity quality. This could explain those controversial results found when comparing SDF and ICSI clinical outcomes.

As current procedures do not allow the analysis of the injected sperm cell, the best approach would be to study those cells with good morphology and motility candidates for ICSI selection. The study of this ICSI-S could give us more information about the real impact of the male factor during an ICSI cycle.
Study design, size, duration:

This methodological and prospective study included 15 infertile patients attending our centre seeking fertility advice from January 2017 to May 2018. All patients signed the corresponding informed consent and the study was approved by the Parc Taulí Hospital Ethics Committee.
Participants/materials, setting, methods: A swim-up (SU) procedure was performed on every ejaculate (E) sample. These samples were analysed using of four different SDF techniques: Neutral Comet, Alkaline Comet, SCD test and TUNEL assay.

ICSI-S were selected and collected in groups of 10-20 to finally be fixed in (1) 1µL agarose drops on agarose pre-treated slides for Neutral Comet, Alkaline Comet and SCD techniques or (2) with Carnoy solution for TUNEL assay.
Main results and the role of chance: A total of 2650 sperm cells were selected using ICSI criteria and fixed depending on the technique later performed. Sperm visualization rates on the slide were 98% for Neutral Comet; 93% for Alkaline Comet; 98% for SCD and 96% for TUNEL, respectively, with a total amount of 2552 ICSI-S visualized. From these ICSI-S, 81%; 79%; 79% and 100%, respectively, could finally be analysed (2126 sperm cells in total). SDF on E and SU samples was analysed with these four techniques simultaneously to ICSI-S samples.

SDF measured with Neutral Comet did not show differences between E (69.8%±7.2), SU (68.2%±7.9) and ICSI-S (67.1%±17.4) samples. However, Alkaline Comet, SCD and TUNEL showed a statistically significant reductions in SDF of SU compared to E. Furthermore, these techniques detected an even major reduction in ICSI-S compared to E. SDF percentages for E, SU and ICSI-S samples were 41.4%±12.0, 32.3%±6.9 and 13.6%±11.5 for Alkaline Comet; 22.8%±9.2, 16.5%±10.3 and 3.0%±6.3 for SCD test; and 18.2%±4.3, 12.6%±3.8 and 1.0%±1.6 for TUNEL assay.
Limitations, reasons for caution: Methodological adaptations to study single sperm cells selected for ICSI has only been done on four SDF detection techniques. Other potential sperm quality biomarkers should be assessed using these, or similar, methodologies to analyse more parameters that can contribute to the male factor in ICSI procedures.
Wider implications of the findings: To our knowledge, this is the first study of SDF on ICSI-S with specifically adapted techniques. As ICSI-S presented reduced SDF in three techniques, we propose sperm quality biomarkers to be

tested on ICSI-S instead of on the ejaculate to improve the evaluation of the male factor in ICSI cycles.
Trial registration number: Not applicable

P-078 Multicolor Flow Cytometry as a screening tool for human sperm

R. Da Costa[1], T. Strünker[1], K. Redmann[1], S. Schlatt[1]
[1]Centre for Reproductive Medicine and Andrology, University Hospital of Münster, Münster, Germany

Study question: Is Multicolor flow cytometry (MFC) a relevant tool for the screening and sorting of defective sperm populations?
Summary answer: MFC is an innovative tool capable of detecting simultaneously, membrane and mitochondrial integrity, oxidative stress and DNA fragmentation, opening novel concepts to understand sperm damage.
What is known already: Classical seminal analysis underestimates the true prevalence of male factors in infertile couples, providing limited diagnostic and predictive information. These limitations leave patients and clinicians in need of additional tools and better diagnostic biomarkers, to evaluate factors that conventional protocols ignore; especially sperm abnormalities at biochemical and molecular level, which can explain the direct causes of infertility. MFC, with his capacity to evaluate simultaneously multiple sperm compartments/functions, represents the missing link between clinical observations and the intrinsic physiological mechanisms in spermatozoa and will guide the development and application of new diagnostic alternatives.
Study design, size, duration: As a model to test the power of the technique we studied the effect *in vitro* on human spermatozoa of 3 sunscreen UV-filters that have been reported to mimic the action of hormones and to affect adversely fertility in animal models. A total of 6 seminal samples (n = 6) from normozoospermic donors were used. Non-exposed and exposed sperm suspensions prepared by swim-up were analyzed considering a number of 10.000 cells for each condition.
Participants/materials, setting, methods: Sperm suspensions were incubated for 30' with the sunscreen UV-filters, 4-methylbenzylidene camphor (4-MBC), 3-Benzylidene camphor (3-BC) and Homosalate (HMS) at 10µM. An untreated suspension and 2 additional controls containing an un-coupler of oxidative phosphorylation, Carbonyl cyanide m-chlorophenyl hydrazone (CCCP) 50µM and a pro-radical, H_2O_2 200µM were incubated simultaneously. Membrane integrity (Live/Dead fixable blue Stain), mitochondrial membrane potential (MitoTracker Deep Red), oxygen radicals production (CellROX Green) and DNA fragmentation (TUNEL) were evaluated by multi-color Flow Cytometry.
Main results and the role of chance: No significant alteration was found in the membrane integrity values for any of the conditions (mean% ±SD, $*p \leq 0.05$): 91.25±9.12 (Cntrl), 91.15±6.10 (4MBC), 88.38±11.74 (3BC), 80.65±11.74 (HMS). Regarding mitochondrial status, only sperm exposed to HMS revealed a statistically significant rise of the sperm numbers showing a decreased mitochondrial membrane potential: 8.98±3.23 (Cntrl), 12.30±05.87 (4MBC), 10.03±07.66 (3BC), 21.42±08.25* (HMS). Concerning oxygen radicals production, only sperm exposed to 3BC and HMS showed a statistically significant increase in the production of reactive oxygen species (ROS): 05.20±03.38 (Cntrl), 06.47±02.86 (4MBC), 18.81±04.58* (3BC), 28.12±08.41* (HMS). Contrary to what is reported in the literature, none of the conditions showed signs of DNA fragmentation, not even when showing high levels of ROS production: 03.53±0.60 (Cntrl), 03.30±1.18 (4MBC), 2.98±0.48 (3BC), 02.82±0.47 (HMS). Validation of this finding was provided by Sperm Chromatin Structure Assay (SCSA) showing no change in the DNA fragmentation index (DFI) associated to the treatments regarding to the control (DFI%): 0.56% (Cntrl), 0.48% (4MBC), 0.67% (3BC), 0.5% (HMS). MFC is therefore a novel tool for the screening of defective sperm populations, being able to simultaneously identify crucial parameters in individual sperm.
Limitations, reasons for caution: This study was carried out under *in vitro* conditions using model substances at pharmacological levels. The system needs to be tested for potentially harmful chemicals in physiological range to determine its clinical applicability.
Wider implications of the findings: The capacity of MFC to evaluate simultaneously multiple sperm functions in individual sperm opens new insights for sperm analysis. Scoring sperm populations, this assessment provides a more accurate in depth analysis compared to conventional methods. MFC has the potential to revolutionize research and diagnosis in spermatology.
Trial registration number: N/A

P-079 The effects of HIV infection and antiretroviral therapy on semen analysis parameters.

F. Selimova[1], S. Perminova[1], E. Mityurina[1], A. Abubakirov[1], A. Popova[2], T. Nazarenko[3]
[1]Research Center of Obstetrics- Gynecology- and Perinatology- Ministry of Health, 1st gynecological department, Moscow, Russia C.I.S.
[2]Research Center of Obstetrics- Gynecology- and Perinatology- Ministry of Health, andrology and urology department, Moscow, Russia C.I.S.
[3]Research Center of Obstetrics- Gynecology- and Perinatology- Ministry of Health, Institute of reproductive medicine, Moscow, Russia C.I.S.

Study question: Do HIV infection and antiretroviral therapy duration have a negative impact on sperm parameters?
Summary answer: HIV-infected patients receiving ART have increased sperm DNA fragmentation and a greater number of abnormal sperm and have a negative effect on sperm motility.
What is known already: The introduction of antiretroviral therapy (ART) has allowed couples in which the male partner is HIV-positive to safely reproduce. However, it is still unclear whether HIV and ART affect ejaculate volume or sperm motility, concentration, and morphology [Nicopoullos, 2004, Nicopoullos, 2010, Pilatz, 2014). It has been suggested that ART may increase sperm DNA fragmentation (Savasi, 2018). Therefore, the lack of consistent data on the specific features of reproductive disorders in HIV-infected males receiving ART prompted this study.
Study design, size, duration: A prospective case-control study was conducted in 115 men who sought fertility assessment and reproductive medical assistance.The main group consisted of 51 males with HIV-infection;the control group comprised 64 HIV-seronegative subjects with normal sperm concentration, motility,and morphology.A total of 97and 111 sperm samples, respectively, were evaluated.The inclusion criteria for the main group were a diagnosis of HIVinfection and the use of ART.The inclusion criteria for the control group were HIV-negativity and normal semen analysis results.
Participants/materials, setting, methods: The HIV infection status of study subjects was evaluated using data on the disease stage and phase, viral load level, CD3+ CD4+ , CD8+ lymphocyte counts, immunoreactive score, and ART duration.

The semen analysis parameters were assessed in accordance with the World Health Organization 2010 criteria (WHO, 2010).

The proportion of sperm with DNA fragmentation was obtained using the TUNEL method.
Main results and the role of chance: The median age of men with HIV-infection was 36 years(interquartile range:33-39).The median duration of HIV-infection at the time of study enrollment was 5 years(2-9 years).All subjects received combination ART: 30 men(48.8%) received nucleoside reverse-transcriptase inhibitors(NRTIs) in combination with non-nucleoside reverse-transcriptase inhibitors(NNRTIs), 16 patients)(31.4%) were on NRTIs and protease inhibitors(PIs), 4 males (7.8%) received NRTIs with integrase inhibitors(IIs), and 1 subject(2%) took three NRTIs.The median duration of drug therapy was 1.5 years.Normozoospermia was revealed in 48.4 % of the HIV-infected subjects. Abnormal semen analysis results included teratozoospermia (40%), oligo-astheno-teratozoospermia(22%), and astheno-teratozoospermia (16 %).The proportion of abnormal sperm was significantly higher in HIV-infected subjects than in HIV-seronegative healthy males(p=0.0001).Correlation analysis demonstrated a moderate negative relationship between the number of abnormal sperm and the CD4+ lymphocyte count (r = -0.362; p=0.026); statistically significant negative relationships were obtained between disease duration and the sperm concentration (r=-0.242;p=0.020), as well as the number of progressively motile(Category C) sperm(r=-0.241; p=0.024). We also observed a positive correlation between duration of HIV infection and the number of immotile sperm (r=0.220; =0.040).ART duration had a negative correlation with the number of progressively motile(Category C) sperm (r=-0.224; p=0.036).Sperm DNA-fragmentation was significantly more pronounced in HIV-infected patients than in healthy HIV-negative males(p=0.001).

Limitations, reasons for caution: no
Wider implications of the findings: no
Trial registration number: not applicable

P-080 Is it time to switch to automated semen analysis? A comparative double-blind study between 2 recent sperm analyzers and manual semen analysis

S. Chtourou[1], A. Reignier[1], J. Lammers[1], C. Splingart[1], P. Barrière[1], T. Freour[1]
[1]University Hospital of Nantes, Service de Médecine et Biologie de la Reproduction, Nantes, France

Study question: How do CASA and electro-optical automated semen analyzers compare to the manual analysis performed according to WHO 2010 guidelines?
Summary answer: The most recent automated semen analyzers represent a trustworthy alternative to manual semen analysis when used by a well-trained staff
What is known already: Despite the WHO efforts to standardize manual semen analysis,the technique still lacks reproducibility and accuracy.This is due to semen heterogeneity itself,but also to inter/intra-operator variability.

Several automated sperm analyzers have been developed and improved over the last 20years,based on various technological approaches i.e. image analysis(CASA)or analysis of electro-optical signals.Their main objectives were to improve lab's workflow and the precision/accuracy of semen analysis via objective and high-throughput cell analysis.

Although most studies have reported modest or acceptable agreement between automated and manual semen analysis,their design and conclusions were heterogeneous and many andrology labs still remain reluctant to invest in this technology.
Study design, size, duration: This prospective, double-blinded, monocentric study comparing 3 diagnostic methods was conducted between February and May 2018. Manual semen analysis was used as gold standard. Results were then compared with those obtained with each of the 2 automated semen analyzers, i.e. Sperm Class Analyzer® (CASA) and SQA-Vision® (electro-optical).
Participants/materials, setting, methods: 102 consecutive patients presenting at the andrology laboratory for a routine semen assessment were included in the study, provided sperm sample volume was >2.5ml. Only patients with azoospermia were excluded. Manual semen analysis was performed strictly according to WHO 2010 guidelines. Each sample also underwent automated analysis with both CASA system (SCA®, Microptics) and electro-optical analyzer (SQA-Vision®, MES) by different staff blinded to each other. Staff was specifically trained, and both automates underwent daily QC.
Main results and the role of chance: Mean patients' age was 35±7.6 years. Mean abstinence delay was 4.5±2 days. Mean sperm concentration, progressive and total motility were not statistically different between the 3 methods (64.8 vs 68.1 vs 53.1 M/ml; 39.7% vs 41.3% vs 39.2%; 60.3% vs 54.8% vs 59.3%, p>0.05 for manual analysis, SQA® and SCA® respectively). Mean proportion of typical forms was significantly higher with SQA® (13.5%) than with manual (8.1%) and SCA® (8.1% and 8.6% respectively, p<0.01). However, very high specificity was found for the detection of teratozoospermia by the two automated systems (98.8% and 96.4% for SQA® and SCA® respectively).

The correlation coefficient between automated and manual measures was excellent for sperm count (r=0.953 and 0.933 for SQA® and SCA® respectively), fair for sperm progressive motility (r=0.624 and 0.697) and moderate for sperm morphology (r=0.39 and 0.55).

Both sperm analyzers had good repeatability regarding sperm concentration, progressive/total motility, and sperm normal morphology, with lower coefficients of variation than manual analysis in most cases.

Out of the 102 samples analyzed, 16 (15%) had a different overall interpretation of sperm analysis according to the method used, i.e. automated or manual.
Limitations, reasons for caution: Staff training is of utmost importance when using automated semen analysis in order to limit the detection bias associated with high viscosity or the presence of round cells or debris. The relevance of these systems in severe oligospermia cases should also be specifically tested.
Wider implications of the findings: Although each andrology lab should test and validate sperm analyzer locally before using in daily routine, these results pave the way for a larger implementation of automated semen analysis. Cost-effectiveness studies are needed to evaluate the overall benefit of automated semen analysis.
Trial registration number: Not applicable

P-081 Biallelic mutations in CFAP65 lead to human primary ciliary dyskinesia and male infertility

W. Wang[1], C. Tu[1], H. Nie[2], L. Meng[2], Y. Li[1], S. Yuan[2], Q. Zhang[1], J. Du[1], F. Gong[1], G. Lu[2], L. Fan[1], G. Lin[1], Y.Q. Tan[1]
[1]Institute of Reproductive and Stem Cell Engineering- School of Basic Medical Science-, Central South University, Changsha, China
[2]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproductive and Genetic Hospital of CITIC-Xiangya, Changsha, China

Study question: There are only ~20 primary ciliary dyskinesia (PCD) genes known to cause male infertility. Novel causative genes still remain to be elucidated.
Summary answer: Biallelic loss-of-function mutations in *CFAP65* might be the genetic causes of PCD and male infertility in two unrelated families.
What is known already: So far, about 40 genes were identified to be responsible for ~70% human PCD cases. However, as not all PCD investigations explored the sperm parameters, only about 20 PCD causing genes are reported to cause male infertility. CFAP65 has once been reported to be a possible causative gene for MMAF, while the validation study and subsequent functional investigations were not performed.
Study design, size, duration: We conducted genetic analysis using whole exome sequencing (WES) in 42 individuals with PCD and male infertility from 40 unrelated families.
Participants/materials, setting, methods: WES was performed in 42 individuals with PCD and male infertility from 40 unrelated families. Mutation screening of *CFAP65* was performed using WES in a cohort of 637 non-PCD individuals, including 219 asthenozoospermia, 195 non-obstructive azoospermia, and 223 fertile controls. Ultrastructural and immunostaining analyses of patient's spermatozoa were performed to characterize the impact of the variant.
Main results and the role of chance: One homozygous nonsense mutation (NM_194302, c.G5341T:p.E1781X) and two compound heterozygous mutations (c.C2284T:p.R762X and c.1751delC:p.P584fs) in *CFAP65*, which may lead to protein degradation, were identified in two unrelated PCD and male infertility families, respectively. The mutations were absent in 637 non-PCD individuals. Immunostaining showed that CFAP65 localized in the acrosome and flagellar midpiece of normal spermatozoa. Ultrastructural and immunostaining analyses of the spermatozoa from one patient showed highly aberrant sperm morphology with severe defects such as disruption of mitochondrial sheath, defect of acrosome and absence of central pair complex and annulus.
Limitations, reasons for caution: The evidence of the effect on patients' cilia caused by *CFAP65* mutations was insufficient, further investigations with screening large numbers of patients with PCD and male infertility and the generation of knockout mouse models are required.
Wider implications of the findings: We firstly identified *CFAP65* might be a cause of PCD and male infertility, and proposed that *CFAP65* could play an essential role in cilium/flagellum assembly and acrosome formation in humans. This finding has important clinical implications for genetic and reproductive counseling of affected families.
Trial registration number: None.

P-082 A microfluidic device to investigate chemotactic behavior of spermatozoa

N. Atak[1], J.T.W. Berendsen[1], J.T. Loessberg-Zahl[1], L.I. Segerink[1]
[1]University of Twente, EWI BIOS Lab-on-a-chip Group, Enschede, The Netherlands

Study question: Can chemotactic behavior of spermatozoa be investigated using a hydrogel-based microfluidic device?
Summary answer: Hydrogel-based microfluidic device was successfully fabricated in which spermatozoa showed chemotactic behavior towards the chemical attractant.
What is known already: Chemotaxis is a movement changing behavior of organisms when there is a chemical gradient in their environment. Sperm

chemotaxis is the process where spermatozoa move towards an oocyte with help of its secretions. Therefore, it has been thought that chemotaxis plays a key role during fertilization. The content of the chemoattractants is uncertain, however, progesterone was proposed to be one of them. Sperm chemotaxis has been investigated with microfluidics, thereby easily mimicking the environment and controlling the parameters. Often these devices are made of polydimethylsiloxane or polymethylmethacrylate. Here we developed a novel hydrogel-based microfluidic device to assess the sperm chemotaxis.

Study design, size, duration: This study was performed with boar spermatozoa that were taken from Varkens KI Twenthe (Fleringen, the Netherlands). Sperm samples ($20x10^6$ cells/ml) were used within 1 to 4 days. Our microfluidic chip consists of 2 side channels and 1 middle channel which has 5 side chambers on each side and 6 inlets/outlets in total. To perform the chemotaxis experiments, 10µl sperm cells samples were injected into the middle channel.

Participants/materials, setting, methods: The microfluidic device was made from a gelatin/agarose mixture and covalently bonded to a glass slide with a surface coating of APTES (3%) and glutaraldehyde (10%) solutions. A fluorescein sodium salt solution (0.005%, MW: 332g/mol) was used to optimize the diffusion time, since its molecular weight is comparable with progesterone's (MW: 314g/mol). Progesterone (1µM) was injected into a side channel and empty chips were used as a control. Results were analyzed using CASA and RStudio.

Main results and the role of chance: Gelatin/agarose mixture (8 wt%:1 wt%) was preferred to fabricate hydrogel-based chips, since pure agarose chips caused cell death and gelatin was more compatible but has a melting point lower than 37°C which is a problem since chips were heated to that temperature during experiments. By using a cell counter plugin in ImageJ, the spermatozoa were counted. We defined a ratio called 'chemotaxis ratio'. It is the proportion of the number of cells in progesterone applied side of the middle channel vs. the other side of middle channel. If this ratio is bigger than 1, it means that spermatozoa moved towards to chemoattractant. Results showed that chemotaxis ratio was between 2 and 1,3. When progesterone was applied to the opposite side the chemotaxis ratio was between 1,6 and 1,3. For our control group, it was 0.97. This confirms that the chip did not affect the cell movement. Additionally, compared to the control chips, there was a significant difference in cell movement and accumulation. Therefore, progesterone has an effect on spermatozoa's chemotactic behavior and our chip can be used to quantify this.

Limitations, reasons for caution: During this study, boar spermatozoa were used. There may be other chemicals which have not been investigated that have affects the spermatozoa behavior other than progesterone. Furthermore, the counting of spermatozoa was done manually with ImageJ cell counter, making it prone to errors.

Wider implications of the findings: The progesterone experiments and developed hydrogel-based microfluidic chip are helpful to understand chemotaxis behavior in mammal's reproductive system and the chemoattractant effect on spermatozoa. Moreover, this study might be useful for sperm selection in the clinical researches.

Trial registration number: Not applicable.

P-083 Heavy metal level in human semen and oxidation-reduction potential.assessment by MiOXSYS.

A. Wdowiak[1], A. Mroczkowski[2], S. Bakalczuk[2]

[1]*Medical Universitiy of Lublin, Diagnostic Techniques Unit, Lublin, Poland*

[2]*Ovum RiA Lublin- Lublin- Poland, Ovum RiA Lublin- Lublin- Poland, Lublin, Poland*

Study question: The purpose of this study is to merge and analyze correlations between heavy metals and oxidation-reduction potential (ORP) measurements in human semen with normal and low fertilities .

Summary answer: There were positive correlations between Lead concentration and ORP in human semen with normal and low fertilities .

What is known already: Cadmium (Cd), lead (Pb), selenium (Se),copper (Cu) and molybdenum (Mo) are well-known reproductive toxicants which humans are exposed to occupationally and environmentally, and can lead to negative effects on the sperm functions. Both are pervasive in the human environment and accumulate in the human body over a lifetime. Heavy metals have a strong capacity to induce oxidative stress in body cells by disintegration of the lipid membrane.

Study design, size, duration: The presented study concerned 50 patients (examined group) and 50 fertile donors (control group) aged 25-35, and was conducted in 2018 in the 'Ovum - Reproduction and Andrology' Non-Public Health Care Unit in Lublin, (Poland).

Participants/materials, setting, methods: All semen samples were analyzed for heavymetals (Cd,Pb, Se,Cu,Mo) by flame emission atomic absorption spectrophotometer and ORP by the MiOXSYS System.The results of the study obtained were subjected to statistical analysis. T Mann Whitney U test was applied to compare the levels of heavy metals and ORP in the examined groups. The relationships between concentrations of heavy metals and ORP were tested using r-Pearson correlations.

Main results and the role of chance: The study showed that the levels of Pb (Z=−3.480; p=0.029) and Cd (Z=−4.980; p=0.018) were higher in the plasma of males with reproductive disorders, compared to the control group. There were no statistically significant differencies between the levels of Se, Cu, and Mo in examined groups. Higher ORP values were presented in infertile semen samples when compared to those of healthy (Z=−2.970; p=0.027). In the case of males with reproductive disorders, possitive correlations were observed between Pb(r=0,155, p=0,039)., Cd (r=0,189, p=0,031) and ORP. There were no statistically significant correlations in the other cases.

Limitations, reasons for caution: Limitation of this study is the small sample size.

Wider implications of the findings: This data suggests that Pb and Cd may be a cause of oxidative stress in infertile patients.

Trial registration number: 188/ES

P-084 Prevalence of human papilloma virus in semen and sperm DNA fragmentation

E. Mastora[1], A. Zikopoulos[1], E. Hatzi[1], I. Georgiou[1], K. Zikopoulos[1]

[1]*University of Ioannina, Department of Medicine, Ioannina, Greece*

Study question: The aim of the present study was to investigate the implication of HPV infection on sperm DNA fragmentation.

Summary answer: HPV seminal infection is probably responsible of a higher DNA fragmentation index.

What is known already: HPV infection is a common sexually transmitted disease, related to genital warts and cancer. In males, HPV DNA has been found in the seminal fluids. HPV is commonly present in semen samples, modifying spermatic parameters as volume, count, motility, viability, viscosity, pH. However, whether the presence of HPV in semen is actually associated with sperm DNA fragmentation has yet to be elucidated.

Study design, size, duration: From January to December 2017, 303 infertile couples were analysed at the Human Reproduction Unit of Ioannina University Hospital. A total of 250 clinical and laboratory data from male partners were included in the study. Sperm DNA fragmentation was compared among those with or without HPV in spermatozoa.

Participants/materials, setting, methods: To detect the presence of HPV a real time polymerase chain reaction assay was performed. All patients underwent a sperm chromatin dispersion semen analysis. The amount of DNA fragmented sperm, expressed in DFI, was valuated using the sperm chromatin dispersion test. In each sample 300 spermatozoa were counted at fluorescent microscope. DNA fragmentation index was compared among HPV positive and HPV negative men.

Main results and the role of chance: 39 (15,6%) of the total semen samples were HPV positive. Overall, 28/250 (11,2%) and 11/250 (4,4%) patients had high risk HPV and low risk HPV, respectively. The amount of DNA fragmented sperm between HPV positive and negative males was different. SDF values were higher (P = 0.005) in infected men compared to those without HPV.

Limitations, reasons for caution: Main limitation is the relatively small sample size.

Wider implications of the findings: Seminal HPV infection was frequently associated with lower sperm quality. Few studies focused attention on the relationship between HPV and sperm DNA fragmentation. The results suggest that HPV infection probably impairs sperm DNA quality. These observations point out the importance of testing seminal HPV presence in everyday clinical practice.

Trial registration number: None.

P-085 Ultrastructural analysis of lyophilized human spermatozoa

R. Bossi[1], M. Cabral[1], M.C. Oliveira[2], S. Lopes[2], M.A. Sampaio[1], S. Geber[3]

[1]Origen, IVF Lab, Belo Horizonte, Brazil
[2]Universidade Federal de Minas Gerais, Faculdade de Farmácia, Belo Horizonte, Brazil
[3]Universidade Federal de Minas Gerais, Faculdade de Medicina, Belo Horizonte, Brazil

Study question: The aim of our study was to evaluate the ultrasctructure of lyophilized spermatozoa using transmission electron microscopy.
Summary answer: Lyophilization of spermatozoa using glycerol-containing media increase ultrastructural damage. Also, the use of equipment with fixed pressure and temperature control impairs the result.
What is known already: Freezing-thawing spermatozoa is an excellent alternative for male fertility preservation. The use of liquid nitrogen is associated to detrimental effect on sperm structure/function and has some drawbacks such as maintenance cost, storage space, transportation difficulties and risk of contamination. Lyophilization might be an alternative since there is no need for storage and transportation is simpler. As it is associated to virus inactivation, the risk of contamination will be eliminated. The feasibility of this method has been reported in animal studies, but in human, only a scarce data has been published without evaluation of the ultrastructure.
Study design, size, duration: We performed an observational study with 21 healthy men who had been subjected to assisted reproductive technology treatment, from August 2014 to August 2015, and donated their remaining semen for the study. The study was approved by the Research Ethics Committee.
Participants/materials, setting, methods: A total of 30 samples were analysed according to the WHO criteria. Samples were divided into two aliquots: cryopreservation and lyophilization and cryopreservation only. Samples were frozen using Freeze Medium or Sperm Freeze Solution. Aliquots for lyophilization were placed in vials loaded into a lyophilization equipment under a pressure 50-100 µbar and temperature at -50°C . Samples were kept at 4°C until rehydration. After rehydration and thawing, samples were analysed under transmission electron microscopy.
Main results and the role of chance: After rehydration, aliquots were fixed for analysis in transmission electron microscopy. Analysis of the aliquots showed that the spermatic morphology was intact, but without motility.

Samples lyophilized with *Freeze Medium* (Irvine Scientific) and *Sperm Freeze Medium* (Vitrolife) cryoprotectants were severely compromised. Spermatozoa heads had ruptured plasma membranes, absence of acrosome, nucleus with heterogeneous and decompressed chromatin. Midpiece mitochondria were degenerate. Longitudinal columns of dense fibers were absent in the flagellum. Also, degenerate or disorganized structures were observed in axonemes. Samples freeze-dried with glycerol-containing media were not lyophilized successfully, which led to organelle damage.

Control group that was frozen with cryoprotectant showed some lesions in midpiece, degeneration of some mitochondria and ruptured plasma membrane in some points. Most spermatozoa showed an intact plasma membrane, nucleus and acrosome. In the flagellum main structure structure with plasma membrane, longitudinal columns of dense fibers and conserved semicircular fibers.

Fresh spermatozoa showed intact head and plasma membrane, nucleus with compact and homogeneous chromatin, normal acrosome and subacrosomic space. In midpiece, we observed mitochondria and external dense fibers. Transverse sections of axonemes from flagellum showed plasma membrane involving the sheath of dense fibers, nine pairs of peripheral microtubules plus 2 pairs of central microtubules.
Limitations, reasons for caution: Due to equipment limitations on pressure and temperature control during lyophilization we understand that the use of more complex equipment might aloow better results. Therefore, more studies are necessary in order to optimize lyophilization technique.
Wider implications of the findings: Lyophilization is expected to be an alternative for sperm preservation, however new studies are necessary to improve the results before it can be offered in clinical basis.
Trial registration number: not applicable

P-086 Sperm telomere length is correlated with sperm quality in normozoospermic patients

A.C. Lopes[1,2], P. Fontes Oliveira[1,3,4,5], S. Pinto[6], C. Almeida[4], M.J. Pinho[4], R. Sá[1,5], A. Barros[7,8,9], M. Sousa[10]

[10]Institute of Biomedical Sciences Abel Salazar- University of Porto, Depart. Microscopy- Lab. Cell Biology, Porto, Portugal

Study question: Is sperm telomere length (STL) correlated with sperm quality in infertile patients?
Summary answer: Sperm telomere length was significantly correlated with total sperm count and sperm fragmentation only in normozoospermic patients.
What is known already: Telomeres play an important role in human reproduction, including an active intervention during gametogenesis, fertilization and preimplantation embryo development. Since short telomeres are associated with cellular disfunction, it has been hypothesized that short STL is associated with poor sperm quality and male infertility. Recent studies have investigated this association in order to ascertain the suitability of STL as a new biomarker of sperm quality. However, published results are not consensual, differing in the infertile population characteristics under analysis regarding the type of sample (raw semen or swim-up samples), sample size, patients age range, seminal characteristics and infertility diagnosis.
Study design, size, duration: The present study was performed in swim-up samples containing rapid progressive motile sperm, to deliberately exclude sperm not used in assisted reproductive technology treatments. Samples were obtained from 78 treatment cycles of In-vitro Fertilization or Intra-cytoplasmatic Injection, between October and December 2018. Patients were randomly selected, and posteriorly subdivided into groups according to their seminal evaluation: 33-normozoospermic, 35-oligozoospermic, 9-asthenozoospermic, 35-teratozoospermic, 4-oligoasthenozoospermic, 8-oligoteratozoospermic, 7-asthenoteratozoospermic, and 3-oligoasthenoteratozoospermic, for a detailed statistical analysis.
Participants/materials, setting, methods: Spermiogram analysis was performed in raw semen samples. In the corresponding swim-up samples, average STL was measured by quantitative polymerase chain reaction, DNA fragmentation was evaluated by terminal deoxynucleotidyl transferase dUTP nick end labelling assay, chromatin maturity was evaluated by aniline blue staining, chromosomic alterations were evaluated by fluorescent in situ hybridization and the oxidative profile was evaluated by Slot blot. Statistical analysis determined the correlation between STL and the different sperm quality parameters evaluated.
Main results and the role of chance: When analyzing the totality of the patients, no significant correlations were found between STL and the broad panoply of sperm quality parameters, except for sperm DNA fragmentation. A negative significant correlation between STL and sperm fragmentation in the post-acrosome region was observed, either in the totality of the patients (n=38, r=-0.371, p=0.022) or in normozoospermic patients (n=22, r=-0.464, p=0.03). Evaluation of the different fragmentation staining patterns has been recently discovered. Our results reinforce the importance of pattern differentiation in order to obtain a full characterization of sperm DNA fragmentation. The post-acrosome region is demarcated as having decondensed chromatin, making it more prone to fragmentation, which may favor STL shortening. In

addition, a positive significant correlation between STL and total sperm count was observed only in normozoospermic patients (n=33, r=0.361, p=0.039). Sperm concentration may be affected by short STL due to induced apoptosis when STL reaches a critical point. However, altered seminal parameters erase this correlation, indicating that sperm concentration can be altered independently of STL. The present results thus suggest that although STL cannot be considered a general indicator of sperm quality, it might have a biological significance.

Limitations, reasons for caution: Additional studies with an increased sample size in the different clinical groups will help to validate the present statistical results.

Wider implications of the findings: Our study clarifies that different sperm sample characteristics may lead to discrepant results when evaluating the importance of STL in male infertility. We conclude that STL is not a suitable biomarker of sperm quality. However, given the importance of telomeres in reproduction, STL may still be associated with treatment prognosis.

Trial registration number: not applicable.

P-087 Abnormal sperm mitochondrial membrane potential in "normozoospermic WHO patients": outcome in ICSI patients

M.S. Bezerra Espinola[1], M. Luchetta[2], C. Aragona[3]

[1] *"Sapienza" University of Rome- Italy, Systems Biology Group Lab- Department of Experimental Medicine, Roma, Italy*

[2] *"Sapienza" University of Rome- Italy, Department of Obstetrics- Gynecology and Perinatology, Roma, Italy*

[3] *"Sapienza" University of Rome- Italy, Systems Biology Group Lab- Department of Experimental Medicine, Roma, Italy*

Study question: Is abnormal sperm mitochondrial membrane potential (MMP) at Andrositol Test (AT) related to ICSI outcome in infertile couples presenting normozoospermia according to WHO, 2010 parameters?

Summary answer: In infertile ICSI couples presenting normozoospermia by WHO, 2010 parameters, abortion rate was found to be significantly higher in "abnormal" than in "normal" AT group.

What is known already: Poor sperm motility and morphology according to WHO parameters, interfere with fertilization and ICSI outcomes. "Idiopathic male infertility" in WHO normozospermia still represents a difficult area where complex and expensive tests have been proposed. Andrositol® Test (Lo.Li. Pharma) is a simple and economic diagnostic procedure capable to qualitatively evaluate sperm MMP ("normal", "medium" and "poor") and allows to identify subfertile normozoospermic patients.

Study design, size, duration: The study is a retrospective review of semen samples investigated in 39 infertile couples undergoing ICSI over a 16 months period.

Participants/materials, setting, methods: 39 sperm samples with "normal" (WHO, 2010) sperm parameters from couples with "tubal factor" undergoing ICSI treatment, in a private fertility clinic, were analyzed by AT. Two groups were identified: group A, with "normal" AT and group B with "abnormal" AT. No differences were present in clinical parameters, stimulation and laboratory figures. Implantation, pregnancy and abortion rates were calculated.

Main results and the role of chance: Implantation and pregnancy rates were similar, on the contrary, abortion rate was found to be significantly higher (33%) in "abnormal" AT group (Group B) than in "normal" AT group (Group A) (16%). Since the clinical and laboratory parameters were similar in both groups, the increased abortion rate in Group B could be tentatively attributed to a post blastocyst negative factor related to abnormal sperm MMP.

Limitations, reasons for caution: Retrospective design and small sample size limit our results.

Wider implications of the findings: Whether confirmed in future studies, inositol supplementation should be considered, in vivo or in vitro, in male patients undergoing ICSI techniques presenting "abnormal" AT.

Trial registration number: The protocol was approved by the local Institutional Review Board.

P-088 Sperm p53 concentration: a potential new biomarker for environmental pollution. Preliminary data.(EcoFoodFertility Project).

T. Notari[1], M. Gentile[2], S. Raimondo[2], L. Bosco[3], T. Gentile[2], L. Montano[4]

[1] *Check Up- Day Surgery Polydiagnostc and Research Center - Salerno- Italy, Reproductive Medicine Unit, Salerno, Italy*

[2] *"Gentile Research Centre"- Gragnano NA- Italy, Seminology Unit, Gragnano- Naples, Italy*

[3] *University of Palermo, Departement of Biological- Chemistry and Pharmaceutical Sciences and Technologies, Palermo, Italy*

[4] *"St. Francis of Assisi" Hospital- Local Health Authority ASL Salerno, Andrology Unit.. EcoFoodFertility Project Coordination Unit, Oliveto Citra- Salerno, Italy*

Study question: We evaluated the p53 protein concentration in sperm cells to test whether environmental pollution can affect expression levels of this protein.

Summary answer: We found a significant difference in p53 levels between two homogeneous groups by age and lifestyle, residents in two areas with different environmental impact.

What is known already: The World Health Organization (WHO) has placed among its priority objectives the understanding of the relationships between the sources of pollution and the effects on human health, which they represent a cause of surprisingly high mortality and morbidity.

International scientific literature shows that strong environmental impact may jeopardize the stability and integrity of cellular DNA. This impairment can affect cellular functions, such as the uncontrolled growth of cells with the development of neoplastic process, until the final process of cell death (apoptosis). P53 seems to play a key role in these mechanisms, as it coordinates cell fate.

Study design, size, duration: 237 healthy males, 18-36 years old, were observed according to their stable residence in low environmental impact area (LEIA) or High environmental impact area (HEIA) of the Campania region (Southern Italy) in a period between July 2014 and June 2018. The study group has been divided into Group A: 109 permanent residents in LEIA, aged 19 - 36 years; Group B: 128 permanent residents in HEIA, aged 18 - 35 years.

Participants/materials, setting, methods: All partecipants were no smokers, not habitual alcohol drinkers, no professionally exposed to environmental pollutants, without varicoceles, prostatitis, urethritis or chronic diseases. Semen analysis was assessed according standard criteria of WHO Manual, fifth edition (2010). All semen samples were examined 30 minutes after collection and immediately processed for the p53 protein assay, using ELISA test, proposed by Raimondo et al. (2010)[1]. Quantitative dosage of p53 protein was expressed in ng / million of spermatozoa.

Main results and the role of chance: We have observed not significant differences in ejaculate volume between group A and group B. About sperm concentration, 44,9% (40/109) of group A samples were normozoospermic while only 20,3% (26/128) of group B samples were normozoospermic. The quantitative dosage of p53 protein has been corrected in relation to sperm concentration number and shows statistically significant differences between two groups: group A had a minimum value of 0,29 ng/million of sperms and a maximum value of 4,05 ng/million of sperms, with a mean value of 1,74 ng/million of sperms; group B had a minimum value of 0,69 ng/million of sperms and a maximum value of 14,36 ng/ million of sperms, with a mean value of 6,45 ng/million of sperms.Statistical analysis of the two groups was performed using Fisher's correlation and then Student's test and we obtained a $p < 0.0005$.The differences observed in this study underlines the efficacy of quantitative dosage of p53 protein in identify a cell suffering due to environmental pollution.

Limitations, reasons for caution: This is a preliminary observational study on a small number of samples. Reasons for caution could be due to unknown confounding factors.A large number of tests are need to confirm our results.

Wider implications of the findings: p53 protein is well known as "guardian of the genome" for its key role in determining the fate of the cell following DNA damage. Quantitative dosage of p53, seems to give valuable informations on the degree of damage to sperm DNA by environmental pollution, suggesting it as potential new biomarker.

Trial registration number: it's a retrospective observational study.

P-089 Association between tobacco smoking and genetic variations of protamines genes PRM1 and PRM2

H. Amor[1], J. Ebler[2], A. Zeyad[1], S. Nyaz[1], T. Marschall[2], M.E. Hammadeh[1]

[1]*University of Saarland, Obstetrics and Gynecology, Homburg/Saar, Germany*
[2]*Center for Bioinformatics- Saarland University-, GermanyDepartment for Computational Biology and Applied Algorithmics, Saarbrücken, Germany*

Study question: Does Tobacco smoke cause genetic variations or polymorphisms in the DNA sequence of protamine genes PRM1 and PRM2?
Summary answer: Tobacco smoke has no effect on genetic variations of PRM1 and PRM2 genes
What is known already: The epigenetic regulatory process as much as DNA demethylation in spermatozoa affect the Protamination process during spermatogenesis. This protamination is important for the protection and stability of the paternal genome and its fertilization capacity during its passage and delivery to the oocyte.

Tobacco smoke is one of the most risk environmental factors that altered the male reproductive function by reducing semen parameters and causing impairment in sperm DNA packaging. Because of its harmful compounds and reactive intermediates like ROS and reactive nitrogen species, smoking may induce a number of genetic and epigenetic changes.
Study design, size, duration: A prospective controlled trial carried out between December 2017 and December 2018 at the Department of Obstetrics and Gynecology, University of Saarland, Germany.. 141 semen samples were included in this study.
Participants/materials, setting, methods: Semen samples of 98 heavy-smokers (G1) and 43 non-smokers (G2) were prepared and purified according to WHO guideline 2010 and sperm nuclear DNA was extracted using Isolate II DNA/RNA/Protein kit then concentration and purity were verified with Nanodrop ND-2000c. PRM1 and PRM2 genes were amplified by PCR and sequenced using Sanger sequencing technique. Protamine deficiency (CMA3+) and sperm DNA fragmentation (sDF) were assessed by Chromomycin CMA3 and TUNEL assay respectively.
Main results and the role of chance: The sperm concentration, progressive motility, normal morphology, CMA3+ and sDF in G1 were (70.46±55.59 mill/ml; 15.78±11.66%; 4.32±2.93%; 33.30±22.33%, 26.68±19.77% and the corresponding values for G2 were (98.56±64.63mill/ml; 31.42±22.24%; 12.91±12.76%; 20.35±13.34%; 14.23±13.07%, respectively). Four single nucleotides polymorphisms (SNP) were identified: rs737008 for PRM1, and rs2070923, rs1646022 and rs424908 for PRM2. In G1, sperm parameters were significantly lower ($p<0.05$) than G2 and CMA3+ and sDF were significantly higher ($p<0.01$).

By testing the association between SNP alleles and each group to find differences in allele distribution among G1 and G2, none of the SNPs were reported significant. Besides, by investigating the associations between these SNPs and the studied parameters, none of the SNPs showed a significant association with any of the phenotypes.
Limitations, reasons for caution: The size number of the sample
Wider implications of the findings: Smoking induces an epigenetic change that alters the gene expression without changing the DNA sequence of PRM1 and PRM2 genes.
Trial registration number: Basic Science

P-090 Male infertility in Ghana: an untold phenomenon. How well known is male infertility among men and women in a Ghanaian metropolis

G. Akuffo Ataa[1], A. Kotoh[2], B. Woodward[3]

[1]*Lister Hospital and Fertility Center, Laboratory, Accra, Ghana*
[2]*University of Ghana school of public health, population family and reproductive health, Accra, Ghana*
[3]*X&Y fertility, Andrology and Embryology, Leicester, United Kingdom*

Study question: What is the level of knowledge on male infertility among men and women in a Ghanaian metropolis and what factors influence this knowledge?
Summary answer: Most (66%) men and women in Ghana have limited knowledge about male infertility, being married and educated enhanced knowledge on male infertility
What is known already: Research has shown there is little knowledge about infertility, and specifically male infertility, in most sub-Saharan African communities. A patriarchal system is predominant in many African communities and men often do not see themselves as a possible cause of infertility in a family. However, it is known that male and female factors contribute equally to a couple's inability to have a child. A recent study performed in Cameroon (West Africa) has shown that 76.8% of couples who presented at a fertility center had male-factor infertility (abnormal semen analysis) (Noumi et al. 2011).
Study design, size, duration: This study was a cross-sectional quantitative study. A representative sample of two hundred male and female respondents from the Ghanaian metropolis were asked to complete a structured questionnaire, which was also used to access their knowledge of facts about male infertility. The study spanned from June to August 2017.
Participants/materials, setting, methods: Men (n=98) and women (n=102) above 18 years, with a mean age of 32 years, were recruited for the study using a multistage sampling method. Participants completed nineteen questions which accessed their knowledge levels about male infertility and identified factors that affected it.
Main results and the role of chance: Overall, majority (66%) of the men and women had poor knowledge about male infertility. They were not able to identify the cause and risk factors of male infertility. They did not know what it was nor about modern treatment options to alleviate male infertility. Women (62%) seemed to be more knowledgeable about the physiology of male infertility than men. Married men and women had better knowledge generally about male infertility (Odds Ratio = 5.7, $p=0.001$). Education significantly boosted knowledge about male infertility (Odds Ratio = 14.7, $p=0.001$). The higher the level of education, the more knowledgeable the individual was about male infertility.
Limitations, reasons for caution: Information on the reproductive health history of respondents could have influenced the knowledge of male infertility. However, this study did not capture this information.
Wider implications of the findings: Many studies conducted into the area of infertility, focus on women's infertility . This appears to have fueled the general perception that women (female factor) are the main reason for infertility. Insights from this study may help to rectify this misconception and reduce the stigma women in childless marriages face.
Trial registration number: not applicable

P-091 Impact of obesity and bariatric surgery on erectile function, reproductive hormones, testicular function, and sperm DNA fragmentation

G. Wood[1,2], B. Tiseo[3], J.P. Cardoso[1], H. De Martin[1], C. Franchim[4], M.A. Santo[3], M. Srougi[1], W. Nahas[1], M.A. Cocuzza[1]

[1]*Hospital das Clinicas HCFMUSP- Faculdade de Medicina- Universidade de Sao Paulo- Sao Paulo- SP- BR, Urology, Sao Paulo, Brazil*
[2]*Huntington Medicina Reprodutiva, Andrology, Sao Paulo, Brazil*
[3]*Hospital das Clinicas HCFMUSP- Faculdade de Medicina- Universidade de Sao Paulo- Sao Paulo- SP- BR, Bariatric surgery, Sao Paulo, Brazil*
[4]*Hospital das Clinicas HCFMUSP- Faculdade de Medicina- Universidade de Sao Paulo- Sao Paulo- SP- BR, Gynecology, Sao Paulo, Brazil*

Study question: What is the impact of obesity and bariatric surgery on semen parameters, erectile function, reproductive hormones and sperm DNA fragmentation index (DFI)?
Summary answer: Bariatric surgery can revert the deleterious effects in reproductive hormones and DFI, but can result in worsening of semen parameters on 6-month follow-up.
What is known already: Obesity has major importance as a global health issue, and although there is a paucity of data regarding its influence on male fertility, growing evidence in the literature suggests that obesity is capable of altering reproductive hormones levels and erectile function. Effects of bariatric surgery, one of the most effective treatments for obesity, on classic semen parameters and DNA fragmentation index (DFI), however, have not been properly established.
Study design, size, duration: 2-phase prospective non-randomized study, with participants divided into 2 treatment groups and 1 control group. The study took place in a university-based teaching hospital, with patients' recruitment over a 2-year period. The first phase performed as a cross-sectional study with

obese and fertile patients, and the second phase carried out as a 6-month prospective case-control study with obese patients submitted to clinical or surgical treatment.

Participants/materials, setting, methods: Fertile controls (N=32) and 42 obese patients waiting bariatric surgery (body mass index greater than 35kg/m^2, N=42) were submitted to complete urological evaluation, International Index of Erectile Function (IEEF-5) score, semen analysis (SA), DNA fragmentation index (DFI – Alkaline comet assay) assessment, and dosing of sexual hormones. On phase 2, 22 obese patients (Group A1) were submitted to bariatric surgery and 20 remained on conservative treatment (Group A2). All patients were invited to 6-month revaluation.

Main results and the role of chance: Obese men presented higher median levels of estradiol (33.3 vs. 22 pg/mL, p=0.003), LH (6.3 vs. 4.1 IU/L, p=0.0004) and FSH (4.8 vs. 3.2 IU/L, p=0.0060), and lower levels of total testosterone (TT, 272.5 vs. 413 ng/dL, p=0.0008) than eutrophic fertile men. Additionally, they present lower ejaculated volume (1.5 vs. 2.5mL, p<0.0001), sperm concentration (43 vs. 82 millions/mL, p=0.0183), total motility (54.5 vs. 72%, p=0.0004), progressive motility (27.5 vs. 54%, p<0.0001), Kruger morphology (2 vs. 3%, p=0.0098), and higher sperm DFI than eutrophic fertile men (48 vs. 24%, p=0.0092). On phase two, mean weight loss on patients submitted to bariatric surgery was 38.2 kg. Group A1 patients showed a decrease on sperm concentration (53.5 vs. 105.2 millions/mL, p=0.0572), total ejaculated sperm count (58.2 vs. 169.8 million, p=0.0098) and total motile sperm count (34.5 vs. 104 million, p=0.0036). TT levels (648.9 vs. 291.1 ng/dL, p<0.0001) and free testosterone levels (276.2 vs. 183.7, p<0.0001) dramatically increased after surgery, while FSH, LH and estradiol were not different from baseline. Moreover, they exhibited a reduction in sperm DNA fragmentation. No differences were observed in group A2. IIEF-5 score was not different nor changed with treatment between groups.

Limitations, reasons for caution: Despite all patients were waiting to be submitted to bariatric surgery, selection bias cannot be completed excluded in a non-randomized study. Additionally, the small sample size and short follow-up is a result of the difficulties involving studies containing invasive procedures and sperm samples from patients not concerned about fertility.

Wider implications of the findings: Improving knowledge in the effects of bariatric surgery in semen parameters and hormone levels of severely obese patients may provide better counseling on those seeking fertility. Obese patients may be advised that bariatric surgery may bring additional barriers to paternity, at least in a short-term setting.

Trial registration number: Not applicable

P-092 Attenuation of sirtuin 3 down-regulates mitochondrial complex I and V via inhibition of voltage dependent anion channel 1,3 proteins to promote asthenozoospermia in rat

R. Chattopadhyay[1], P. Chakraborty[2], S. Ghosh[3], S.K. Goswami[3], S. Chatterjee[4], D. Patra[4], K. Dutta Chowdhury[5], M. Chakraborty[3], B. Chakravarty[3]

[1]*Institute of Reproductive Medicine, ART, Calcutta, India*
[2]*Institute of Reproductive Medicine, Department of Infertility, Calcutta, India*
[3]*Institute of Reproductive Medicine, Department of Assisted Reproduction, Calcutta, India*
[4]*Vidyasagar College, Tissue culture and Molecular Biology Laboratory, Calcutta, India*
[5]*Rammohan College, Department of Zoology, Kolkata, India*

Study question: Does sirtuin (SIRT) 3 influence mitochondrial respiratory function in isolated asthenozoospermia (AS) in rodent spermatozoa?

Summary answer: A drop in SIRT 1,3 immuno-expression may attenuate Voltage Dependent Anion Channel (VDAC) 1, 3 proteins to impair mitochondrial activity and acrosomal integrity in AS.

What is known already: Mitochondria generate the bulk of cellular ATP via oxidative phosphorylation (OXPHOS), supported by reducing equivalents generated by tricarboxylic acid cycle and fatty acid b-oxidation. Sperm mitochondrial dysfunction and *oxidative stress* are viewed as possible reasons for *AS*, characterized by reduced sperm motility. *D*erangement of SIRT1 / peroxisome proliferator activated receptor gamma coactivator 1 alpha/SIRT3 induce imbalance of reactive oxygen species (ROS) and antioxidant defense to promote dysfunctional electron transport chain; deleterious to sperm capacitation. Although previous studies have shown a physiological relevance of SIRT1/SIRT3 in maintenance of testicular bioenergetic capacity, the specific mechanism underlying this association is unknown.

Study design, size, duration: Experimental study; Mature Sprague-Dawley rats (n = 23) weighing ~330 -360g were treated with Ornidazole (ORN) at a dose of 400 mg/kg body weight daily by oral gavage for 12~14 days to mimic AS. Control set (n = 11) received vehicle (sodium carboxymethylcellulose (CMC-Na)) in water at same volume. The study was approved by Animal Ethics Committee (IAEC-37/PC/2018/9) of Institute of Reproductive Medicine, Kolkata.

Participants/materials, setting, methods: Effect of ORN on sperm parameters (count, motility) and testicular morphology was studied by Makler's chamber, and haematoxylin-eosin staining respectively. Testicular bioenergetics was evaluated on basis of intracellular ROS, oxidative stress, mitochondria membrane potential, VDAC and sirtuin proteins, OXPHOS complexes (C1–C5) and intracellular ATP concentration by flow cytometry, immunohistochemistry, immunoblot, immunofluoroscence, and bioluminescent kit respectively. Data presented as mean ± standard deviation were compared with Student's t-test. $P < 0.05$ was considered as significant.

Main results and the role of chance: Sperm proportion and progressive motility decreased significantly ($p < 0\ 001$) in ORN-treated rat (18.2 ± 3.3%) compared to control (51.7 ± 3.1%) supported by atrophied seminiferous tubules with increased number of vacuoles. A significant increase (p<0.001) in intracellular ROS (0.92 ± 0.38 *vs* 0.65 ± 0.34) production along with simultaneous reduced percentage of MitoTracker Deep Red FM (MT-DR FM)-positive sperm in ORN-treated (88.85 ± 4.81) set was documented in midpiece compared to control (13.75 ± 6.49, p< 0 001) suggesting mitochondrial dysfunction in asthenozoospermic rat. Increased expression (p<0.01) of hypoxia inducing factor-1a was observed in nuclei of pachytene spermatocytes and to a lesser extent in the adjacent round spermatids supported by immunoblot expression. Among OXPHOS proteins, complexes I, and V were significantly decreased (p<0.05) by ~70% indicating decreased oxidative capacity in the treated set. Significant down-regulation in SIRT 1, 3 revalidated by immunofluoroscence document reduced localizations (p<0.01) of both in midpiece. The drop in ATP level (p<0.001) was evident and this was followed by a compromised acrosomal status of the spermatozoa by effective diminution of VDAC 1, and 3 localization in ORN-treated set.

Limitations, reasons for caution: The main limitation of this study was the absence of direct quantification of SIRT1 and SIRT 3 enzymatic activity due to the lack of an appropriately sensitive method and hence the regulatory pathway could not be assessed.

Wider implications of the findings: The present findings may provide a valuable background for studying the regulation of SIRT3 during spematogenesis and its relevance as a sensor of Leydig cell redox state and energy status. SIRT 3 agonists may provide a novel prospect for impacting mitochondrial function in AS to improve sperm motility in future.

P-093 Micro-Anatomical features and arteriovenous communications of Spermatic Cord in Varicocele Patients

K.U. Rehman[1], Z. Hafsa[2], R. Habib[3]

[1]*Lahore Institute of Fertility & Endocrinology, androurology, Lahore, Pakistan*
[2]*University of Veterinary and Animal Sciences, Anatomy, Lahore, Pakistan*
[3]*University of Veterinary and Animal Sciences, Physiology, Lahore, Pakistan*

Study question: To record and video document, micro anatomy of the spermatic cord of infertile individuals undergoing microsurgical varicocelectomy

Summary answer: Fine arteriovenous communication were observed between internal spermatic artery and vena- comintantes. Lymphatics were seen forming notable boundary between internal spermatic vessels and vasal complex.

What is known already: Varicocele is known to be associated with sperm disorders but some individuals with significant varicoceles remain fertile. This cannot be fully explained by current knowledge. A limited number of studies have addressed the micro-anatomy of spermatic cord especially in Asian varicocele patients. We have already published that in our population, the blood in varicocele veins has higher oxygen saturation as compared to other veins. This may be due to micro-anatomical peculiarities, so further studies are required to investigate the microsurgical anatomy of varicocele.

Study design, size, duration: Sixty consecutive patients between 20 – 45 years age, diagnosed with infertility and varicocele, undergoing microsurgical varicocelectomy at a tertiary & teaching hospital over a period of three years were included in the study, after informed consent. IRB approval was obtained before initiation of the study.
Participants/materials, setting, methods: In all participant, semen parameters and scrotal color Doppler ultrasonography (CDUS) were recorded preoperatively. During surgery, micro-anatomy of the spermatic cord was carefully noted at 10x to 25 x magnification on karl Zeiss operating microscope. Important findings were documented and still as well as video recordings were made. A single surgeon performed all procedures. The data was processed by SPSS for descriptive statistics.
Main results and the role of chance: The internal spermatic veins were dilated in all patients (mean diameter 3.2 +- 0.7). The external spermatic, external pudendal and Gubernacular veins were dilated in 75%, 19% and 70% patients respectively. Collateral venous channels were noticed in 28% patients. The main testicular artery was found in close proximity, behind internal spermatic veins in 65% patients, whereas in 8.3% patients the artery was found to be lying anteriorly or elsewhere in the anterior compartment in 16.7% patients. Venae comitantes were found surrounding the main testicular artery and communicating with each other in all cases. There were communications between venae comitantes and the adjacent internal spermatic veins in 87% patients. Most importantly we found fine arteriovenous communications between internal spermatic artery and vena- comitantes in 12 % cases. We also noted a separately identifiable group of lymphatic channels forming an almost bloodless boundary between the internal spermatic vessels and the vas and vasal vessel complex. Relevant pictures and videos were recorded for presentation.
Limitations, reasons for caution: We have investigated varicocele patients at a single centre and most patients were from the same geographical region. Further studies on patients from various geographical regions and races as well as a larger number of patients are required to confirm our findings.
Wider implications of the findings: a: The location of lymphatic channels at the boundary between internal spermatic vessels and vasal vessel complex appear of significance as a land mark during microsurgery.

b : The arterio-venous anastomosis at sub inguinal level, between testicular artery and adjacent veins may help to understand the pathophysiology of varicocele.
Trial registration number: not applicable

P-094 Is there an association between clinical outcome and aneuploidy of embryo in patients with severe male factor infertility?

K. KANG[1], B.Y. Kim[1], J.W. Park[1], E.A. Park[1], Y.J. Cho[1], E.B. Joe[1], S.Y. Moon[1], J.Y. Lee[1], H.S. Kim[1], M.J. Lee[1], J.I. Baek[1], K.A. Lee[2], J.J. Ko[2], Y.S. Kim[3], T.K. Yoon[3]
[1]CHA Fertility Center Seoul Station, Fertility Center, Seoul, Korea- South
[2]CHA University, Department of Biomedical Science- College of Life Science, Pocheon, Korea- South
[3]CHA Fertility Center Seoul Station, Department of Obstetrics and Gynecology, Seoul, Korea- South

Study question: We aimed to evaluate embryo aneuploidy in severe male factor infertility (oligozoospermia, severe- oligozoospermia, TESE-sperm) by preimplantation genetic testing (PGT-A) based on identified clinical outcome.
Summary answer: There was a significant difference in clinical outcome but no significant difference of embryo aneuploidy in severe male factor groups with PGT-A.
What is known already: Several studies presented that patient using testicular sperm showed higher implantation and pregnancy rates than patients with severe oligoasthenoteratozoospermia syndrome and also that sperm are susceptible to damage during passage through the male reproductive tract. Increased DNA damaged sperm may be able to fertilize an oocyte; however, this may result in low embryo development and pregnancy rates. Another study reported that severe male factor infertility showed similar incidence of aneuploidy and there was no statistical significance. There is an increasing concern of possible rise of embryo aneuploidy in patients with poor sperm quality in severe male factor.
Study design, size, duration: Our center performed 13,258 IVF-ICSI cycles from January 2016 to November 2018. Among them only 474 cycles with severe male factor were analyzed in this retrospective study. From those, only 59 cycles were performed with PGT-A. The clinical pregnancy rate was identified in severe male factor patients without PGT-A. Furthermore, embryo aneuploidy was evaluated in severe male factor groups after PGT-A. Statistical analysis was performed using t-test and chi-squared test where appropriate, significance at $p<0.05$.
Participants/materials, setting, methods: In this study, the clinical pregnancy rate was evaluated in Non-biopsied IVF-ICSI cycles. Female factor with repetitive implantation failure, recurrent miscarriage and increasing of maternal age was considered for PGT-A for embryo aneuploidy. All IVF-ICSI cycles were divided into three groups. Group 1: Oligozoospermia ($\geq 0.1\times10^6$/ml~ $< 15\times10^6$/ml), Group 2: Severe-oligozoospermia ($< 0.1\times10^6$/ml), Group 3: TESE sperm (sperm retrieved from non-obstructive azoospermia patients).
Main results and the role of chance: The clinical pregnancy rate of Group 2 was significantly lower than Group 1 and 3 (Group1(43.98%(141/62) vs Group 2 (29.33%(75/22); p=0.036 and Group 2 (29.33%(75/22)) vs Group 3 (44.86%(185/83)); p=0.021), but not in Group 1 (43.98%(141/62) and Group 3 (44.86%(185/83)); $p>0.05$, in non-PGT-A. In addition, there was no statistically difference in both the maternal age (Group 1: 36.00±4.13 (n=141), Group 2: 35.74±4.27 (n=75), Group 3: 36.00±4.50 (n=185); $p>0.05$), and the paternal age (Group 1: 38.00±5.06 (n=141), Group 2: 37.52±4.50 (n=75), Group 3: 39.00±5.76(n=185); $p>0.05$) in between all groups. In embryo aneuploidy rate of three groups, there was no significant difference in both trophectoderm biopsy cycles (Group 1 : 67.00%(n=100) vs Group 2 : 75.00%(n=8); $p>0.05$ and Group 2 : 75.00%(n=8) vs Group 3 : 56.67%(n=30); $p>0.05$ and Group 1 : 67.00%(n=100) vs Group 3 : 56.67%(n=30); $p>0.05$) and blastomere biopsy cycles (Group 1 : 79.57%(n=93) vs Group 2 : 89.29%(n=28); $p>0.05$ and , Group 2 : 89.29%(n=28) vs Group 3 (84.21%(n=19); $p>0.05$ and Group 1 : 79.57%(n=93) vs Group 3 : 84.21%(n=19); $p>0.05$). There was also no significant difference in both the maternal and paternal age ($p>0.05$).
Limitations, reasons for caution: Our center performs only limited PGT-A cycles and also severe male factor cycles are especially rare in total IVF-ICSI cases. Due to this small sample size, number of analyzed cycle for embryo aneuploidy by PGT-A in severe male factor was very restricted.
Wider implications of the findings: This study revealed that severe male factor infertility does not influence on the embryo aneuploidy. Consequently, PGT-A procedure may not be essential for IVF-ICSI cycles in severe male factor infertility while producing a good quality of embryo may be more important for enhanced reproductive clinical outcomes.
Trial registration number: Not applicable.

P-095 Effect of raised male body mass index (BMI) on IVF success rate in egg donation cycles

V. Casciani[1], E. Iovine[1], M.G. Minasi[1], A. Ruberti[1], L. Gnessi[2], F. Scarselli[1], V. Zazzaro[1], D. Uva[1], A. Pristerà[1], E. Cursio[1], S. Muzzì[1], A. Greco[1], C. Arrivi[1], M.T. Varricchio[1], E. Greco[1]
[1]European Hospital, Centre for Reproductive Medicine, Rome, Italy
[2]Università degli Studi di Roma La Sapienza, Quinta clinica medica, Rome, Italy

Study question: Does increased male BMI affect IVF outcome measures such as fertilization (FR), clinical pregnancy rate (CPR) and implantation (IR)?
Summary answer: Higher male BMI is associated with significant reductions in CPR and IR. No effect is observed on FR and number of embryos obtained.
What is known already: Fertility rate is reduced in couples with obese men who have a body mass index (BMI, Kg/m2) ≥30. Obese men can have lower serum testosterone and higher estradiol levels that can affect spermatogenesis. Higher BMI was also shown to relate to poorer semen parameters (lower ejaculatory volume, oligoozoospermia, abnormal morphology and increased sperm DNA damage). Given that oocytes donors are carefully selected from a population of young and healthy women, the use of donor oocytes allows minimizing the effect of oocyte competence and represent a model to analyze different parameters of the male partners and their effect in IVF outcomes.
Study design, size, duration: We retrospectively analyzed the outcomes of 317 egg donation cycles (OD) performed in October 2014-January 2019. Our population includes cycles with 6-9 vitrified/warmed oocytes/cycle inseminated by ICSI with fresh ejaculated semen. PGS cycles were excluded. Only

data relative to fresh embryo transfers were included since the complete cumulative data was not yet available. We considered a BMI threshold value of 25. Data shown as average±SD were analyzed with Fisher's exact, Chi-square or Student-t tests.

Participants/materials, setting, methods: The population was divided into two groups. Group-1 includes men with BMI <25 (n=155 OD, BMI=23.24±1.14; 1110 oocytes received). Each recipient received on average 7.2±1.07 oocytes/cycle. Group-2 includes men with BMI≥25 (n=162, BMI=28.33±3.53; 1188 oocytes). Each recipient received 7.3±1.00 oocytes/cycle. In groups 1 and 2 donor age was respectively 25,50±3.58 and 25,35±3.55 (NS). The female recipient age was respectively 44,04 ±3.23 and 43,47±3.78 (NS). No significant different were found in male age into two groups.

Main results and the role of chance: Respectively in groups 1 and 2, the number of surviving and injected oocytes was 989 and 1053; FR was 72.2% (714/989) and 71.7% (755/1053) (NS) and no difference was found in the number of embryos obtained. A not quite significant difference was found in beta-positive patients/starting cycle (PR): 66.5% (103/155) in group-1 and 55.6% (90/162) in group-2 (P=0.051). Significant differences were found in clinical pregnancy/starting cycle [CPR: 57.4% (89/155) and 42% (68/162) in groups 1 and 2 (p=0.007)] and IR [39.8% (106/266) and 28.9% (81/280) in groups 1 and 2 (p=0.0088)]. However, the female recipient BMI was statistically different: 21.68±2.91 (Group-1) and 23.41±3.65 (Group-2) (p=0.0001). We then selected a subpopulation of normal-weight women (female-recipient BMI range 18.4-24.9): no significant differences in fertilization rates between men with BMI<25 (male BMI=23.27±1.13, N=131) and ≥25 (male BMI=28.14±3.22, N=115) (men age: 45.26±5.71 and 44.68±6.13, NS; women age=44.1±3.08 and 43.24±3.97, respectively, NS). However, PR, CPR and IR were significantly different between men with BMI<25 and BMI≥25 [PR: 68.7% (90/131) and 54.8% (63/115) (p=0.026); CPR: 60% (76/131) and 40.9% (47/115) (p=0.0104); IR: 39.5% (89/225) and 28.5% (57/200) (p=0.0187)]. It must be said that also within normal-weight women BMI was significantly different (female BMI=21.19±1.62 and 21.87±1.63, p=0.0012).

Limitations, reasons for caution: It could not separate male BMI and female recipient BMI variations therefore the latter is a confounding factor in evaluating clinical outcomes. Moreover, we lack data about men's diet/lifestyle and serum levels of FSH and LH. These parameters would add knowledge relative to the role of BMI in male fertility.

Wider implications of the findings: Semen quality could be affected by male diet/lifestyle which in turn affects BMI. Preimplantation genetic screening could add information relative to the embryo competence to implant and develop into a live-birth. The follow up of children is crucial for understanding the possible inheritance of specific conditions related to parents BMI.

[7]Isala, Department of Obstetrics and Gynaecology, Zwolle, The Netherlands
[8]Vivaneo Medisch Centrum Kinderwens, Fertility Clinic, Leiderdorp, The Netherlands

Study question: Are six cycles of intracervical insemination (ICI) non-inferior to six cycles of intrauterine insemination (IUI) in donor sperm treatment in the natural cycle in terms of ongoing pregnancy?

Summary answer: ICI in the natural cycle is inferior to IUI in the natural cycle in donor sperm treatment in terms of ongoing pregnancy rate.

What is known already: Both ICI and IUI in the natural cycle are performed as first line treatments in women who are eligible for donor sperm treatment. IUI is more costly than ICI, due to the involvement of sperm processing. High quality data on the effectiveness of ICI versus IUI the natural cycle in terms of ongoing pregnancy are lacking. A large retrospective cohort study showed that ICI and IUI in the natural cycle in donor sperm treatment resulted in similar ongoing pregnancy rates of 40% after six cycles.

Study design, size, duration: We performed a multicenter, non-blinded, non-inferiority randomized controlled trial in six fertility clinics in the Netherlands and Belgium. Based on the retrospective cohort study we assumed a live birth rate of 40% after six cycles of IUI. To assess a non-inferiority margin of 12%, we needed to include 416 women.

Participants/materials, setting, methods: Women scheduled for donor sperm treatment were eligible, regardless of the indication for treatment. The primary outcome was ongoing pregnancy leading to a live birth within eight months after randomisation. Secondary outcomes were multiple pregnancy, miscarriage, time to ongoing pregnancy and pregnancy complications.

We calculated relative risks (RR) and risk difference (RD) and 95% CI. We analysed the data on an intention to treat basis.

Main results and the role of chance: Between June 2014 and January 2019, we included 417 women, of whom 209 women were randomly allocated to ICI and 208 to IUI. At the moment of writing this abstract, we have access to 89% of the data regarding ongoing pregnancy. Women's age was on average 34 years (SD ± 4) in both groups. Of the 417 women included, ten women (5%) allocated to ICI and 10 women (5%) allocated to IUI did not start treatment mostly due to personal reasons. Ongoing pregnancy occurred in 43 women (21%) in the ICI group and 74 women (36%) in the IUI group (RR 0.58 (95% CI 0.42 to 0.80)). ICI was inferior to IUI; the left boundary of the 95% confidence interval was minus 0.23 and crossed the pre-set absolute difference of 12% (RD of -0.15 (95% CI -0.23 to -0.06)).

Limitations, reasons for caution: The current follow-up is based on 89% of the data. Full data will be available before June 2019. These data will also include timing of ICI and IUI and quality of frozen- thawed donor sperm.

Wider implications of the findings: In women undergoing donor sperm treatment in a natural cycle, ICI results in lower ongoing pregnancy rates than IUI. Therefore, IUI should be the preferred treatment.

Trial registration number: NL4309 **(**NTR4462)

P-097 Human testicular sperm vitrification and storage through Sperm vitrification device versus conventional slow freezing cryopreservation: a prospective randomized sibling oocyte study

N. Kazdar[1], J. Tek[1], C. Yazbeck[2], A. Berkovitz[3], F.X. Aubriot[2], E. Amar[4], V. Izard[2]

[1]Laboratoire d'AMP Eylau Unilabs de la clinique Pierre Cherest- 55 rue Saint Didier, Reproductive Medecine, Paris 16, France
[2]Centre chirurgical Pierre Cherest- 5 rue Pierre Cherest, Reproductive Medecine, Neuilly sur seine, France
[3]Department of Gynecology and Obstetrics- Meir Medical Center- 59 Tchernichovsky St, Reproductive Medecine, Kfar Saba, Israel
[4]Cabinet d'andrologie- 17 Avenue Victor Hugo, Reproductive Medecine, Paris 16, France

Study question: Does SpermVD provide an efficient approach for testicular sperm preservation before oocyte retrieval for men suffering from azoospermia and undergoing testicular biopsy?

Summary answer: ICSI outcomes were comparable between spermVD and slow freezing techniques. Moreover, the duration of micro-injection procedure was significantly shorter in SpermVD group.

What is known already: In order to avoid iterative testicular surgery, an efficient and validated cryopreservation method of testicular sperm retrieved by microTESE followed by ICSI in asynchronous procedures can be proposed for men suffering from azoospermia. Testicular sperm vitrification has been recently used as an alternative to slow freezing technique, but so far no prospective randomized studies with sibling oocytes were conducted to compare these techniques.

Study design, size, duration: We conducted a single-center prospective randomized sibling oocyte study on 16 ICSI cycles in men suffering from azoospermia and with micro-TESE between January and December 2018.
Participants/materials, setting, methods: Half of spermatozoa from positive testicular biopsies were frozen with each of 2 freezing methods: slow conventional and vitrification .Sibling MII oocytes were microinjected by sperm coming from these 2 methods. MII oocytes were allocated by randomization to one of the 2 freezing groups, to achieve a balanced distribution. The sperm were thawed on the day of oocyte retrieval. Comparisons were done using paired T-test and sign-test . p-value was considered significant when < 0.05
Main results and the role of chance: A total of 66 surgical TESE were performed during the period out of which 16 ICSI cycles were conducted with cryopreserved sperm from the positive testicular biopsies.

64 MII oocytes were allocated in the slow freezing group versus 68 in the vitrification group

Men age was 35.7 ± 3.7 years and female age 33.6 ± 4.3 years. Female BMI was 22.3 ± 2.2 kg/m2. The recovery rate was 90.3%. There was no significant difference in fertilization rates between the two groups : slow freezing and vitrification (53.9% vs 67.1% respectively ; p=0.15). However, a significant difference was observed in the duration of microinjection with a reduced time in the vitrification group versus the slow freezing group (7.8 min versus 29.7 min, $p< 0.05$). There was no significant difference in blastulation rates (43.9% vs 50.0% respectively ; $p>0.05$). The choice of transferred embryos was based on the embryonic morphology, 80% of transferred embryos were obtained from spermVD group and yielded a 62.5% pregnancy rate.
Limitations, reasons for caution: These preliminary results need to be confirmed by a large trail with possible focus on non-obstructive azoospermia cases where the amount of spermatozoa is low, the synchronous procedure often recommended, and where SpermVD might be an accurate device for convenient asynchronous microTESE planning.
Wider implications of the findings: The spermVD device is an efficient and safe carrier and seems to be appropriate for the asynchronous preservation of a small number of spermatozoa allowing us to plan asynchronous micro TESE before oocyte retrieval and perform rapidly safe delayed ICSI.
Trial registration number: The study was approved by Unilabs IRB

P-098 Analysis of sperm nuclear integrity and screening for DNAH1 gene mutation in infertile Tunisians patients with MMAF syndrome (Multiple Morphological Abnormalities of the sperm Flagella)

A. Braham[1], H. Ghedir[1], A. Saad[1], S. Ibala-romdhane[1]
[1]*Farhat Hached Hospital Sousse- TUNISIA, Cytogenetic- Molecular Genetics and Biology of Human Reproduction Laboratory, Sousse, Tunisia*

Study question: The impact of nuclear sperm integrity in patients with MMAF syndrome and genetic defects could assess the chances of success in assisted fertilization?
Summary answer: Patients with MMAF syndrome have impaired nuclear sperm which affects assisted fertilization and mutations in DNAH1 gene is not the main cause of this syndrome.
What is known already: MMAF syndrome is a rare but severe form of teratozoospermia defined by the presence in the ejaculate of immotile spermatozoa with several abnormalities of the sperm flagellum including short, coiled, absent and flagella of irregular caliber. Mutations in *DNAH1*, an axonemal inner dynein arm heavy chain gene, have been shown to be responsible in 28% of MMAF patients (Ben Khelifa et al., 2014). Recently, Tang et al., 2017 have identified others mutations in CFAP43 and CFAP44 genes, encoding cilia- and flagella-associated proteins, in patients with MMAF syndrome. Otherwise, few data regarding the nuclear integrity were reported in the literature.
Study design, size, duration: This is a case control study carried out on 52 Tunisian infertile patients with MMAF syndrome and 25 fertile men with normal semen profiles included as a control group. Patients were recruited between January 2015 and September 2018.
Participants/materials, setting, methods: Semen samples were analyzed according to the World Health Organization criteria (2010). Sperm DNA fragmentation was evaluated by terminal desoxynucleotidyl transferase mediated deoxyuridine triphosphate biotin nick-end labelling (TUNEL) assay. Chromatin condensation was assessed by aniline-blue Staining. Fluorescence *in situ* hybridization for chromosomes X, Y and 18 was performed to study the chromosomal meiotic segregation. We performed PCRs and Sanger sequencing for mutations screening of *DNAH1* associated to MMAF syndrome.
Main results and the role of chance: Semen morphology analysis shows a mosaic of multiple morphological abnormalities of the flagella with an average rate of 46.73% short flagella, 16.22% bent flagella, 22.07% coiled flagella and 10.90% absent flagella which describe a MMAF syndrome. We also showed a high percentage of microcephalic heads (37.41 ± 19.80%) and acrosome abnormalities (42.75 ± 16.3%). The mean DNA fragmentation index (DFI) was significantly higher in patients compared to controls (25± 4.61% vs 10± 3.77%; $p<0.05$). The results of aneuploidy frequencies showed a significant difference between both groups (15.89±7.18% vs 1.52±0.25%; $p<0.05$) predominant in the mean disomy rate of sex chromosomes (8.43±4.63% vs 1.05±0.56%; $p<0.05$).Whereas, the difference was not significant for the rate of aniline blue-reacted spermatozoa in patients compared to the control group (13 ± 2.21% vs 12 ± 3.22%, $p> 0.05$). For the molecular analysis, DNAH1 gene showed no mutation in exon 23, 31, 74 and 78 for our patients.
Limitations, reasons for caution: A limitation of this study is the unavailability of Next-Generation Sequencing Technology (NGS) to look for others associated genetic causes.
Wider implications of the findings: In these cases, we have demonstrated impaired sperm nuclear quality, which will affect the results in ART. There is no mutation in screening of *DNAH1* gene that's why we plan to complete the mutational research on other exons of *DNAH1*or in other genes like *CFAP43 and CFAP44*.

P-099 IVF/ICSI outcomes in HIV- vs hepatitis-B positive men. An analysis of 249 fresh and frozen treatment cycles in a prospective case-control study

F. Sergouniotis[1], K. Westling[2], K. Wånggren[3], K. Rodriguez-Wallberg[4]
[1]*Specialist doctor, Section of Reproductive Medicine - Karolinska University Hospital, Stockholm, Sweden*
[2]*Karolinska University Hospital, Department of Infectious Diseases- - Huddinge University Hospital-Karolinska Institutet, Stockholm, Sweden*
[3]*Karolinska University Hospital, Section of Reproductive Medicine, Stockholm, Sweden*
[4]*Karolinska University Hospital-Karolinska Institutet, Section of Reproductive Medicine-Karolinska University Hospital and Division of Oncology-Pathology-Karolinska Institutet, Stockholm, Sweden*

Study question: What are the IVF/ICSI outcomes for HIV-positive men within serodiscordant couples using frozen washed sperm and do they differ from control men with hepatitis B?
Summary answer: IVF/ICSI treatment in serodiscordant couples with HIV-positive men had higher cumulative miscarriage rate compared to controls but a similar cumulative live-birth rate.
What is known already: IVF/ICSI with washed sperm for treatment of HIV-positive men with seronegative partners has shown to be an effective treatment with no higher risk of viral transmission to the partner or the child. Previous studies suggest that the antiviral therapy for HIV might have a negative impact on sperm quality although it is unclear if the IVF/ICSI treatment outcome is compromised in comparison to other couples that undergo IVF/ICSI with the washed-sperm procedure.
Study design, size, duration: Prospective case-control study of serodiscordant couples with HIV-positive men that underwent IVF/ICSI treatment with washed-sperm procedure between Januari 2004 and December 2017. All HIV-positive men were under antiviral treatment at the time of IVF/ICSI and had undetectable serum viral load. The control group consisted of couples with hepatitis-B positive men that underwent IVF/ICSI with washed sperm under the same period. HIV-positive men were categorized to investigate a possible impact of antiviral treatment on sperm quality.
Participants/materials, setting, methods: 53 serodiscordant couples with HIV-positive males underwent 82 fresh and 39 frozen cycles. IVF/ICSI was performed with frozen/thawed sperm that had been washed using double gradient centrifugation. In the control group 56 couples with hepatitis-B positive men underwent 92 fresh IVF/ICSI cycles and 36 frozen. The antiviral treatment

in HIV-positive men included combination of Nucleoside/Nucleotide analog-(NRTI) and Non-nucleoside reverse-transcriptase inhibitors(NNRTIs) in 22 cases or a combination of NRTI with other medication in 31 cases.

Main results and the role of chance: Couples with HIV-positive men were similar to controls in regards to infertility duration (3.76 vs 3.70 years, p=0,9), woman's age (33.40 vs 31.85, p=0.07), woman's BMI (24.42 vs 24.25,p=0,82), man's age (39.19 vs 38.24, p=0.45), smoking in women (17.65% vs 14.29% , p=0,63) or men (40.43% vs 45.45%, p=0,60) .

The treatments resulted in similar yields of mature oocytes (7,62 vs 8,09, p=0,63) and number of fertilized oocytes (5.38 vs 5.43, p=0,94). The cumulative miscarriage rate was higher, but not significantly, in the HIV-group (18,8 vs 11% P=0,31). The cumulative live-birth rate did not differ between the groups (54.72 vs 51.79, p=0,75). HIV virus was not detected in any of the sperm samples at the time of treatment. No partner seroconversion or child infected were reported.

The percentage of motile sperms was significantly lower in NRTI/NNRTI patients than in patients treated with NTRI combined with another medication (36.41 vs 54.48%, p<0.001). However sperm concentration and total sperm count were similar between the treatment categories (57.93 vs 59.13 million sperm/mL, p=0.92 and 190.6 vs 175.8 million sperm,p=0,75, respectively).

Limitations, reasons for caution: Although our center is the only performing treatments for serodiscordant couples in Sweden, the size of this cohort is relatively small. Further research is required to confirm our results.

Wider implications of the findings: Our analysis indicate that IVF/ICSI treatment after sperm washing in serodiscordant couples with HIV-positive men has similar outcomes to that of couples that undergo a similar procedure of sperm washing and ICSI due to viral infections. The type of antiviral regimen might affect the sperm motility in HIV-positive individuals.

Trial registration number: Not applicable

P-100 Adult testicular somatic cell feeders do not facilitate human embryonic stem cell differentiation towards male gametes.

S. Homayun Sepehr[1], C. Rombaut[1], Y. Baert[1], C. Markouli[1], M. Geens[1], K. Sermon[1]

[1]VUB Jette, Reproduction Genetics and Regenerative Medicine -Biology of Testis, Brussels, Belgium

Study question: Does the addition of testicular somatic feeders enhance the differentiation of human embryonic stem cells (hESCs) towards male gametes?

Summary answer: HESCs seeded on testicular somatic feeders did not show higher differentiation efficiency compared to hESCs cultured on Matrigel.

What is known already: For men with non-obstructive azoospermia, creation of functional gametes *in vitro* starting from patient-specific pluripotent stem cells might offer the possibility to father genetically related children. Recent studies reported mouse ESCs (mESCs) differentiating towards functional male gametes resulting in live offspring. Easley et al. (2012) obtained human haploid germ cells from hESCs, but elongated spermatids were not produced. So far, complete *in vitro* spermatogenesis from hESCs has not been reported.

Study design, size, duration: Two hESC lines were cultured for 10, 15 or 20 days on Matrigel using the conditions described by Easley et al. in 2012 (controls). Undifferentiated hESCs were co-cultured on top of inactivated testicular somatic cells for 20 days (exp1). Alternatively, hESCs that have been cultured for 10 days on matrigel (pre-differentiated hESCs) were co-cultured on top of adult testicular somatic cells for another 10 days (exp2). Gene and protein expression and hormonal production were evaluated.

Participants/materials, setting, methods: Testicular tissue from three adult patients undergoing bilateral orchiectomy as part of a prostate cancer tratment was digested and cells were FACS-sorted. The somatic fraction ($EPCAM^-/HLA^+$) was mitotically inactivated. Differentiation efficiency of hESC lines (n=2) was evaluated by immunocytochemistry for the germ cell markers VASA, BOLL, CREM and ACROSIN and by qRT-PCR for VASA, GFRA1, TP1 and ACROSIN. The function of the testicular somatic cell feeder was assessed by testosterone (T) and inhibin B quantification.

Main results and the role of chance: When hESCs were cultured on Matrigel, VASA expression was detected after 10 days of culture and significantly increased after 15 and 20 days. The pre-meiotic marker BOLL and post-meiotic marker ACROSIN were rarely expressed. However, qRT-PCR results showed that GFRA1 and the post-meiotic markers TP1 and Acrosin increased during culture. Although no T was detected, Inhibin B production was detected at the end of the Matrigel culture.

When undifferentiated and pre-differentiated hESCs were seeded on top of inactivated somatic cell feeders, cells either formed colonies in between the somatic cells or formed massive cell clusters on top of the feeder cells. VASA was detected at the end of undifferentiated cell co-culture (20 days). BOLL was barely expressed and the post-meiotic marker CREM was not found.

At the end of the pre-differentiated cell co-culture, VASA was detected. BOLL and CREM were barely expressed.

When VASA positive populations were compared, the highest number of VASA positive cells could be found in the Matrigel culture (1.9-3%) compared to the pre-differentiated cell co-culture (0.2-1.5%) and undifferentiated cell co-culture (0.2-1%).

Limitations, reasons for caution: One medium composition was used during the entire culture period, although spermatogenesis is a very complex multi-step process. hESCs are less naive than mESCs, which might explain the success of the mouse studies.

Wider implications of the findings: This study demonstrated that the presence of an adult testicular somatic feeder did not enhance the differentiation of hESCs. Fetal testicular feeders might be a better environment for initial differentiation.

Trial registration number: N/A

P-101 The effect of advanced paternal age on sperm parameters and on the outcome of in vitro fertilization treatments

N. Toth[1], É.B. Bogar[1], K. Varga[1], A. Vereczkey[1]

[1]Versys Clinics, Human Reproduction Institute, Budapest, Hungary

Study question: How does advanced paternal age (APA) affect sperm parameters and the outcome of intracytoplasmic sperm injection (ICSI) cycles?

Summary answer: Based on our study, APA negatively affects initial sperm count and motility as well as blastulation rate, however, not affects clinical outcomes of ICSI cycles.

What is known already: Over the last decade, delayed childbearing has become a trend in developed countries. It is proven that advanced maternal age (AMA) plays a dominant role in determining the success of *in vitro* fertilization (IVF) treatments. However, the impact of APA on IVF outcomes is still poorly known. Recent studies found that a man's age can affect testicular functions and sperm parameters. Paternal aging was also found to be associated with increased incidence of DNA damage, chromosomal aberrations and embryonic aneuploidy. These can lead to decreased fertilization and blastulation rate or increased miscarriage rate and thus a decreased live birth rate.

Study design, size, duration: In this retrospective study, we collected data on all couples with female age less than 35 years at our private fertility clinic between January 2013 and December 2018. A total of 135 fresh embryo transfer cycles were analysed, and two groups were formed based on the paternal age: <40 years and ≥40 years. Cycles with preimplantation genetic testing were excluded from the analysis.

Participants/materials, setting, methods: In the <40 years group (average age 34.00±3.79) 101 fresh blastocyst transfers were carried out, while in the ≥40 years group (average age 43.18±2.47) 34 blastocyst transfers. Evaluation of all semen parameters were done according to WHO standard criteria (2010). All embryos were fertilized by ICSI using fresh, frozen or testicular sperm extraction sample. The measured IVF outcomes were implantation rate, clinical pregnancy rate and miscarriage rate.

Main results and the role of chance: The mean maternal age did not differ in the two examined groups (31.43±3.32 in the <40 years group and 31.76±4.29 in the ≥40 years group). The mean initial sperm count was significantly higher in the <40 years group than in the ≥40 years group (58.87% vs. 44.38%, p=0.0464) and sperm motility was also significantly higher in the <40 years group (49.98% vs. 37.18%, p=0.0054). The fertilization rate was slightly higher in the <40 years group (70.11%) but not significantly different from the ≥40 years group (66.67%, p=0.4371). We found a significantly higher blastulation rate in the <40 years group compared to the ≥40 years group (60.87% vs. 56.18%, respectively, p=0.02). The clinical pregnancy rate (42.57% (43/101) vs. 61.76% (21/34), p=0.0734) and implantation rate (41.22% (54/131) vs.

52.17% (24/46), p=0.1689) did not differ significantly in the examined groups. We also did not find a significant difference in case of miscarriage rates (22.22% (12/54) in <40 years group vs. 16.66% (4/24) in ≥40 years group, p=0.7634).

Limitations, reasons for caution: The main limitations of this study are small sample size and inclusion of retrospective cases.

Wider implications of the findings: Based on our results, the quality of sperm seems to decline with age, which demonstrates that man's fertility also has a defined lifetime. However, ICSI can compensate for this. With our findings, we would like to draw man's attention to the increasing health risks associated with late childbearing.

Trial registration number: not applicable

P-102 PREVALENCE OF MYCOPLASMA HOMINIS AND UREAPLASMA UREALYTICUM INFECTION IN CRYOPRESERVED SPERM FROM DONOR SPERM BANK

A. Liprino[1], A. Guglielmino[1], C. Alecci[2], S. Romano[2], P. Grasso[2], B. Bonaccorsi[2], F. Giacone[2], S. Chamayou[2]

[1]UMR - Unità di Medicina della Riproduzione, ivf, Catania, Italy

[2]UMR - Unità di Medicina della Riproduzione, laboratory, Catania, Italy

Study question: What is the prevalence of Mycoplasma Hominis and Ureaplasma Urealyticum infection in cryopreserved donor sperm?

Summary answer: Mycoplasma Hominis and Ureaplasma Urealyticum may contaminate sperm bank imported sperm straws with a prevalence of 3.5% and 5.2% respectively, in normal sperm parameters post-thaw.

What is known already: Between 8 and 35% of male infertility is associated with infection of the genital tract. Even if many data are available for symptomatic infections, it is difficult to estimate the impact of asymptomatic infections on fertility. The asymptomatic infections can reduce fertility through alteration of spermatogenesis and reduction of sperm motility. Mycoplasma Hominis and Ureaplasma Urealyticum reduce sperm quality acting on the nuclear chromatin of the spermatozoa and on the embryonic development. Although the effects of these microorganisms are known, sperm banks do not always scan for them if donors do not show the classic symptoms of infection.

Study design, size, duration: This laboratory - based cross sectional study was performed on straws of cryopreserved sperm from 114 donors imported from a Danish sperm bank between January 2015 and December 2018. For each sperm donor two straws of the same collection were requested, one was kept in quarantine and the other was evaluated for conventional parameters, in accordance with the WHO 2010 Guidelines, and for Mycoplasma Hominis and Ureaplasma Urealyticum infection as required by Italian regulation.

Participants/materials, setting, methods: For each sperm donor one straw was kept in quarantine and the other one was evaluated for quality conventional parameters and for infection by bacteriological culture. In cases of positivity of the culture with concentrations $^{3}10^{4}$cfu/ml (MYCOPLASMA IST2-Biomerieux SA-France) a confirmation test Real-Time PCR, using 2 ml of DNA(Roche diagnostics GmbH, Mannheim, Germany), was performed.

Main results and the role of chance: After thawing the sperm parameters was normal according to WHO guidelines 2010. The cryo-survival rate was over 50% of the initial motility, no leukocytospermia was found. In the donor sperm, the prevalence of infection were, respectively, 3.5% (4/114) for Mycoplasma Hominis only, 5.2% (6/114) for Ureaplasma Urealyticum only and 3.5% (4/114) for both pathogens. The samples positive for at least one of the two microorganisms were not used for reproductive treatment and were eliminated as required by Italian regulation.

Limitations, reasons for caution: only donor semen samples have been analyzed in this study. No data about sperm donor pregnancies during other donations or abortion rates were evaluated.

Wider implications of the findings: The sperm from donor sperm banks can be contaminated with Mycoplasma Hominis and Ureaplasma Urealyticum, with possible negative effects on oocyte fertilization and embryonic development. These results demonstrate how scanning for these microorganisms is opportune during the recruitment of donors, thus improving the outcome of donation treatment.

Trial registration number: Not applicable

P-103 Sperm DNA Damage have an Effect on aneuploidy-euploidy of Embryos in ICSI-CGH Array Cycles

Z. Zandieh[1], A. Gavahi[1], F. Asgari[1], F. Amjadi[1], V. Akram[2], L. Bajelan[3], A. Aflatoonian[4], R. Aflatoonian[5]

[1]Iran University of Medical Sciences- Akbarabadi hospital, IVF unit, Tehran, Iran

[2]Tehran University of veterinary medicine, Biochemistry, , Iran

[3]Mehr hospital, Mehr IVF unit, , Iran

[4]Shahid Sadoughi university of medical sciences, Research and clinical center for infertility, Yazd, Iran

[5]Royan Institute, Department of Endocrinology and female Infertility- Reproductive biomedicine Center, Tehran, Iran

Study question: What is the effect of sperm DNA damage on embryo chromosome aneuploidy and the level of semens MDA, ROS and TAC parameters in ICSI-CGH array cycles?

Summary answer: sperm DNA damage increase embryo chromosome aneuploidy. Also DFI have negative effects on semens MDA, ROS and TAC parameters.

What is known already: Studies have shown that sperm DNA fragmentation is higher in infertile men. There is clinical evidence to show that sperm DNA damage could be a marker of sperm quality and extensive data exist on the relationship between DNA damage and male fertility status. Sperm DNA fragmentation can be the most common reason for the transmission of anomalies of the father's DNA to a child that seen in a high percentage of sperms in infertile men.

Study design, size, duration: 40 patients with recurrent implantation failure (RIF) were selected. both women and men appeared to have no problem. All women were between 25-35 and stimulated with GnRH agonist. 2 groups were defined, 1: DFI > 20 % and 2: DFI < 20%. Intra-cytoplasmic sperm injection was also performed and then the day 3 embryos were subjected to blastomere biopsy and evaluated by Genomic Comparative Hybridization (CGH array).

Participants/materials, setting, methods: semen parameters in two groups were analyzed by CASA for motility and morphology and live ratio. Also, the level of total ROS, TAC, DNA fragmentation and MDA were evaluated by DCFH(by Fluorimetry) , ELISA kit, TUNEL assayby flowcytometry and ELISA respectively. Day 3 embryos were evaluated for aneuploidy by aCGH method. Also the correlation between embryo aneuploidy and DFI and semen parameters were evaluated in both groups.

Main results and the role of chance: The results of this study showed that sperm with high DFI (DFI> 20) significantly increased the number of the aneuploidy embryo than sperm with low DFI (P <0.001). Also, by increasing the DFI, the level of MDA significantly increased (P <0.001). The level of ROS and TAC were increased and decreased respectively but they was not significant by DFI (P >0.001). but there is no relationship between sperm ROS, TAC and MDA with day3 embryo aneuploidy.

Limitations, reasons for caution: the main limitation of the present research was the lack of embryo transfer at blastocyst stage.

Wider implications of the findings: These data indicate that sperm DNA damage have a significant effect on embryo chromosome aneuploidy. Embryo selection by aCGH should be considered in couples with high DNA fragmentation.

Trial registration number: NA

P-104 DNA damage after in vitro exposure to very low concentration of combusted cerium nanoparticles (CoCeO2NPs) and to CoCeO2NPs + benzo(a)pyrene in rat and human gametes

M. Cotena[1], M. Auffan[2], V. Tassistro[1], A. Netter[1], J. Rose[2], J. Perrin[3]

[1]Aix Marseille Université, Faculty of Medicine, Marseille, France

[2]European center of research and teaching of geosciences of environment, Nanotoxicology, Marseille, France

[3]Aix Marseille Université - AP-HM La Conception- Centre Clinico-Biologique d'Assistance Médicale à la Procréation - CECOS, Faculty of Medicine, Marseille, France

Study question: Do *in vitro* gametes exposure to very low concentration of $CoCeO_2$NPs and to $CoCeO_2$NPs + Benzo(a)pyrene induce significant and similar DNA damage ?

Summary answer: *In vitro* gametes co-exposure to $CoCeO_2$NPs + Benzo(a)pyrene induced statistically higher DNA damage than exposure to $CoCeO_2$NPs alone in rat and human.

What is known already: Cerium dioxide nanoparticles (CeO_2NPs) are widely used as diesel additive and are released in the air after engine combustion. The Organization for Economic Cooperation and Development included CeO_2NPs in the priority list of nanomaterials requiring urgent evaluation. *In vitro* exposure of human and mouse sperm and cumulus oocyte complexes (COC) to very low concentrations of pristine CeO_2NPs induce significant DNA damage. Benzo(a)pyrene (BaP) is also released in the air by diesel combustion and is known to induce DNA damage in sperm and COC. Nevertheless, pristine CeO_2NPs are modified by combustion; the impact of $CoCeO_2$NPs exposure and to $CoCeO_2$NPs+BaP remains unexplored.

Study design, size, duration: Pristine CeO_2NPs were extracted from Envirox™ diesel additive and combusted at 850°C, (average combustion temperature in a diesel engine), to obtain $CoCeO_2$NPs. Crystalline structure of $CoCeO_2$NPs was analysed by X-ray Diffraction. Rat gametes were sampled in epididymis and oviducts after euthanasia of five mature males and fourty 4 weeks old females (after ovarian stimulation). Human frozen sperm from fertile donors were purchased from Germetheque biobank (France).

Participants/materials, setting, methods: Human and rat gametes were exposed *in vitro* to very low concentrations of CoCeO2NPs [1 to 1.10^3 $\mu g.l^{-1}$] and human sperm to 1 $\mu g.l^{-1}$ $CoCeO_2$NPs + 25µMol BaP during 1 hour in Ferticult© Medium + 1% DMSO at 37°C, 5% CO2. DNA damage was analysed by alkaline comet assay (ACA) and quantified by Olive Tail Moment (OTM) in oocytes and follicle cells and by % Tail DNA in sperm.

Main results and the role of chance: In rat oocytes and follicle cells, exposure to 1 $\mu g.l^{-1}$ $CoCeO_2$NPs induced significantly higher DNA damage (mean±SEM OTM = 10.26±0.36 and 4.91±0.29, respectively) compared with unexposed controls (2.21±0.18 and 0.72±0.05, respectively) and with higher $CoCeO_2$NPs concentrations ($p < 0.0001$). In rat sperm, exposure to 1 $\mu g.l^{-1}$ $CoCeO_2$NPs induced significantly higher DNA damage (mean %Tail DNA±SEM = 21.23 ± 0.37) compared with unexposed control (11.06±0.24) and with higher $CoCeO_2$NPs concentrations ($p <0.0001$). In human sperm, exposure to 1 $\mu g.l^{-1}$ $CoCeO_2$NPs also induced significantly higher DNA damage (mean % Tail DNA±SEM = 32.06 ± 0.54) compared with unexposed control (11.96 ± 0.30) ($p < 0.0001$); co-exposure to 1 $\mu g.l^{-1}$ $CoCeO_2$NPs + 25µM BaP induced significantly higher DNA damage (mean % Tail DNA±SEM = 33.63 ± 0.67) compared with 25µM BaP alone (28.57 ± 0.54) and 1 $\mu g.l^{-1}$ CoCeO2NPs alone (24.62± 0.52) ($p < 0.0001$). As in our previous results, obtained in human sperm after *in vitro* exposure to various concentrations of pristine CeO_2NPs [10 to 1.10^4 $\mu g.l^{-1}$], DNA damage was inversely proportional to the $CoCeO_2$NPs concentrations; we might hypothesize that our results are related to the lower aggregation states at low concentration, inducing a higher surface contact between cells and $CoCeO_2$NPs.

Limitations, reasons for caution: These results cannot be extrapolated to *in vivo* toxicity of $CoCeO_2$NPs after inhalation, but demonstrate that interactions between $CoCeO_2$NPs and germ cells induce significant DNA damage. Additional data should be needed to assess DNA damage in rat COC after *in vitro* exposure to very low $CoCeO_2$NPs concentrations and BaP.

Wider implications of the findings: The co-exposure to very low concentrations of $CoCeO_2$NPs and BaP showed for the first time a cumulative genotoxic impact on human sperm. Potential impacts of diesel exhaust exposure in couples and pregnant women are a major concern for public health, highlighting the need for *in vivo* studies.

Trial registration number: Animal experiment agreement N° 15447-2018061110211950.

P-105 The curious incidences of male factor infertility and number of ICSI cycles in the UK.

I. Karapanos[1], G. Bahadur[1], P. Hinstridge[1]

[1]*North Middlesex Hospital, Obstetrics and Gynaecology, London, United Kingdom*

Study question: What is the correlation between male-factor subfertility and the rate of IVF/ICSI cycles in the UK from 1995 to 2016?

Summary answer: The rate of IVF cycles using ICSI does not reflect the drop in male factor infertility throughout the years.

What is known already: The WHO guidance on normal semen analysis has changed over the years, resulting in a significant change of what is considered abnormal. Severe male infertility can justify the use of IVF/ICSI procedures. Specialist-Urology referral is currently reserved for patients for whom ICSI is not available. However, increasing numbers of men diagnosed with male factor issues are seeking advice and further investigations. Experienced clinical andrologists investigating these men know that treatable conditions often can be detected.

Study design, size, duration: Continuous collection of UK data is part of the regulatory functions of the HFEA statutory body, and clinics have to submit their annual data as part of their licence to operate. The data is available freely on their website and the various sub categories were analysed from 1995 to 2016.

Participants/materials, setting, methods: The data is derived from the HFEA website from figures available in the public domain, involving 1223629 cycles of IVF/ICSI. The data forms part of the mandatory requirement for clinics to obtain a licence to practice IVF/ICSI procedures in the UK and is therefore a comprehensive survey of UK practice.

Main results and the role of chance: The percentage of IVF cycles with 'primary male infertility' has diminished hugely since the beginning of our data set: 36.5% in 1995 to 0.26% in 2016.The percentage of IVF cycles with 'male factor' recorded as a contributor to their subfertility has reduced over the years. However, the most obvious drops can be explained by the reissuing of WHO guidance on semen analysis in 1999 and again in 2010 (before 1998 it was >80%; from 2001-2009 it was 40-50%; from 2011-2016 it was 30-40%). The rate of ICSI cycles as a percentage of all IVF cycles increased rapidly from 1995-2000 (this is to be expected as the technique was first described in 1991). It continued to rise throughout the 2000s, peaking at 43% in 2010 and 2011. Since then it has reduced somewhat to 38% in 2016. However, since 2011 there is a persistent discrepancy in between the percentage of IVF cycles using ICSI and the percentage where male factor is recorded as a contributor. In each year, between 5.2 and 6.4% of IVF cycles used ICSI despite there being no recorded male factor subfertility. In 2016, this equated to >4000 cycles per year.

Limitations, reasons for caution: The HFEA data is comprehensive, therefore removing biases of data collection. However, it is equally difficult for researchers to validate the data entered and therefore some caution must be applied to interpretation. Multiple factor correlation would therefore be difficult to evaluate for contributors and confounders.

Wider implications of the findings: It is possible that the above findings represent under-reporting to the HFEA, but with such a consistent rate it is hard to put this down to random error only. It raises the possibility that ICSI is not universally being recommended in an evidence-based manner.

Trial registration number: Not applicable

P-106 Cryopreservation of extremely low quantities of spermatozoa retrieved with microdissection testicular sperm extraction (micro-TESE) from non-obstructive azoospermia (NOA) patients

L. Shatalova[1], O. Pravdyuk[1], M. Gryshchenko[2]

[1]*Academician V.I. Gryshchenko Clinic for Reproductive Medicine, Embryological laboratory, Kharkiv, Ukraine*

[2]*Academician V.I. Gryshchenko Clinic for Reproductive Medicine, Reproductive Technology, Kharkiv, Ukraine*

Study question: Is that possible both to keep the viability and to exclude quantity losses during cryopreservation of single microsurgical retrieved spermatozoa from NOA patients?

Summary answer: The utilized method allows to cryopreserve extremely low numbers of spermatozoa retrieved with micro-TESE from NOA patients with normal survival rate and without quantity losses.

What is known already: Cryopreservation of single spermatozoa(CSS) is needed when only very limited numbers of viable spermatozoa are available as in cases of NOA. Conventional cryopreservation in relatively large volume is not optimal for those samples because associated with the quantity losses of spermatozoa and also requires prolonged post-thawing search-and-find step prior to ICSI. There are different carriers proposed for CSS: hamster zona, ICSI pipettes, alginate spheres, cryoloop, high security straw, cell slipper. However, there is no standard technique for CSS.

Study design, size, duration: For this case series twenty-three men with NOA who had micro-TESE in the Academician V.I. Gryshchenko Clinic for Reproductive Medicine were selected from November 2017 till December 2018. CSS was performed only in cases where an extremely limited number of motile spermatozoa was observed. Samples with a high number of motile spermatozoa were cryopreserved by a conventional method.
Participants/materials, setting, methods: Micro-TESE samples were prepared and evaluated for presence or absence of motile spermatozoa. For CSS from 4 up to 12 (24 in total) motile spermatozoa were selected and moved with micromanipulator to the microdrops of cryopreservation medium on the surface of polystyrene plate which was then frozen in LN_2vapor phase and subsequently immersed into liquid nitrogen. For thawing plates with microdrops containing cryopreserved spermatozoa were immersed in ICSI dishes with oil prewarmed to 37C.
Main results and the role of chance: Micro-TESE samples from twenty-three patients were evaluated for the presence of spermatozoa. In nine patients motile spermatozoa were found, in three patients only immotile spermatozoa were found, and in eleven patients spermatozoa were not found. CSS was performed for seven patients, in six of which homogenized testicular tissue was also cryopreserved by conventional method in parallel.

Five CSS samples were thawed to evaluate post-thawing motility and recovery rate. Out of 24 cryopreserved spermatozoa all 24 spermatozoa were found. Post-thawing motility of cryopreserved spermatozoa was 50±9% (12 of 24). In one case single frozen spermatozoa were used to inject the oocytes in ICSI cycle. Normal fertilization was achieved.
Limitations, reasons for caution: Based on the small number of participants in this study, a larger study is needed to evaluate the potential of this technique.
Wider implications of the findings: Based on the results obtained the utilized CSS technique can be potentially useful for severe male factor cases besides NOA and also for male fertility preservation.
Trial registration number: not applicable

P-107 Comparison of clinical pregnancy rate in donor insemination between women without a male partner and women with a partner at the insemination moment.

I. ROMERO GARCIA[1], J.C. García Lozano[2], L.A. María Dolores[3], G. Julia[2], G. Antiñolo Gil[4]
[1]MIR 4º año Obstericia y ginecología, Obstetricia y Ginecología Hospital Virgen del Rocío, Sevilla, Spain
[2]FEA en Obstetricia y ginecología, Medicina Materno Fetal- Genética y Reproducción, Sevilla, Spain
[3]Embrióloga, Genética y Reproducción Hospital Virgen del Rocío, Sevilla, Spain
[4]Profesor Titulado de la Universidad de Sevilla- jefe de la Unidad de Medicina Fetal-Genética y Reproducción del Hospital Virgen del Rocío, Unidad de Medicina Materno Fetal- Genética y Reproducción del Hospital Virgen del Rocío, sevilla, Spain

Study question: Are there any differences between the D-IUI results performed on women without male partners at the moment of insemination, and women with male partners?
Summary answer: The pregnancy rate through D-IUI was higher in the group of women with male partner
What is known already: Most studies have not shown differences in the pregnancy rate through D-IUI between women with a male partner and women without a male partner, whether homosexual or heterosexual.

Published studies suggest a higher incidence of polycystic ovarian syndrome and some factor related with PCOS in homosexual women, these circumstances can increase even more the success percentages of reproduction techniques.

Giselle Crawford published a study in 2014 in which she proved that pregnancy rates through FIV were higher when women were exposed to seminal plasma at the previous moments before the realization of the technique, with a statistical significance
Study design, size, duration: Retrospective study in which donor's semen inseminations done in our Reproduction Unit have been analysed between January 2006 and December 2017, and the results of two different groups have been compared: one of them formed by women with a male partner at the time of the insemination and another group of women without a male partner, either homosexual or heterosexual.
Participants/materials, setting, methods: Participants were all women that underwent D-IUI cycles in this centre between January 2006 and December 2017.

188 patients participated, 81 of them not having a male partner and 107 of them with a male partner.

Inclusion criteria used for the D-IUI were: 1.Age (between 18 and 40); 2.Women without another previous healthy child; 3.Permeable tubes; 4. Ovarian function preserved. The maximum of cycles per woman was 6.
Main results and the role of chance: We analysed 501 D-IUI cycles, from which 223 cycles were realized on women without a partner, and 278 of them were done on women with a male partner. The clinical pregnancy rate per woman was lower in the group with women without a male partner than in the group of women with a male partner (35.8%) than in the group of women with a male partner 57.94% (p = 0.002).

The average number of D-IUI needed to obtain a clinic pregnancy in the group of women without a partner was 7.69, and in the group of women with partners was 4.48. When dividing each group by age:

- <35 : The pregnancy rate in the group of women without a partner was lower (41.9%) than in the group of women with a male partner (66.2%) (p =0.02).

The number of cycles needed to achieve a pregnancy in the group of women without a partner was 6, and in the case of women with a male partner was 3.9.

- >35 years: the pregnancy rate was 32.6% in women without a partner and 42% in women with a partner (p= 0.26). The average number of cycles per pregnancy was 8.9 and 6.4, respectively.

Limitations, reasons for caution: Some patients of the group without a male partner at the time of insemination may be maintaining relationships with men but do not recognize them as a couple at the time of therapy, which could equalize the conditions with the other group of patients and skew the results.
Wider implications of the findings: In opposition to what has been suggested in previous studies, D-IUI success rates are higher in women with a male partner at the time of the insemination. The immunoregulation created by the uterus's exposure to the seminal plasma might be one of the processes that influence such success
Trial registration number: Not applicable

P-108 Dynamic H2AX-phosphorylation reveals the sperm capacity to label DNA damage in protection of paternal genome

M. Ferrer Buitrago[1], A. Barberà[2], J.J. Bataller-Sánchez[2], V. Moliner-Aguilar[1], C. Calatayud-Lliso[3], M. Ruiz-Jorro[4]
[1]CREA-Centro Médico de Reproducción Asistida, Research and Education, Valencia, Spain
[2]CREA-Centro Médico de Reproducción Asistida, Andrology, Valencia, Spain
[3]CREA-Centro Médico de Reproducción Asistida, Clinical Department, Valencia, Spain
[4]CREA-Centro Médico de Reproducción Asistida, Clinical Department. Andrology, Valencia, Spain

Study question: Are mature sperm capable to identify and label DNA double strand breaks?
Summary answer: Dynamic H2AX-phosphorylation revealed a time-dependent increase of double strand breaks, and the capacity of mature sperm to identify and label this type of DNA damage.
What is known already: The phosphorylation of histone-2AX (gamma-H2AX) is an epigenetic hallmark which occurs in response to DNA double strand breaks (DSBs) in any cell type, including sperm and oocytes. Gamma-H2AX stimulates oocyte's DNA repair machinery to overcome DSBs lesions via NHEJ-pathway at pronuclear stage. Moreover, mouse zygotes expressing high levels of gamma-H2AX into male pronuclei showed poor embryo development or total arrest. These observations support the importance of DNA repair signaling, and the negative impact of paternal DSBs on embryo development. Sperm gamma-H2AX is associated with chromatin remodeling and physiological DNA fragmentation. However, variation of gamma-H2AX levels in laboratory conditions remains unknown.
Study design, size, duration: A total of 10 sperm samples were evaluated at three time points: t-0h, t-2h, t-24h. t-0h defines the time for sample fixation immediately after density gradients. Sperm samples were left at room

temperature for 2 and 24 hours. Two replicates were prepared per sperm sample, with a total of 200 sperm analyzed per replicate. Mean proportion of positive gamma-H2AX per sample was reported. Negative control was included in each sample preparation.

Participants/materials, setting, methods: Participants in our IVF program underwent sperm gamma-H2AX analysis and DNA fragmentation test (TUNEL). Gamma-H2AX sites were detected by immunofluorescence following standard fixation and permeabilization procedures. An additional DNA digestion procedure was used to expose target epitopes to primary antibody. Sperm samples were prepared by density gradients before performing DNA fragmentation and gamma-H2AX assays.

Main results and the role of chance: We observe that H2AX-phosphorylation increases in a time-dependent manner. Basal levels of gamma-H2AX were 2,99%±1,38%. After 2 hours, H2AX-phosphorylation showed in average a higher proportion of positive sperm (4,80%±5,08%). Similarly, an increase in the percentage of gamma-H2AX sperm after 24 hours was observed (7,31%±6,93%; Test-t p=0,025). To normalize the variation of gamma-H2AX levels over time, results were expressed as the proportion of positive sperm detected after 2 hours (t2-t0/2) and 24 hours (t24-t0/24). We observed that gamma-H2AX levels increase particularly during the first 2 hours after the sample preparation (t2-t0/2=1,10; t24-t0/24=0,11). Interestingly, in those samples with abnormal TUNEL dynamics (t2-t0/2) ≥ 2,5 %), gamma-H2AX levels at both, 2 and 24 hours, were higher than in samples in which TUNEL dynamics were normal (t2-t0/2= 1,96 vs t2-t0/2= 0,04 and t24-t0/24= 0,12 vs t24-t0/24= 0,10).

Limitations, reasons for caution: Detection of gamma-H2AX is an added-value to infer DNA fragmentation results. Dynamics of gamma-H2AX allows evaluating the efficiency of DNA damage signaling machinery in mature sperm.

Wider implications of the findings: The current data has been obtained in a limited number of samples. Further investigations are required estimate the impact of gamma-H2AX further human embryonic development.

Trial registration number: n/a

P-109 Temporal trend in semen quality among candidate sperm donors over 23 years: fertility potential over time.

U.R. Punjabi[1,2], A. Sugihara[1,2], D. De Neubourg[1,2]

[1]*University Hospital of Antwerp, Centre for Reproductive Medicine, Edegem, Belgium*

[2]*University of Antwerp, Faculty of Medicine and Health Sciences, Antwerp, Belgium*

Study question: Is there a temporal trend in semen parameters and fertility potential of unselected candidate sperm donors over the last 23 years?

Summary answer: There has been no substantial clinical change in semen quality and fertility potential of candidate donors over a period of 23 years.

What is known already: A recent meta-regression analysis by Levine et al.2017 reported a temporal trend in sperm count showing a significant decline in sperm count between 1973 and 2011 in Western countries. Studies have shown geographical variation of semen quality. Semen quality has been shown to have declined in many areas of the world, plausibly associated with multiple environmental influences and lifestyle factors. Significant decline in male reproductive health has serious implications. Nonetheless, the issue remains controversial due to methodological errors in semen analysis.

Study design, size, duration: A retrospective cohort study of semen analysis of 439 men presenting as candidate sperm donor, regardless of proven fertility capacity, at the University Hospital of Antwerp between January 1995 and December 2017.

Participants/materials, setting, methods: The recruitment process was mostly conducted by national media campaigns and oral publicity. The reported sperm parameters were analyzed on the fresh ejaculate within 1 hour after production. Semen analysis was performed in accordance with the recommendations of the WHO manuals. Technicians received specific training via semen courses before carrying out the analysis over the entirety of the study period. Internal and external quality controls were performed regularly.

Main results and the role of chance: The mean (± standard deviation) age of candidate donors was 29.5 (± 7.3 years). The mean ejaculate volume (3.6 ± 1.7 ml), sperm concentration (71.1 ± 60.6 M/ml), progressive motility (56.2 ± 15.6 %) and morphology (10.0 ± 5.7 %) of a candidate's first semen sample was markedly higher than the fifth percentile values published in the WHO 5th Edition.

The multiple linear regression model taking into account year of donation, abstinence duration and year of birth showed a discrete, though statistically significant, decline per year of donation for total motility (β= -0.03, p< 0.05) and morphology (β= -0.15, p< 0.05). Substitution of year of birth by age revealed similar results (respectively β= -0.02, p< 0.05 and β= -0.18, p< 0.05). Semen concentration, ejaculate volume and total sperm count did not change significantly over the study period. The mean (± standard deviation) clinical pregnancy rate per effective donor recruited (n=104), defined as the number of pregnant women per number of women who initiated treatment with a donor's sperm, was 68.8% ± 26.2%. This measure did not show a significant change in function of year of donation (β= -0.30, p= 0.52).

Limitations, reasons for caution: Retrospective study, no adjustment for potential confounders such as lifestyle of the candidate donor or factors related to the acceptor.

Wider implications of the findings: These findings concerning sperm quality/fertility potential of candidate donors are reassuring given reports of decline. However, sperm quality remains the cornerstone of male fertility diagnosis and is considered an indicator of overall health, as such vigilance is required and research focusing on the prevention of sperm deterioration should be ongoing.

P-110 Nanofibrous scaffold as a promising substrate for differentiation of embryonic stem cells toward germ-line

M. Vardiani[1], G. Mazaher[2], G.N. Marefat[3], K. Morteza[4], N. Hamid[3]

[1]*Department of Biology and Anatomical Sciences- School of Medicine- Shahid Beheshti University of Medical Sciences- Tehran- Iran, Department of Biology and Anatomical Sciences, Tehran, Iran*

[2]*Iran University of Medical Sciences- Tehran- Iran, Department of Tissue Engineering & Regenerative Medicine- Faculty of Advanced Technologies in Medicine-, Tehran, Iran*

[3]*Shahid Beheshti University of Medical Sciences- Tehran- Iran, Department of Biology and Anatomical Sciences- School of Medicine, Tehran, Iran*

[4]*Iran University of Medical Sciences- Tehran- Iran, Department of Anatomical Sciences, Tehran, Iran*

Study question: Can nanofibrous scaffold (NS) promote differentiation of embryonic stem cells (ESCs) to germ-line cells.

Summary answer: NS significantly increase the differentiation rate of ESCs toward to germ-line cells when co-cultured with sertoli cells.

What is known already: The increasing prevalence of male infertility due to disability in production of functional sperms has remained as a main problem worldwide. The development of a new and reliable procedure for guided differentiation of stem cells toward sperm-producing cells may be a new window of hope for such infertile males.

Study design, size, duration: In this study, we studied the effects of nanofibrous scaffold on differentiation of ESCs co-cultured with sertoli cells toward germ-line cells. Nanofibrous scaffold were fabricated by electrospinning. Sertoli cells and ESCs were isolated from NMRI mice. The cells were treated with bone morphogenetic protein 4 (BMP4) to stimulate differentiation of ESCs. The differentiation of ESCs were studied at days 3 and 7 of induction with BMP4.

Participants/materials, setting, methods: Mechanical and biological properties of the scaffold for sertoli cells and ESCs were then studied *in vitro*. ESCs were cultured on gelatin nanofibrous sheet and then transferred to cell culture plate seeded with sertoli cells. The cells were feed using differentiation media containing BMP4. The differentiation value of ESCs was then measured after 3 and 7 days by different cellular and molecular evaluations.

Main results and the role of chance: NS showed a uniform morphology with good biocompatibility for both sertoli cells and ESCs. The ESCs cultured on NS co-cultured with mitomycin C-treated sertoli cells showed higher level of differentiation toward germ-line specific gene markers such as MVH, DAZL and others. The results showed that more than 50% of the ESCs seeded on NS expressed MVH, significantly higher than those cells cultured on plastic surface of cell culture plate. The ESCs seeded on culture plate showed minimum differentiation. Based on our findings, co-culture of ESCs with sertoli cells on both 3D nanofibrous scaffold and culture plate showed higher level of guided

differentiation when compared to those ESCs cultured on NS and culture plate without sertoli cells. This data is consistent with other relevant studies.
Limitations, reasons for caution: Culture of ESCs on one side of NS is difficult due to low mechanical property of nanofibrous sheet. It is suggested to improve mechanical behavior of NS using cross-linking agents or some blends. The function of the differentiated cells also need to be determined.
Wider implications of the findings: Our results are in agreement with other studies showing the positive effects of 3D scaffolds for improving proliferation and guided differentiation of stem cells. Many studies are underway to develop a new strategy or factors to increase differentiation of stem cells to a specific cell line.
Trial registration number: NA

P-111 Sperm freezing in 0.25 ml straws. Protocol optimization

A. Belmonte Tebar[1], I. Ochando Sanchez[2], P.J. Soria-Meneses[1], J. Bartolomé-García[2], A. Jurado-Campos[1], R. Bernabeu[2], J.J. Garde[1], M.D.R. Fernandez-Santos[1]
[1]University of Castilla-La Mancha, SaBio IREC UCLM-CSIC-JCCM, Albacete, Spain
[2]Instituto Bernabeu, Biología de la reproducción, Albacete, Spain

Study question: What is the most appropriate protocol for the sperm freezing in 0.25 ml straws?
Summary answer: Cooling time of 20 minutes at 4°C followed by 20 minutes nitrogen vapors recover higher proportion of live sperm unaffecting their motility and mitochondrial activity.
What is known already: Despite the successive improvements in the techniques of human sperm cryopreservation, today there are no optimized protocols that allows to recover samples with similar quality to that observed in fresh. Find the freezing and thawing rates and the most appropriate hardware are some of the most important aspects to consider for the optimization of this process.
Study design, size, duration: 48 sperm samples from 12 healthy young donors were collected (abstinence 48-72h) and cryopreserved following the WHO manual (2010) guidelines.Each sample underwent four cooling protocols: 40 minutes at 4°C plus 40 minutes nitrogen vapor, 20 minutes at 4°C plus 40 minutes nitrogen vapor, 40 minutes at 4°C plus 20 minutes nitrogen vapor and 20 minutes at 4°C plus 20 minutes nitrogen vapor.Evaluation after thawing: Motility (CASA), viability, mitochondrial membrane potential and membrane integrity (flow cytometry).
Participants/materials, setting, methods: Sperm donors were selected according to ESHRE guidelines for gamete donation. After liquefaction, we washed the sperm samples with PBS and diluted them in freezing medium (Irvine Scientific). Extended spermatozoa were loaded into 0.25-mL plastic straws and cooled down following the experimental design. The straws were thawed at 37 °C for 7 min. Data were analyzed by linear mixed-effects models using *SPSS Statistics* (IBM, versión 23).

Subsequently, motility, viability and membrane integrity studies were carried out.
Main results and the role of chance: The treatment of 20 minutes at 4°C followed by 20 minutes in nitrogen vapors, is the most suitable for freezing in straws of 0.25ml since it is the one that allows recovering a greater proportion of live sperm ($p = 0.036$) not affecting motility, viability or membrane integrity.
Limitations, reasons for caution: It would be interesting to compare the results obtained against those obtained with the protocol in straws of 0.5 ml. The number of samples is limited and more studies are needed to contrast these results.
Wider implications of the findings: The routine use of this protocol would mean a better management of the procedures for freezing, preparing and using of sperm, avoiding unnecessary losses of specimens.
Trial registration number:.

P-112 Evaluation of the ProAKAP4 Detection kits as functional tests of sperm quality under stress conditions

M. Delehedde[1], B. Demouveaux[2], G. Remy[3], J.L. Desseyn[2], V. Mitchell[4], A.L. Barbotin[5], P. Gosset[3], M. Pichavant[3], N. Sergeant[6]
[1]SPQI, Research, Lille, France
[2]Institut National de la Santé et de la Recherche Médicale, Unité Mixte de Recherche 995, Lille, France
[3]Institut Pasteur de Lille, Unité 1019 INSERM CNRS UMR8204, Lille, France
[4]SPQI, CHRU de Lille, Lille, France
[5]Institut National de la Santé et de la Recherche Médicale, CHRU de Lille, Lille, France
[6]SPQI, Institut National de la Recherche Médicale UMRS 1172, Lille, France

Study question: Is proAKAP4 sperm concentration as evaluated by 4MID® tests, a pertinent new parameter to evaluate sperm quality in environmental stress conditions?
Summary answer: The 4MID® tests can be easily used to quantify proAKAP4 concentrations and concentration modulations under environmental and oxidative stress conditions in various settings.
What is known already: ProAKAP4 is the precursor of the AKAP4 protein that is required for motility, capacitation and fertilization. ProAKAP4 was recently described as a reservoir of sperm motility and a pertinent read out of sperm quality in mammals. As sperm quality assessment is still challenging, there is a real need for functional test of spermatozoa quality to improve fecundation success rate.
Study design, size, duration: In this study, both clinical data from a cohort of patients in assisted reproduction center and preclinical data from mice models design to study oxidative effects on fertility were collected.
Participants/materials, setting, methods: ProAKAP4 modulations were measured in patients and animals using dedicated 4MID® kits and by proteomic methods. 100 patients including smokers and no-smokers as well as normozoospermic patients and men with abnormal sperm parameters (WHO 2010 criteria) were included. In the experimental setting, mice were under low or high fat diet and placed in a cigarette smoke atmosphere for 5 months. Mice testes and epididymis spermatozoa were collected and analyzed for proAKAP4 and oxidative marker expression.
Main results and the role of chance: Using 4MID® kits and proteomic methods, our results showed that proAKAP4 in both human and mice sperm is significantly correlated with sperm motility and inversely correlated with DNA fragmentation. Cigarette smoke had clearly a negative impact on proAKAP4 expression in both human and mice spermatozoa. Indeed, in our different mice models, we showed that proAKAP4 concentrations were diminished by up to 2.5-fold in male under cigarette smoking. Furthermore, antioxidants as added in drinking water improved significantly the proAKAP4 levels in smoking mice as well as in overweight and obese mice. Furthermore, in a preliminary series of ART patients, we showed that high level proAKAP4 were significantly correlated with a lower proportion of abortions in intrauterine insemination settings. The marker proAKAP4 can be considered then as a pertinent new sperm parameter that could be assessed under any environmental conditions impacting male fertility or any antioxidant therapy. The detection of proAKAP4 using the 4MID® kit is a robust method to evaluate sperm quality.
Limitations, reasons for caution: The limited patient cohort might not be fully representative of the general population. Larger cohorts of mens from infertile couples and from volunteers are needed to substantiate the clinical application of the 4MID® test. With animal models to evaluate oxidative stress, we evaluate proAKAP4 present in epididymis spermatozoa.
Wider implications of the findings: The 4MID® tests could represent a pertinent sperm parameter to be evaluated routinely, that then may highlight the quality of spermatogenesis and consequently the sperm quality. This new parameter may be assessed during investigations for male infertility or to evaluate impact of antioxidative therapeutic approaches.
Trial registration number: not applicable

P-113 Novel association between apoptotic sperm biomarkers with seminal biochemical parameters and acetylcholinesterase activity in patients with teratozoospermia

A. Oumaima[1], I. Zidi[1], O. Tekeya[1], F. Neffati[2], A. Jlali[1], M. Mehdi[1]
[1]Laboratory of Histology Embryology and Cytogenetic UR 12 ES 10- Faculty of Medicine University of Monastir- Street Avicenne- Monastir 5019- Tunisia., Department of Histology Embryology and Cytogenetic, Monastir, Tunisia

[2]*Laboratory of Biochemistry and Toxicology- FattoumaBourguiba University Hospital of Monastir- Monastir- Tunisia., Laboratory of Biochemistry and Toxicology, Monastir, Tunisia*

Study question: In order to determine whether the dysfunction of physiological apoptosis and specific seminal biochemical parameters could be associated with infertility and sperm morphology defects.
Summary answer: the present results emphasize the impact of apoptosis in the physiopathology of teratozoospermia and suggest that seminal biochemical disturbance might arise such damage.
What is known already: sperm morphological defects are associated with apoptosis
Study design, size, duration: Ejaculated sperm samples of seventy patients with isolated teratozoospermia and twenty-one fertile donors were analyzed.
Participants/materials, setting, methods: The proportion of both viable and dead spermatozoa expressing activated caspases was detected by Fluorescence microscopy through the use of different specific carboxyfluorescein-labeled caspase inhibitors FLICA. The different stages of apoptosis in human were qualitatively and quantitatively determined using the AO/EB Fluorescent staining method. The levels of the seminal biochemical parameters (Acetylcholinesterase (AChE), Lactate Dehydrogenase (LDH), Creatine Phosphokinase (CK), Iron (Fe), Calcium (Ca), and Phosphorus (P)) were evaluated spectrophotometrically
Main results and the role of chance: Patients with teratozoospermia showed significantly high proportions of Dead and live spermatozoa with activated caspases and spermatozoa in the late stage of apoptosis when compared to controls. Among the different studied biochemical seminal parameters, the rates of acetylcholinesterase activity,creatine phosphokinase, iron, Calcium were significantly increased the patient group. However, the rate of phosphorus was significantly decreased. Interestingly, significant relationships were found between the studied biochemical and apoptotic biomarkers and the rates of atypical sperm forms. Furthermore, positive correlations were found between phosphorus acetylcholinesterase, iron, CPK, and LDH with apoptotic markers
Limitations, reasons for caution: we suggest further comparative studies connecting the spermatozoa morphology and the DNA integrity with more apoptotic markers.
Wider implications of the findings: the use of both AO/BET staining and the polycaspases assay data provide clear evidence that the apoptotic alterations are closely correlated to the morphological features of sperm. The defiance or overload of seminal trace elements or enzymes may cause functional and qualitative defects on spermatozoon.
Trial registration number: not applicable

P-114 Microfluidic sperm selection enhances ICSI outcomes by selecting spermatozoa with the highest chromatin integrity

K. Hancock[1], A. Parrella[1], M. Goldman[1], Z. Rosenwaks[1], G.D. Palermo[1]
[1]*Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.*

Study question: Does selecting spermatozoa with superior chromatin integrity lead to higher implantation and clinical pregnancy rates with ICSI?
Summary answer: Microfluidic sperm selection (MFSS) provides spermatozoa with optimal chromatin integrity and yields higher implantation and clinical pregnancy rates with ICSI.
What is known already: Sperm preparation methods aim at providing specimen for insemination with the highest progressive motility independent of phenotypic and genomic integrity. Both single-strand (ss) and double-strand (ds) DNA nicks and breaks inhibit the ability of the male genome to support embryonic development. While different mechanisms are in place to prevent this phenomenon, they may be hindered by a defective epididymal function or a suboptimal or aged oocyte.
Study design, size, duration: From October 2016 to January 2019, consenting men (N=32) known to have higher DNA fragmentation in their ejaculate and prior ART failure had their ejaculates simultaneously processed by density gradient centrifugation (DGC) and MFSS. TUNEL was carried out on the raw specimens and on the differently selected aliquots. In men (N=13) treated by ICSI with their female partners, clinical outcomes were recorded. Semen parameters, chromatin integrity, embryo implantation, and pregnancy characteristics were compared.
Participants/materials, setting, methods: Fresh ejaculated specimens from consenting men were collected for standard semen analysis in accordance with WHO 2010 criteria. DGC and MFSS were used to isolate motile spermatozoa based on cell motility and fluid dynamics. Sperm chromatin fragmentation (SCF) was assessed by terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) on at least 500 spermatozoa under a fluorescent microscope utilizing a threshold of ≥15%. ICSI was performed in the standard fashion.
Main results and the role of chance: A total of 32 men with an average age of 41±9 years had the following average semen parameters: concentration of 48.1±37 x 10^6/mL, motility of 31.5±14.6, and 2.4±1% morphology. After DGC and MFSS, the sperm concentration was 33.8±25 and 11.6±12 x10^6/mL, with 59.4±33% and 97.6±9% motility, respectively ($P<0.0001$).

The morphology of the raw sperm sample improved from 2.3±1% to 4.0±1% after MFSS, while it remained at 2.6±1% after DGC. The average SCF decreased from 24% in raw samples to 15% following DGC and became 1.7% after MFSS processing ($P<0.0001$).

Couples (n=13) who underwent ICSI had an SCF in their raw sample of 30.3%, which reached 22% after DCG selection and was only 1.5% after MFSS ($P < 0.0001$). These couples (female age, 36.5±3 years; male age, 42±9 years) underwent 28 cycles with DGS sperm selection, achieving a fertilization rate of 67%. The implantation rate was only 3.4% (1/29) with a clinical pregnancy rate of 6.6% (1/15) that ended in pregnancy loss. Subsequently, these couples underwent ICSI cycles with MFSS and achieved a fertilization rate of 61%. The implantation rate rose to 31% (7/23) *($P<0.05$)* with a clinical pregnancy rate of 54% (7/13) *($P<0.05$)*. The pregnancy loss was 15.3% (2/13).
Limitations, reasons for caution: This study represents a preliminary experiment on a small number of subjects. If confirmed, MFSS yields a male gamete with the highest chromatin integrity, progressive motility, and improved morphology. MFSS should be used in couples afflicted by high levels of SCF in their raw ejaculate.
Wider implications of the findings: According to our study, SCF appears to be linked to the kinetic characteristics of the sperm cell. MFSS yielded the highest portion of progressive motility with the highest DNA integrity. This novel microfluidic system may serve to identify spermatozoa with the highest functional and genomic integrity.
Trial registration number: N/A

P-115 Exploring the interaction of seminal fluid exosomes within the male reproductive tract

J. Stewart[1], P. Xie[1], A. Parrella[1], Z. Rosenwaks[1], G. Palermo[1]
[1]*Weill Cornell College of Medicine, Ronald O. Perelman & Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.*

Study question: To identify, quantify, and describe exosomes at different levels of the male reproductive tract in order to understand exosome function within seminal fluid.
Summary answer: Exosomes are differentially produced at various levels of the male reproductive tract. Exosome composition differs amongst men with infertility and those with proven fertility.
What is known already: Exosomes are small lipid-membrane bound vesicles containing functional biomolecules, such as proteins, lipids, micro-RNA, and DNA. They are released from most cells in the body and are also present in many bodily fluids. Seminal fluid exosomes have been previously isolated, however, little is known about their source and their role in the male reproductive tract. Exosomes in other tissues have been shown to mediate immunomodulatory functions and even to direct tumor metastasis. Seminal fluid exosomes have been postulated to act via a similar mechanism during fertilization and implantation, as well as to possibly participate in directing spermatogenesis.
Study design, size, duration: A total of 30 ejaculated specimens from 30 different subjects with normal semen analysis parameters (5 ejaculated specimens from men with normal semen analyses and proven fertility served as controls) and 17 surgically retrieved testicular specimens from 17 different subjects (13 non-obstructive azoospermia, 4 obstructive azoospermia) were obtained from consenting men from March 2018 to August 2018.

Participants/materials, setting, methods: Specimens were centrifuged at 500xg for 10 mins followed by 3,000xg for 20 mins, and then 12,000xg for 20 mins. The resulting supernatant was centrifuged at 100,000xg for 70 mins for exosomal isolation. Protein concentration was measure by BCA. The NanoSight LM10 nanoparticle analysis system was used for exosome characterization. Isolated exosomes were labeled with PKH-26 and cultured with spermatozoa labeled with PKH-67 for 24 hours, then observed with confocal microscopy at various time points.

Main results and the role of chance: The total number of isolated exosomes was significantly higher in ejaculated specimens compared to testicular specimens (2075x109/µL vs 71x109/µL, respectively, $p<0.01$). This likely reflects the known proportional contribution of the male genital tract organs to the ejaculate (2-3% testicular contribution to the ejaculate). Additionally, there was significantly higher overall exosomal protein concentrations within ejaculated specimens compared to testicular specimens. However, when analyzed on a protein concentration per exosome basis, there was significantly more protein per exosome in testicular specimens compared to ejaculated specimens (0.6 µg/exosome vs 0.08 µg/exosome, respectively, $p<0.01$). There was no significant difference in exosomal number in testicular specimens from men with non-obstructive azoospermia compared to those with obstructive azoospermia. There was no significant difference in mean exosome size between ejaculated and testicular specimens. Data were analyzed using Welch's t-test and the Mann-Whitney U test for non-parametric data. After incubation, seminal fluid exosomes were visualized to be taken up in the head of spermatozoa at 3 hours and at 24 hours.

Limitations, reasons for caution: All specimens were obtained from different subjects, and therefore there is not an ejaculated specimen and a testicular specimen from the same subject available for comparison in the study cohort.

Wider implications of the findings: The unique packaging pattern of exosomes indicates a specialized population of exosomes within the testicle, which may be involved in the communication between Sertoli cells and in ordaining waves of spermatogenesis within the seminiferous tubule network.

Trial registration number: None.

P-116 Artificial intelligence as a tool in predicting sperm motility and morphology

M. Riegler[1], J. Andersen, Marie[2], H. Hammer, Lewi[3], S. Hicks, Alexander[1], W. Oliwia[2], T. Haugen[2]

[1] *Simula Metropolitan Center for Digitalisation and Engineering, Holistic Systems Department, Oslo, Norway*

[2] *OsloMet – Oslo Metropolitan University, Faculty of Health Sciences, Oslo, Norway*

[3] *OsloMet – Oslo Metropolitan University, Faculty of Technology, Oslo, Norway*

Study question: Can artificial intelligence (AI) algorithms predict sperm motility and sperm morphology following the WHO criteria, from videos of wet semen preparation.

Summary answer: AI methods have the potential to predict both sperm motility and sperm morphology with high reliability from live sperm videos.

What is known already: Although computer-aided sperm analysis (CASA) has been available for several decades, manual semen analysis according to WHO guidelines is still regarded as the gold standard. The assessment of sperm motility by CASA systems is rapidly performed, however, the tracking for spermatozoa in fresh semen is prone to error, and results may differ from manual analysis. Assessment of sperm morphology is performed on stained cells for both manual and CASA and is time-consuming. AI methods may have a large potential in classification and interpretation of sperm imaging and thereby replace the subjective and time-consuming methods.

Study design, size, duration: Semen characteristics and videos from semen samples from 85 participants recruited from the general population and clinics. One video was captured for each semen sample. We used three-fold cross-validation to compensate for the relatively limited dataset.

Participants/materials, setting, methods: Men aged 18 years and above. Sperm motility and morphology was manually assessed according to WHO criteria. Sperm videos were recorded at 400x magnification and analysed using the 250 most representative frames per video as input for a 2D convolutional neural network (CNN) InceptionV3 architecture. For training the CNN regression, Nadam as optimizer and mean absolute error (MAE) for loss function were used. For baseline, ZeroR (pseudo regression) was performed. Results are reported as MAE.

Main results and the role of chance: Prediction for sperm motility based on videos led to an additive MAE of 20.92 compared to the ZeroR baseline which had an additive MAE of 25.07. This indicates an overall good performance. The MAE of the AI method for the progressive motile spermatozoa was 12.85 and for the non-progressive motile 8.07, compared to 17.21 and 7.86 from the baseline. This shows that the AI method is better in predicting the progressive motile spermatozoa than the non-progressive. For the sperm morphology, the additive MAE for the AI method is 21.61 compared to 21.80 from the ZeroR baseline. Although smaller than with motility, this is an improvement. The individual MAE is considerably smaller for morphology prediction than for the motility. The AI method has an MAE of 1.91 for normal spermatozoa, 2.63 for head defects, 8.32 for midpiece defects, 6.39 for tail defects and 2.35 for cytoplasmic droplets.

Limitations, reasons for caution: For this algorithm, the optical flow between frames was not taken into account. The performance of the model should be tested in further studies by comparison with human performance, including inter-observer variation.

Wider implications of the findings: The error values for the automatic predictions are low, and the model shows a good performance taking into account that only videos were used to perform the prediction. The AI model created may have a potential in semen analysis, especially in predicting sperm motility from videos of wet sperm preparation.

Trial registration number: not applicable

P-117 RNA aptamers for the recognition of the human SRY protein

D. Florián [1], J. Nakamoto, Alberto [1], P. Milón [1]

[1] *Universidad Peruana de Ciencias Aplicadas, Facultad de Ciencias de la Salud, Lima, Peru*

Study question: This research project aimed to produce RNA aptamers for the sex-determining region Y (SRY) protein by the systematic evolution of ligands by exponential enrichment (SELEX) technique.

Summary answer: The SELEX technique was successfully implemented, and we identified seven RNA-based synthetic molecules. The best of them showed a *Kd*of 314 nM.

What is known already: To date, sexual sorting is achieved with the fluorescent dye Hoechst 33342 and sorting of the X- and Y- spermatozoa by the fluorescent intensity they emit. However, the Hoechst stain binds to the spermatozoa's DNA, which leads to viability reduction and membrane status changes. The SRY is a gene that produces the testis-determining factor, also known as SRY protein; exclusively in Y- spermatozoa. This nuclear and cytosolic protein could be a good target for sperm identification and sex-sorting.

Study design, size, duration: Does not apply. This was a basic science study with *in vitro* biochemical and biophysical experiments.

Participants/materials, setting, methods: A recombinant human SRY protein was produced and used for the SELEX technique to identify RNA-based synthetic molecules. Five SELEX cycles were performed and final products were identified by Next Generation Sequencing. The bioinformatic toolkit FASTAptamer highlighted top-ranked RNA molecules. These were chemically synthetized and their affinities to the SRY protein were measured using Micro Scale Thermophoresis.

Main results and the role of chance: Seven RNA aptamers were identified and were tested to determine their affinities using a Micro Scale Thermophoresis apparatus. The best of them showed a Dissociation constant of 314±48 nM.

Limitations, reasons for caution: The pool of RNA molecules for SELEX was incubated using a recombinant human SRY protein produced in a*E. coli* system. The RNA aptamers identified were tested using the same protein as well.

Wider implications of the findings: RNA aptamers that bind the SRY protein could be further modified to produce RNA aptamer beacons to bind SRY and emit a fluorescent signal. This approach could lead us to develop new sperm sex-sorting techniques that do not compromise DNA integrity.

Trial registration number: Not applicable.

P-118 Prevalence of Ureaplasma urealyticum and Mycoplasma hominis in infertile couples

N. Daoued[1], M. Hamdoun[1], H. Hannachi[1], M. Braham[2], K. Kacem[3], K. Friji[1], F. Zhioua[2], O. Bahri[1]

[1]*Aziza Othmana Hospital, Microbiology and biochemistry laboratory, Tunis, Tunisia*
[2]*Aziza Othmana Hospital, Gynecology- obstetrics and Reproductive Medicine Departement, Tunis, Tunisia*
[3]*Aziza Othmana Hospital, Reproductive Medicine Laboratory, Tunis, Tunisia*

Study question: To determine the prevalence of genital colonization by *Ureaplasma urealyticum* (*Uu*) and *Mycoplasma hominis* (*Mh*) in infertile couples

Summary answer: Genital colonization by *Uu* and *Mh* seems to be widespread among infertile couples, especially in women and with a higher prevalence in both sexual partners.

What is known already: *Uu* and *Mh* colonize the genital tract of sexually active men and women. It is still unclear whether they should be considered as commensals or associated with pathological conditions. They are suspected to be the causative agents of urethritis, pregnancy complications, prenatal infections, bacterial vaginosis and pelvic inflammatory disease.Their impact on fertility has been widely studied but still remains controversial. Considering the impact that these microorganisms can have on fertility, and the high number of unrecognized colonized individuals, a better knowledge of the prevalence of *Uu* and *Mh* is crucial to detect potential reservoirs.

Study design, size, duration: We conducted a retrospective study over the period of six months (from January 1st to June 30th 2018), including 443 couples attending the gynecology and obstetrics clinic. All patients were undergoing investigations for infertility and the samples collected were obtained as part of the diagnostic work-up.

Participants/materials, setting, methods: Cervicovaginals swabs from women and semen samples from their male partners were collected on the same day. Samples were obtained after 3 days of sexual abstinence. Patients were not taking antibiotics for at least 2 weeks prior to the analysis. Gram staining and bacteriological and yeast cultures were performed on all samples. *Uu* and *Mh* DNA was detected using *C.trachomatis/Ureaplasma/M.hominis* Real-TM PCR kit (Sacace biotechnologies Srl®, Italy) according to the manufacturer's instructions.

Main results and the role of chance: *Uu* was detected inc ervicovaginal samples in 34.7% of cases, *Mh* in 6.3% and the association *Uu+Mh* in 3.8%.Female colonization by *Uu* and *Mh* was significantly associated withbacterial vaginosis ($p<0.001$). Semen samples were positive in 20.8% of cases for Uu and in 2.3% for *Mh*. The association of both species was observed in 1.4%of cases.All men were asymptomatic; 49.1% of the women presented genital symptoms including abnormal discharge (38.8%), itchiness (26.7%), dyspareunia (28.5%) and urinary symptoms (11.5%). However, these symptoms were not associated with *Uu/Mh* colonization. Women whose male partners tested positive for *Uu* were five times more likely to be colonized by *Uu* ($p<0.001$; odds ratio: 5.73 [3.49-9.42]).Female partners of *Mh*-colonized men were 18 times more likely to be infected with *Mh* ($p<0.001$; odds ratio: 17.82 [4.82-65.99]).

Limitations, reasons for caution: We found that *Uu* and to a lesser extent *Mh* were frequently present in infertile patients.However, further research is needed to determine whether colonization by these pathogens is more frequent in infertile couples than in general population.

Wider implications of the findings: Taking in consideration the high prevalence of *Uu* and *Mh* in infertile couples, further research is warranted to evaluate the actual impact of these pathogens on male and female fertility.

Trial registration number:

P-119 High level of Oxidative stress does not predict normal sperm parameters

M. Jerbi[1], S. Mnallah[1], H. Elloumi[1], M.H. Ben Aribia[1], M. Khrouf[1], K. Mahmoud[1], M.C. Said[1], N. Chalbi[1], W. Kerkni[1], K. Belhaj[1], F. Zhioua[1]

[1]*Clinique La rose, Centre FERTILLIA, Tunis, Tunisia*

Study question: The evaluation of seminal oxidation–reduction potential can predict normal sperm parameters ?

Summary answer: Seminal oxidation–reduction potential, DNA fragmentation and chromatin decondensation were inversely associated with normal sperm parameters.

What is known already: Oxidative stress (OS) is one of the major mediators in etiologies of male infertility; it has deleterious effects on spermatozoa, including DNA damage. The evaluation of seminal oxidative stress have a crucial role in the identification of patients who may benefit from treatments. Various tests including total antioxidant capacity assay, reactive oxygen species assay or malondialdehyde assay used to evaluate OS. Seminal Oxidation-reduction potential (sORP) is a measure of overall balance between oxidants and antioxidants, providing a comprehensive measure of oxidative stress. The MiOXSYS System has been introduced recently as a measure of OS with high specificity.

Study design, size, duration: This is a prospective comparative study includes patients with primary or secondary infertility($\geq$ 3 years). Human semen samples were obtained from 134 patients performing a complete exploration of semen parameters at a private ART clinic. Sperm parameters were evaluated according to World Health Organization (WHO) 2010 guidelines. Exclusion criteria included azoospermia and samples with a concentration $<3 \times 10^6$ sperm/mL.

Participants/materials, setting, methods: In each semen sample, which was collected after sexual abstinence of 2–5 days in addition to conventional sperm parameters the following parameters were measured : (i)Spermatozoa with DNA fragmentation using the TUNEL assay, (ii)Abnormal chromatin condensation using Aniline Blue assays, (iii) Oxidative stress was measured by MioXSYS System.

Main results and the role of chance: The study subjects were grouped into two groups refering to a cut-off value of 1,48 mV/10^6 sperm/mL. There was 84 patients in group 1 with low level of sORP (<1,48 mV/10^6 sperm/mL) and 52 patients in group 2 with high level of sORP ($\geq$1,48 mV/10^6 sperm/mL). Comparing to patients of group 1, patients of group 2, had a significantly lower mean sperm count (25.33 vs 39.41 x 10^6 sperm/mL), progressive motility (23.5% vs 30.5%), and vitality (58% vs 63%). Conversely patients of this group had significantly higher levels of DNA fragmentation and chromatin decondensation. This results confirm that sORP, DNA fragmentation and chromatin decondensation were inversely associated with normal sperm parameters. When subgroups of patients were investigated according to normal or abnormal semen parameters we identified 2 subgroups in each group : a subgroup containning 37% of patients (n=31) of group 1 failed to meet one or more criteria for sperm quality and a second subgroup contain 88% (n=48) of group 2. For these two subgroups we identified a negative correlation between sperm parameters and levels of these two parameters : DNA fragmentation and chromatin hypocondensation ($p<0.001$).

Limitations, reasons for caution: We must continue our study with a greater cases number to determinate a new cut-off value and for a stronger conclusion statement.

Wider implications of the findings: Sperm DNA fragmentation, chromatin hypocondensation and sORP should be included in assessment of male infertility because they can have prognostic implications for couples experiencing male infertility and undergoing ART.

Trial registration number: Not applicable

P-120 Artificial intelligence predicts sperm motility from sperm fatty acids

O. Witczak[1], J.M. Andersen[1], S. Hicks[2], H.L. Hammer[3], M.A. Riegler[2], T.B. Haugen[1]

[1]*OsloMet – Oslo Metropolitan University, Faculty of Health Sciences, Oslo, Norway*
[2]*OsloMet – Oslo Metropolitan University, Simula Metropolitan Center for Digital Engineering, Oslo, Norway*
[3]*OsloMet – Oslo Metropolitan University, Faculty of Technology- Art and Design, Oslo, Norway*

Study question: Can artificial intelligence (AI) predict sperm motility from sperm fatty acids (FAs) and estimate sperm FA levels from videos of live sperm?

Summary answer: Sperm fatty acid data can be used to predict sperm motility, and sperm videos can be used to estimate sperm fatty acid levels.

What is known already: Omega-3 FAs are abundant in the sperm and are positively associated with sperm motility, especially progressive motility. Other sperm FAs present in lower levels may also be associated with sperm characteristics. AI may have the potential to predict sperm motility based on FA composition and thereby provide more insight into FAs impact on sperm function.

Study design, size, duration: Sperm videos, sperm motility evaluations and fatty acid data from 85 men 18 years old and above. Participants were recruited from the general population and clinics. One video was captured for each semen sample. Three-fold cross-validation was used to compensate for the low sample size.

Participants/materials, setting, methods: Sperm motility was classified according to WHO guidelines (2010), and sperm videos were recorded at 400x magnification. Sperm FAs were measured by gas chromatography. Prediction of FA composition from videos was performed using 250 representative frames per video as input for a convolutional neural network (CNN) InceptionV3 architecture. Motility prediction from FAs was performed using random forest, linear regression and ZeroR (baseline). Results are reported as mean absolute error (MAE) and by Pearson's correlation coefficient.

Main results and the role of chance: Random forest was the best predictor of progressive motility (correlation = 0.53, MAE = 14.06) and of non-progressive motility (correlation = 0.24, MAE = 7.31) based on sperm fatty acid values. It outperformed the average baseline (ZeroR) and standard linear regression. Progressive motile spermatozoa had the lowest individual MAE whereas non-progressive had the highest. Random forest could predict total sperm motility with an additive MAE of 21.37 and performed better than the average baseline (ZeroR) and standard linear regression. Progressive motile spermatozoa had the lowest individual MAE whereas non-progressive had the highest. Linear regression also outperformed the average baseline but not for every single MAE, whereas random forest did. The MAE for predicting the observed FA levels from the videos using CNN was 19.62. This is good taking into account that only sperm videos were used to predict the FAs. Using the predicted FAs from the videos to perform motility prediction lead to an additive MAE of 22.71 which is only 1.34 higher than the MAE from the measured FAs. This is a good indicator that FAs predicted from the videos have the same predictive power as the measured one.

Limitations, reasons for caution: The present study was performed on a relatively limited data set. A follow-up study including a larger sample size should be conducted.

Wider implications of the findings: AI-models applied on sperm FA data can predict sperm motility, and sperm videos can be used to predict sperm FA composition with similar predictive power as the measured ones. This indicates a strong relation between sperm motility and sperm FA composition.

Trial registration number: Not applicable

P-121 Improvement of sperm quality in hyperviscous semen following DNase I treatment

M. Varla-Leftherioti[1], P. Venieratos[2], V. Tsilivakos[1], A. Gritzapis[2], E. Nosi[3], A. Konstantinidou[3], C. Papanikopoulos[4]

[1]Locus medicus SA, Pathology, Gholargos, Greece
[2]Locus medicus SA, Cellular Biology and Immunology, Gholargos, Greece
[3]-National and Kapodistrian University of Athens - Faculty of Medicine- Greece, First Department of Anatomical Pathology, Athens, Greece
[4]Locus medicus SA, Obsterics, Gholargos, Greece

Study question: TTo evaluate the ability of exogenous DNase I to release entrapped human sperm cells, with a view to improving spermatozoa quality

Summary answer: DNase I treatment results in a spectacular improvement of spermatozoa motility and morphology

What is known already: Studies have documented that semen hyperviscosity (HSV) occurs in 12–29% of ejaculate. SHV is a condition that can result in male infertility, and it has been associated with reduced sperm motility, a poor outcome in intrauterine insemination (IUI), and increased production of Reactive Oxygen Species. Several therapeutic approaches have been proposed in the settings of reducing the viscosity of SHV semen. Over hydration, prostate massage and semen gentle aspiration and expulsion through a 5-ml syringe, were not effective. Proteolysis through the use of chymothrypsin improves the handling of HSV semen although some alterations occur in sperm proteins.

Study design, size, duration: A prospective study was conducted in patients with a history of infertility at the "Locus Medicus" Medical Clinic, for three years. Semen samples with HSV and with normal viscosity (NSV) were obtained as study and control group, respectively. A set of NSV(ten) and HSV(thirty two) were treated with DNase-I. Another set (twenty six and fifty two, respectively), were processed by Density Gradient Centrifugation, and nineteen with HSV were processed by a combination of the methods.

Participants/materials, setting, methods: Semen samples after liquefaction underwent conventional analysis, motility (types a, b, c, d), vitality and morphology. Taking into consideration that postwashed total progressively motile sperm count (TPMSC) could be useful for predicting the efficacy of IUI the yield of the each method was also evaluated. Moreover, the outcome of yield (i.e. % final PR/ total spermatozoa before) was compared to the % initial PR/total spermatozoa before any treatment. TZI was also reevaluated after each treatment.

Main results and the role of chance: The use of DNase I increases the motility of PR spermatozoa in samples from HSV men in a statistically significant manner But had no effect in sampmles from NSV men.

We then compared the results from sperm that underwent density gradient centrifugation(DGC) following DNase I treatment, with these found after DGC treatment alone. The density gradient centrifugation treatment was employed for IntraUterine Insemination (IUI) as well. The percentage of (a) movement after DGC following DNase I treatment, increased 10.27-fold compared to 4.242-fold improvement in the case of DGC alone. Furthermore, PR movement in the first group increased 2.375-fold in comparison to a 1.776-fold improvement in the second group.

The yield in DGC treatment between individuals with NSV and HSV is statistically significant, i.e. $p=0.0179$. The yield of DGC treatment in the case of HSV individuals was 18.519% while under DNase treatment the corresponding yield was 42.47% ($p<0.0001$). The combination of DNase treatment which is followed by DGC outcomes to yield 29.782% ($p=0.0029$ with DGC alone).

The appraisal of spermatozoa morphology following incubation with DNase-I, results in a statistically significant increase in the percentage of normal spermatozoa ($p=0.0076$). As a result TZI decreased from 1.205 to 1.084 ($p<0.0001$).

Limitations, reasons for caution: In this study we hypothesized that SHV is caused by neutrophil extracellular traps (NETs) and that they are sensitive to DNA degradation via DNase-I. The data presented show that the digestion of NETs is feasible, leading to spermatozoa motility improvement making them suitable for use in assisted reproductive technologies

Wider implications of the findings: The concept which attributes hyperviscosity to inflammation has almost been established. The inflammatory reactions encompass NETs formation from neutrophils for microorganism trapping. Our findings suggest that a main cause of SHV is the formation of NETs and we thus propose the therapeutic potential and utility of this approach

Trial registration number: not applicable

P-122 Shedding light on the origin of seminal microbiome

N. Molina Morales[1], J. Plaza-Díaz[2], A. Sola-Leyva[1], R. Mendoza-Tesarik[3], I. Galán-Lázaro[3], J. Tesarik[3], M.J. Sáez-Lara[1], R. Sánchez-Ruíz[4], M.C. Gonzalvo-López[4], A. Clavero-Gilabert[4], J.A. Castilla-Alcalá[4], S. Altmäe[1,5]

[5]Competence Centre on Health Technologies, Estonia,

Study question: Do maturing sperm cells contain its own microorganisms in the testis?

Summary answer: Using 16S rRNA gene sequencing, our preliminary data suggest that immature spermatozoa in the testis are not sterile and carry its own bacteria.

What is known already: Semen has its own microbiome, harbouring polymicrobial communities, where *Firmicutes, Bacteroidetes, Proteobacteria* and *Actinobacteria* are the most widespread phyla. Comparing microorganisms in semen

samples to urine samples in men, it has been identified that these microbial communities shared only 30% of species, indicating that not all the seminal microorganisms originate from the urinary tract. Novel studies are beginning to demonstrate that male reproductive organs, such as prostate, seminal vesicle and testes contain its own microbiome. However, it is not known in which step microorganisms contribute to the seminal microbiome and whether the maturing spermatozoa are sterile or not.

Study design, size, duration: Microbiome analysis using 16S rRNA gene sequencing was carried out on testicular spermatozoa samples. 2 infertile men with azoospermia donated in total 35 single spermatozoa cells for research.

Participants/materials, setting, methods: In total 35 single testicular spermatozoa cells were picked out from fresh testicular biopsies that were beforehand cultivated for 6-24h. The testicular spermatozoa were pooled into 5 samples, followed by genomic DNA extraction and PCR amplification using primers targeting V3-4 hypervariable regions of 16S rRNA gene. The resultant amplicons were sequenced using paired-end Illumina MiSeq system. The quality of raw reads was assessed with Mothur. MG-RAST was used for analysis of all sequences.

Main results and the role of chance: The bacterial 16S rRNA gene was analysed in the testicular spermatozoa and additionally in the cell storage buffer as negative control samples. There were few bacteria present in the storage buffer samples, which were taken into account when analyzing spermatozoa samples. *Actinobacteria* (especially *Bifidobacteriales*), *Bacteroidetes* and *Verrucomicrobia* comprise the highest proportion of detected bacteria.

Limitations, reasons for caution: This is a preliminary study on limited sample size, which will be confirmed in a bigger sample set.

Wider implications of the findings: This is the first study demonstrating presence of microorganisms on testicular spermatozoa. Our findings provide new insight into the origin of seminal microbiome, indicating that some accompanying bacteria originate already from the testicular maturation phase.

Trial registration number: NA

P-123 CRISP1 (Cysteine-rich secretory protein-1) as an epididymis-specific protein in seminal plasma has a prognostic role for the distinction among 3 different subgroups of non-obstructive azoospermia

E. Savadi Shiraz[1], A. Pilatz[1], T. Diemer[1], P. Stanton[2], W. Weidner[1], R. Soleimani[3]

[1]Department of Urology- Pediatric Urology and Andrology- Justus Liebig University- Giessen- Germany, Department of Urology- Pediatric Urology and Andrology- Justus Liebig University- Giessen- Germany, Giessen, Germany

[2]Hudson Institute of Medical Research- Department of Molecular and Translational Science- Monash University- Melbourne- Australia, Department of Molecular and Translational Science, Melbourne, Australia

[3]Department of Reproductive Medicine- Ghent University Hospital, Department of Reproductive Medicine, Ghent, Belgium

Study question: Are there protein markers in seminal plasma that can predict the presence of testicular sperm before an invasive surgery in men suffering from non-obstructive azoospermia?

Summary answer: CRISP1 (Cysteine-rich secretory protein 1) in seminal plasma has the potential role to predict the success of micro-dissection sperm retrieval in non-obstructive azoospermia men (NOA)

What is known already: Men with NOA have no sperm in the semen. Testicular sperm suitable for Intracytoplasmic sperm injection (ICSI) and other assisted reproductive technologies (ART) could be present in NOA patients.

Sperm is collected by micro-testicular sperm extraction (M-TESE). However, there is not a reliable diagnostic test to predict the presence of sperm in the testis biopsy before surgery. About half of azoospermic men are unable to have sperm retrieved at M-TESE and therefore have surgery unnecessarily. The ability to predict the presence of sperm in the testis prior to invasive TESE would improve sperm retrieval rates and avoid harmful surgery.

Study design, size, duration: Specific proteins related to spermatogenesis in seminal plasma(SP) could provide newfound proteomics assay for sperm presence prior to biopsy. This study designed to compare the SP proteomes of 3 different subgroups of NOA. Men with mixed-testicular atrophy(MA) and men with Spermatogenesis arrest(SA) with a positive sperm retrieval at M-TESE. Sertoli-cell-only(SCO) patients with a negative sperm retrieval at M-TESE. Results also compared with men suffering obstructive azoospermia(OA), Klinefelter syndrome and at the end with the control-group.

Participants/materials, setting, methods: SP was collected from men before and after vasectomy (n=10/group). All samples were compared by two-dimensional gel electrophoresis proteomics. Differentially expressed proteins were defined as those with a fold-change >1.5 and a significant difference between the groups ($p<0.05$). Among the significant proteins identified, CRISP1 with more than 3 fold down-regulation (after vasectomy) was selected for further validation by 2 different antibodies, which recognizing 2 different epitopes of protein in the method of Western blotting (n=15/group).

Main results and the role of chance: The significant difference was seen among 3 different subgroups of nonobstructive azoospermia (MA, SCO, and SA). CRISP1 was significantly higher in the seminal plasma of SA patients in compare of SCO ($p<0.01$) and MA ($p<0.001$). On the other hand, CRISP1 was significantly higher than MA patients ($p<0.05$) in patients with SCO and as mentioned in the above less than SA. In the end, MA patients had a significantly less amount of CRISP1 in compare to two other groups.

In addition, the significant difference was found between OA and NOA. This subject had been proved and reported already by *Legare et al. 2013* and our results proved it again.

Interestingly, the achieved results from both antibodies which had different epitopes affinity showed the same pattern of comparison for all different groups of patients. Regarding the achieved results in the compare of controls with other groups of patients, the results were more or less similar for both antibodies. However, it was not 100%. For example, the one antibody showed a significant difference between control and SA, but another antibody didn't show that.

Limitations, reasons for caution: To get a higher impact of achieved significant differences, it is required to increase the number of samples. To find the cut off of protein rate for each subgroup of NOA should be examined.

Wider implications of the findings: CRISP1 was significantly different in SP among 3 different subgroups of NOA patients(namely spermatogenesis arrest, mixed atrophy and Sertoli-cells-only syndrome) by confirmation of at least 2 different antibodies for proteomics-method of Western blotting, and thus has the potential to predict the presence of sperm in the testis prior to biopsy.

Trial registration number: The trial registration number for this project is IRTG-62280541.

P-124 Specific alternative splicing events associated with human oocyte meiotic maturation

D. Cornet[1], M. Barrgan[1], F. Zambelli[1], A. Ferrer[1], S. Balcells[2], A. Rodriguez[1], D. Grinberg[2], R. Vassena[1]

[1]Clinica Eugin, Assisted reproduction, Barcelona, Spain

[2]Universidad de Barcelona, Department of Genetics- Microbiology and Statistic-CIBERER- IBUB- IRSJD, Barcelona, Spain

Study question: Is alternative splicing involved in the developmental competence acquisition in *in vivo* mature oocytes?

Summary answer: There is a pattern of alternative spliced genes involved in the regulation of transcription and mitochondrial translation processes present in *in vivo* matured oocytes.

What is known already: During growth and maturation, the oocyte transitions from a transcriptionally active state (oogonia) to a transcriptionally inactive stage, the GV, which subsequently matures to the MII without generally reactivating transcription. Therefore, regulation of expression at the MII stage is mostly driven by post-transcriptional regulatory mechanisms. Alternative splicing (AS) is an important regulatory mechanism throughout development, but little is known regarding its role in the acquisition of oocyte competence. The purpose of this study is to characterize and compare the splicing patterns of fully grown GV oocytes and *in vivo* MII oocytes.

Study design, size, duration: The AS signature of GVs and MII oocytes were compared. Oocytes from 16 women were grouped according to age (young or old) and antral follicle count (high AFC or low AFC) resulting in 4 groups: GVs from young women with high AFC (GV); MII from young women with high AFC (H-MII); MII from women with low AFC (L-MII) and MII from old women with high AFC (O-MII).

Participants/materials, setting, methods: Total RNA from each oocyte was isolated, amplified, labeled and hybridized on HTA-2.0 microarrays. Microarray data analysis was performed in groups: GV group (4; 26.3±4.1 y.o and 27±13 follicles), H-MII group (4; 26±4.6 y.o and 24±3 follicles), L-MII group (4; 27.5±5.4 y.o and 7±1 follicles) and O-MII group (4; 32.8±1.5 y.o and 27±6 follicles). AltAnalyze (FIRMA and ASPIRE algorithms) were used for statistical analysis using default parameters and results validated by qPCR.

Main results and the role of chance: Genes regulated by AS in three different comparisons (H-MII vs GV, L-MII vs GV and O-MII vs GV) were identified using the FIRMA algorithm. The 1253 AS events detected were involved in regulation of transcription and mitochondrial translation. More than 50% of AS events were related to cassette-exon and alternative C' terminus events, suggesting that our results might reflect the physiological control of pre-mRNA processing during oocyte maturation to achieve proper oocyte developmental competence. To determine the inclusion or exclusion of a given exon, we subjected the AS events detected with FIRMA to additional analysis with the ASPIRE algorithm, which takes into consideration the exon-junction values. A total of 36 differential AS events in 35 genes were confirmed to occur between in vivo MII and GV oocytes. Hierarchical clustering of differential AS events showed that the 4 GVs clustered together, and the 12 MII oocytes clustered in a single group despite their differences in age and ovarian reserve. Ten of these genes were differentially spliced in all three comparisons and two of them, *PIK3CD* and *DIAPH2*, have been previously associated with ovarian dysfunction suggesting a possible role in acquisition of developmental competence.

Limitations, reasons for caution: GVs oocytes were collected after ovarian stimulation and thus might not represent the transcriptome of the immature GVs in the ovary.

Wider implications of the findings: The differences observed in the transcribed splice variants in MII and GV oocytes could provide biomarkers of oocyte quality, since we found a profile of confirmed AS events that could determine acquisition of oocyte developmental competence.

Trial registration number: not applicable

P-125 Zygotic cytoplasm size pattern (ZCP) as an early predictor of blastocyst formation

M. Zhao[1], L. Hanhui[2], L. Tin Chiu[1], C. Yiu Leung

[1]*The Chinese University of Hong Kong, Obestrics and Gynaecology, Shatin, Hong Kong*

[2]*Guilin University of Eletronic Technology, School of Information and Communication, Guilin, China*

Study question: A robust early embryo predictor is lacking, can the dynamic change of zygote cytoplasm serve as an early predictor for embryo development?

Summary answer: The dynamic change of two zygotic cytoplasm size patterns (ZCPs) can serve as an early predictor for blastulation.

What is known already: After fertilization, a series of dynamic and complex events are triggered in a zygote. The size of a zygote cytoplasm is changing over time before its first cleavage. Zygotes with changing of cytoplasmic size behavior, such as too active or inactive, tend to have low grade embryos.

Study design, size, duration: This was a prospective study and involved 184 zygotes cultured in the time-lapse incubator. Their images were captured every ten minutes from 18 hours after fertilization to the first cleavage. The size of cytoplasmic cross-section at the focal plane was measured by our previous developed automated recognition system (Poster presentation P-348, ASRM 2017). The dynamic size of zygote cytoplasm size changes was considered as time series.

Participants/materials, setting, methods: We used dynamic time warping (DTW) for calculating the similarity among each zygote and partition around medoids (PAM) to cluster the zygotes into different patterns. For each pattern, DTW barycenter averaging method was used to figure out the dynamic patterns. We used the pattern value to predict blastocyst formation by logistic regression. The receiver operating characteristic curve (ROC) was used for evaluating the predicting value of zygote cytoplasmic size pattern.

Main results and the role of chance: We measured the size of 184 zygotes from 9397 images. Two ZCPs were clustered based on the similarity of cytoplasmic changes. Zygotes of ZCP 1 follow the change that their cytoplasm size decreases all over time. However, Zygotes of ZCP 2 follow the change that their cytoplasm decreases at first but gradually recovers to its original size and then further increases. The logistic regression result showed that for a given zygote, the closer the development pattern to ZCP 2 the higher probability of the it to develop into a blastocyst. For blastulation prediction, the area under the ROC is 0.65 comparable to the Alpha/Eshre morphology assessment method. It should be noted that the ZCPs only use the information of Day 1 development. It has a high potential to combine with existent time-lapse algorithm.

Limitations, reasons for caution: The zygote is spherical, but we can only get its size of cross-section under the time-lapse incubator.

Wider implications of the findings: We first exploited zygotic cytoplasm change dynamics, for predicting the blastulation. We found two main patterns during zygote development and the information is useful as an early predictor for blastocyst formation. This morphology-based predictor has a potential to combine with other embryo selection algorithms for choosing better quality embryos.

Trial registration number: not applicable

P-126 Impact of different time intervals from ovulation trigger on implantation and treatment outcome in IVF and ICSI procedures.

M. Papayannis[1], M.A. Demarco[2], M. Gomez Peña[1], C. Bisioli[1], G. Terrado Gil[2], I. De Zuñiga[2], F. Sobral[2], L. Kopcow[2], A. Oubiña[2], M. Horton[2]

[1]*Pregna Medicina Reproductiva, IVF Lab, Buenos Aires, Argentina*

[2]*Pregna Medicina Reproductiva, Department of Gynaecology and In Vitro Fertilisation Unit, Buenos Aires, Argentina*

Study question: Does the variation in time intervals from hCG triggering in IVF and ICSI procedures affect reproductive outcome?

Summary answer: In ICSI cycles we observed better outcome with shorter time intervals to injection; in IVF cycles, a longer gap prior to insemination had better outcomes.

What is known already: Previous reports have observed a greater number of available embryos and a significant increase in fertilization and clinical pregnancy rates when oocyte collection occurred at or even after 36 h from the hCG trigger. Other authors have also proposed delaying oocyte retrieval to optimize oocyte maturation.

Modifying oocyte incubation time could also affect reproductive outcomes and synchronise nuclear and cytoplasmic maturation. Some authors concluded that the incubation of oocytes for approximately 1.5-2 hours before denudation significantly influences the implantation rate.

Study design, size, duration: An initial set of 1305 patients performing ART treatment using their own oocytes over an 18 month period was reviewed. After exclusion of patients with less than 3 oocytes retrieved (226), a cohort of 1079 patients was analysed. Among them, 567 underwent ICSI and 512 conventional IVF insemination. We analysed the number of oocytes retrieved, the maturity rate, fertilisation rate, blastulation rate, as well as the implantation and clinical pregnancy rates at different time intervals.

Participants/materials, setting, methods: Patients were grouped into the following time-intervals:

(1) hCG trigger to oocyte retrieval (<35 and >35 h; early and late retrieval)
(2) oocyte retrieval to denudation (<2.30 and >2.30 h)
(3) denudation to ICSI (<10 and >10 min)
(4) oocyte retrieval to IVF/ICSI (<3 and >3 h)
(5) administration of hCG to IVF or ICSI (<38 and >38 h).

Continuous variables were compared by T-test; categorical variables were compared by X2 test.

Main results and the role of chance: We compared 295 patients (early retrieval group) and 784 (late retrieval group) showing similar baseline characteristics. In ICSI cycles, we observed a higher fertilization rate (69.7% vs. 75.6% p=0.002) and a higher number of good quality embryos on day 3 (55.5% vs. 63.9% p=0.0001) in the late retrieval group. Also in ICSI cycles, there was an increase in clinical pregnancy (44.7% vs. 28.6%, p=0.003), ongoing pregnancy (36.8% vs. 22.6%, p=0.006), implantation rates (31.4% vs. 19.7%, p=0.002) and live birth rate (41.1% vs. 27.3%, p=0.01) when time between oocyte collection and denudation was less than 2h 30min. Furthermore, these improved outcomes were also verified when the time interval between oocyte collection and ICSI was less than 3h and when oocytes were injected at least 10 minutes after denudation. Similarly, differences between groups were also observed in IVF cycles, which showed an increased fertilization rate (67.4% vs. 72.5%, p=0.004) and clinical pregnancy rate (17.65% vs. 28.52%, p=0.03) in the late retrieval group.

Limitations, reasons for caution: This is an analysis of time intervals in an unselected population, where most retrievals were done in a narrow window between 35 and 36 hours of hCG trigger. Subtle differences between patients or undetected premature luteinization could affect these results.

Wider implications of the findings: Even a slight alteration in time intervals from hCG trigger can have a substantial impact on treatment outcome because it could influence oocyte nuclear and cytoplasmic maturation and quality. Modifying these intervals in different laboratory procedures could optimize reproductive outcomes.

Trial registration number: Not applicable.

P-127 Artificial collapse improves the efficiency of a closed blastocyst vitrification system: retrospective analysis of 1459 warming FET cycles

X. Zhang[1], T. Dineen[1], A. Kovacs[1], R. Mihart[1], J. O'Callaghan[1], J. Culligan[1], A. Tocado[1], N. Daly[1], M. Walsh[1], J. Waterstone[2]

[1]*Waterstone Clinic, Laboratory, Cork, Ireland*

[2]*Waterstone Clinic, Clinic, Cork, Ireland*

Study question: The effect of artificial collapse by laser on a closed blastocyst vitrification system.

Summary answer: Artificial collapse (AC) by laser on Day 5 or Day 6 embryos significantly increases the survival rate in closed blastocyst vitrification compared with non-collapsed.

What is known already: Blastocysts contain a large amount of fluid in the blastocoel, which poses a risk of ice crystal formation in in the course of cryopreservation. This risk may be higher for closed vitrification compared to open vitrification because the former theoretically suboptimal as it is bound to inhibit rapid cooling. Studies have shown that artificial shrinkage of the blastocyst prior to vitrification can have a positive effect on blastocyst survival after warming and can improve clinical outcomes. However, the evidence is scarce when it comes to assessing closed embryo vitrification systems.

Study design, size, duration: This retrospective study was conducted to review vitrified-warmed embryo transfers in the period between Feb 2012 and Oct 2018. A total of 1459 vitrified-warmed cycles were included in this study.

Participants/materials, setting, methods: Supernumerary expanded blastocysts on day 5 or 6 were vitrified using a closed system following AC or without AC. AC was achieved by creating a breach in the blastocoel with a laser pulse. After warming, viable blastocysts were transferred to patients in hormone replacement cycles. Blastocyst survival, clinical pregnancy (foetal cardiac activity at 8 weeks), implantation and ongoing/ live birth rates were compared between the AC and Non-AC patients.

Main results and the role of chance: A total of 1459 vitrified-warmed cycles were included in this study, of which 1268 embryos in 1001 cycles had AC performed prior to vitrification and 652 embryos in 458 cycles did not have AC. 4 cycles in AC group and 25 cycles in non-AC group were cancelled due to embryos not surviving. A higher number of embryos warmed per cycle was noted in the non-AC group (1.42 vs 1.27). The survival rate was significantly higher in the AC group (97.71%) than the non-AC group (87.88 %), p<0.001.

There were no differences in patient age (35.8 vs. 35.3) or number of embryos transferred per cycle (1.24 vs. 1.32) between the AC and Non-AC groups. The positive, clinical pregnancy, implantation, and ongoing/ live birth rates of the AC group were not significantly different to the non-AC group (52.36% vs. 55.43%, 36.58% vs. 37.88%, 32.28% vs. 32.64%, and 34.0% vs. 35.6%, P>0.05). On average, an implantation could be achieved from every 3.17 vitrified-warmed embryos in the AC group, as opposed to every 3.49 embryos in the non-AC group (p<0.05).

Limitations, reasons for caution: The confirmation of these findings requires further prospective studies to adequately judge the efficiency of AC as a routine intervention prior to vitrification.

Wider implications of the findings: Artificial collapse by laser pulse before blastocyst vitrification improves the efficiency of a closed vitrification system.

Trial registration number: not applicable

P-128 Piezo ICSI has clinical advantage to conventional ICSI by remarkably simple and stable technique that enables minimal damage on oocyte.

N. Okuyama, MSc[1], R. Obata[1], N. Oka[1], E. Sagara[1], N. Aono[1,2], T. Hashimoto[1], K. Kyono[1,2]

[1]*Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan*

[2]*Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan*

Study question: Does Piezo ICSI (PI) has an effect on the fertilization rate, degeneration rate and embryo development compared to conventional ICSI (CI) in IVF cycles?

Summary answer: The degeneration rate of PI oocytes with fragile and normal oolemma was significantly lower than those of CI oocytes.

What is known already: Clinically, CI is a common method and widely used, while there are few reports with respect to PI. There are several animal studies reporting that PI is effective in degeneration rate and fertilization rate. It is known that the survival rates of mice oocytes are low after CI; however, degeneration rate improved markedly using PI. PI is an effective technique for cases with fragile oocytes. However, with PI, it is recognized that mercury is necessary in the microinjection pipette and there is concern about toxicity (Ricky Li et al., 2017).

Study design, size, duration: This is a retrospective single-center study conducted from April 2018 to November 2018. Of the 295 cycles, CI was performed in 142 cycles in134 patients, while PI was performed in 153 cycles in 132 patients. 16 cycles in 16 cases were sibling studies. Written informed consent was obtained from all the patients involved in this study.

Participants/materials, setting, methods: CI consists of mechanical penetration of the zona pellucida, breaking the oocyte membrane by aspiration of cytoplasm. CI was performed in 896 mature oocytes obtained from 142 cycles. PI consists of breaking the oocyte membrane and zona pellucida by Piezo pulse. PI was performed in 689 mature oocytes obtained from 153 cycles. In consideration of toxicity, fluorocarbon was used for all PI. P-value of 0.05 or less was considered to be statistically significant.

Main results and the role of chance: The average age of women at PI was significantly higher (39.5±4.7 years old) than that at CI (37.5±4.2 years old, P<0.001). There was no significant difference in terms of men's age between PI and CI (41.5±7.4 vs. 40.4±6.6 years old, P=0.235).

The degeneration rate after PI was significantly lower (2.8%) than that after CI (5.1%) (P=0.018). The degeneration rate of fragile oocytes (membrane breakage without using aspiration or pulsing) after PI was significantly lower (8.1%) than that after CI (20.5%) (P=0.011). On the other hand, there was no statistically significant difference in the fertilization rates, cleavage rates, blastocyst rates or good quality blastocyst rates between CI and PI (77.9% vs. 81.4% (P=0.085), 98.3% vs. 97.0% (P=0.165), 60.3% vs. 57.3% (P=0.301) and 43.1% vs. 41.3% (P=0.542), respectively).

Limitations, reasons for caution: The clinical results using vitrified oocytes or artificial oocyte activation were not included in this study. The pregnancy outcome has not been confirmed in our study.

Wider implications of the findings: Compared to CI, PI yielded more surviving oocytes. This study showed that PI could minimize damage to those oocytes with fragile oolemma. This study demonstrates that stable clinical results can be easily obtained with PI while reducing risk of toxicity by using fluorocarbon as a substitute for mercury.

Trial registration number: Not applicable.

P-129 impact of direct unequal cleavage on embryo developmental potential and clinical outcome

S. Shibasaki[1], N. Aono[1,2], Y. Nakajo[1], H. Hattori[1], Y. Nakamura[1], M. Takahashi[1], N. Okuyama[2], M. Kataoka[1], S. Nagaura[1], M. Koizumi[1], M. Toya[1], T. Hashimoto[2], T. Tai[1,2], H. Igarashi[1], K. Kyono[1,2]
[1]Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan
[2]Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyon, Japan

Study question: Does the timing of direct unequal cleavage (DUC) influence embryo developmental potential and clinical outcome? What factor does influence the incidence of DUC?
Summary answer: Embryo developmental potential and pregnancy rate are related with timing of DUC. ICSI with testicular sperm significantly increased DUC compared with ICSI with ejaculated sperm.
What is known already: Time-lapse (TL) imaging has revealed cleavage anomalies in embryos, such as DUC. Recent studies suggested that DUC was closely related with lower embryo developmental potential compared with normal embryos. Although embryos with DUC show lower blastocyst formation rate and implantation rate compared with normal embryos, there is still controversy regarding the increase in aneuploidy in embryos with DUC. In addition, the influence of the timing of DUC on embryo development and the risk factor related with incidence of DUC are not well understood.
Study design, size, duration: This retrospective study was conducted at Kyono ART Clinic from August 2013 to April 2018. This study includes a total of 6691 two-pronuclear embryos after IVF/ICSI with ejaculate sperm or testicular sperm. All embryos were cultured in a TL system. DUC was defined as the abrupt cleavage of one blastomere into three daughter blastomeres at the same time.
Participants/materials, setting, methods: Depending on the timing of DUC, DUC embryos were classified as follows: DUC1, at the first cleavage; DUC2, at the second cleavage; DUC3, at the third cleavage. We examined the correlation between embryo development with each kind of DUC and maternal age, and between DUC incidence and fertilization method (ICSI or IVF). Furthermore, we compared the incidence rate of DUC in ICSI cycles between ejaculated spermatozoa and testicular sperm.
Main results and the role of chance: The incidence of DUC1, DUC2, and DUC3 was 2.2% (138/6300), 2.9% (185/6300), 0.6% (40/6300), respectively. Good quality embryo rates in DUC1 (3.6%, 5/137), DUC2 (3.3%, 6/183), and DUC3 (15.0%, 6/40) embryos were significantly lower than that of non-DUC embryos (36.3%, 2054/5659) ($p<0.05$). Blastocyst formation rate in DUC1 (11.5%, 15/130) embryos was significantly lower than those of DUC2 (49.1%, 85/173), DUC3 (65.7%, 23/35), and non-DUC embryos (55.5%, 2894/5212) ($p<0.05$). There was no significant difference in the incidence of DUC between each age groups, <34 (6.2%, 93/1508), 35-39 (7.0%, 148/2257), 40< (5.3%, 127/2540). Interestingly, there was no significant difference in the pregnancy rate of frozen-thawed blastocyst transfer between DUC1 (25.0%, 1/4), DUC2 (40.0%, 8/20), DUC3 (50.0%, 3/6), and non-DUC embryos (45.8%, 11/24). None of the infants from DUC1 embryos (n=1) and DUC2 embryos (n=3) showed congenital malformation. There was no significant difference in the incidence of DUC between ICSI and IVF: 3.5% (158/4539) vs. 2.9% (46/1603). However, DUCs and DUC1 incidence were significantly higher in testicular sperm compared with ejaculated sperm, [DUC: 11.8% (46/391) vs. 3.5% (158/4539), $p<0.05$; DUC1: 7.8% (29/374) vs. 2.4% (106/4487), $p<0.05$].
Limitations, reasons for caution: We did not analysis the correlation between the incidence of DUC and chromosomal abnormalities. Because the number of infants derived from DUC embryos was small, further investigation is necessary to confirm the safety of DUC embryos. As of now, DUC, especially DUC1 embryos, should not be selected for day3 transfers.
Wider implications of the findings: The incidence of DUC, particularly DUC1, had a negative effect on embryo development outcome. Our data suggests that blastocysts derived from DUC embryos might be suitable for selection for transfer when non-DUC embryos cannot develop to blastocyst.
Trial registration number: Not applicable.

P-130 the cohesin release factor Wapl interacts with Bub3 to govern SAC activity in female meiosis I

C. Zhou[1], Y. Miao[1], B. Xiong[1]
[1]Nanjing Agricultural University, College of Animal Science and Technology, Nanjing, China

Study question: What is the function of the cohesin release factor Wapl in female meiosis I?
Summary answer: The cohesin release factor Wapl stabilizes Bub3 to promote SAC(spindle assembly checkpoint) activation in female meiosis I
What is known already: Cohesin complex mediates sister chromatid cohesion to guarantee faithful chromosome segregation. During mitotic prophase, a bulk of cohesins is removed from chromosome arms by Wapl, a pivotal cohesin release factor, to ensure sister chromatid separation. However, during female meiosis I, homologs separate from each other and the resolution of chiasmata requires proteolytic cleavage along chromosome arms of cohesin's Rec8 subunit by Separase.
Study design, size, duration: Mouse oocytes were randomly assigned to control and Wapl-depleted groups. In Wapl-depleted groups, gene-targeting morpholino microinjection were performed to deplete Wapl, non-targeting morpholino oligo concurrently was injected as a control. The meiotic progression, spindle assembly,kinetochore-microtubule (K-MT) attachment and euploidy were assessed in control and Wapl-depleted oocytes.
Participants/materials, setting, methods: 3-4 week-old female ICR mice were used in all experiments. Fully-grown oocytes were collected from ovaries in M2 medium and cultured further in M16 medium under liquid paraffin oil at 37°C in an atmosphere of 5% CO2 incubator for *in vitro* maturation. At different time points after culture, oocytes were collected for subsequent analysis. Immunofluorescence, immunoblotting, LC-MS/MS and immunoprecipitation were performed to assess oocyte meiotic competence and explore molecular mechanisms.
Main results and the role of chance: Depletion of Wapl in oocytes accelerates meiotic progression and inactivates SAC($p<0.001$). Depletion of Wapl also causes meiotic defects such as aberrant spindle assembly($p<0.01$), improper chromosome alignment ($p<0.001$)and incorrect kinetochore-microtubule (K-MT) attachment($p<0.001$), consequently leading to aneuploid eggs($p<0.01$). The involvement of Wapl in SAC control is mediated by its role in maintenance of Bub3 stability. Expression of exogenous Bub3 could restore the meiotic defects in oocytes depleted of Wapl($p<0.01$).
Limitations, reasons for caution: We investigated the involvement of Wapl in SAC control on the oocyte meiotic maturation in vitro, but not in vivo.
Wider implications of the findings: Our findings not only discover a novel function and a new downstream effector of Wapl during meiosis, but also extend our understanding of the molecular basis underlying the occurrence of aneuploid eggs in human clinics.
Trial registration number: not applicable

P-131 Oocyte size and morphology are predictive of embryo quality.

S. Darmon[1], A. Weghofer[2], V. Kushnir[3], H. Jafri[3], E. Lazzaroni-Tealdi[3], L. Zhang[3], D. Albertini, F[3], D. Barad, H[3], N. Gleicher[3]
[1]Center for Human Reproduction, n/a, New York- NY, U.S.A.
[2]Medical University Vienna, Obstetrics & Gynecology, Vienna, Austria
[3]Center for Human Reproduction, n/a, New York, U.S.A.

Study question: Do oocyte size and morphology serve as predictive factors for embryo quality?
Summary answer: Oocytes with larger total and oolemma diameter were more likely to develop into high-quality cleavage stage embryos.
What is known already: Though oocyte quality is crucial for embryo quality and has been demonstrated to affect embryo development, most in vitro fertilization (IVF) laboratories do not assess oocyte size and morphology. Oocyte cryopreservation and legally mandated limits on the number of oocytes to be fertilized demand more thorough oocyte quality assessment.
Study design, size, duration: This observational study prospectively performed morphokinetic evaluation of 351 mature (MII) oocytes from 80 women who consecutively underwent controlled ovarian hyperstimulation and intracytoplasmatic sperm injection (ICSI).

Participants/materials, setting, methods: Women undergoing ICSI at an academically-affiliated private IVF center were eligible for enrollment. Total oocyte diameter was measured as the maximum diameter of zona pellucida enclosed oocytes. Oolemmal diameter was measured as the maximum diameter of the oolemma.
Main results and the role of chance: Patients produced 19.0±17.3 oocytes. Oocyte measurements did not relate to oocyte yield. Oocytes with larger oolemma diameter fertilized more frequently than those with smaller oolemma diameter (110.4±4.3 vs. 109.1±4.9 µm, P=0.016), the relationship persisted after adjustment for age. Ooplasm granulation was inversely related to fertilization (P=0.009). Oocytes with larger total oocyte (164.4±6.6 µm) and oolemma diameter (110.8±4.4 µm) were more likely to become cleavage stage embryos of high-grade (P=0.011 and P=0.016, respectively). This effect was again independent of female age. Consequently, embryos from oocytes with larger total diameter were more likely to be transferred or cryopreserved (P=0.023).
Limitations, reasons for caution: Observational study.
Wider implications of the findings: Detailed oocyte assessments may improve embryo selection.
Trial registration number: Not applicable

P-132 Oocyte size and morphology are related to female age, ovarian reserve and body weight in non-polycystic ovary syndrome patients.

E. Lazzaroni-Tealdi[1], A. Weghofer[2], V. Kushnir, A[3], S. Darmon, K[3], H. Jafri[3], L. Zhang[3], D. Albertini, F[3], D. Barad, H[3], N. Gleicher[3]
[1] *Center for Human Reproduction, n/a, New York- NY, U.S.A.*
[2] *Medical University Vienna, Obstetrics & Gynecology, Vienna, Austria*
[3] *Center for Human Reproduction, n/a, New York, U.S.A.*

Study question: Do age, body weight and ovarian function affect oocyte size and measurements in non-PCOS patients?
Summary answer: Advancing age and increasing BMI are associated with smaller total oocyte diameter. Ooplasmic granulation appears reflective of advancing age, lower AMH and fewer oocytes.
What is known already: Most in vitro fertilization programs select embryos suitable for transfer based on embryo morphology, though currently utilized embryo grading has limited potential to identify embryos with maximum implantation potential. Morphokinetic studies show embryo quality to primarily relate to oocyte, rather than to sperm parameters. Indeed, oocyte sizes were previously reported to be smaller in obese women with polycystic ovary syndrome.
Study design, size, duration: This observational study prospectively performed morphokinetic evaluation of 308 mature (MII) oocytes from 77 women who consecutively underwent controlled ovarian hyperstimulation and intracytoplasmatic sperm injection (ICSI) between April and October 2017.
Participants/materials, setting, methods: Women undergoing ICSI were eligible for enrollment in the absence of polycystic ovary syndrome. Total oocyte diameter was measured as the maximum diameter of zona pellucida enclosed oocytes. Oolemmal diameter was measured as the maximum diameter of the oolemma. Perivitelline space (PVS) and ooplasmic granulation were assessed.
Main results and the role of chance: Patients presented with a mean age of 40.3±5.0 years, had a BMI of 25.1±6.1 kg/m^2, AMH levels of 1.2±1.7 ng/ml and produced 6.9±8.9 oocytes. Mean total oocyte diameter was 163.2±7.4 µm (range 145.8-182.1 µm), while oolemmal diameter was 109.4±4.1 µm (range 98.5-122.3 µm). BMI was inversely related to total oocyte diameter (P=0.019), this effect persisted after controlling for female age and oocyte yield (P=0.047 and P=0.016, respectively). Total oocyte diameter was also inversely associated with AMH levels and oocyte yield. In contrast to total oocyte diameter, oolemmal diameter was not related to patient characteristics. Ooplasmic granulation was more frequently observed in oocytes from older women, those with lower AMH and lower BMI (P=0.001 for all). Conversely women with large oocyte yields demonstrated fewer oocytes with ooplasmic granulation (P=0.004). These relationships persisted after adjustment for age. Fertilization was more likely in oocytes with larger oolemmal diameter (p=0.008). Embryos from oocytes with larger total and ooplasmic diameters were more likely to be transferred or frozen (p=0.004 and p=0.011).
Limitations, reasons for caution: Results may not be applicable to younger women with excellent pregnancy potential.
Wider implications of the findings: These findings indicate the importance of detailed oocyte assessments, which may aid the currently used criteria for embryo selection.
Trial registration number: Not applicable

P-133 MicroRNA miR-294 in spent culture medium is correlated to embryo apoptosis and can serve as a biomarker for non-invasive embryo assessment.

D. Makri[1], W. Maalouf[1], K. Sinclair[2]
[1] *University of Nottingham, Child Health- Obstetrics- and Gynaecology, Nottingham, United Kingdom*
[2] *University of Nottingham, School of Biosciences, Nottingham, United Kingdom*

Study question: To study whether microRNA analysis of spent culture medium (SCM) from individually cultured embryos can be used as a non-invasive approach to assess embryo apoptosis.
Summary answer: MiR-294 is detectable in SCM of singly cultured blastocysts and its levels are strongly correlated to the extent of embryonic apoptosis.
What is known already: MicroRNAs have important regulatory actions on cell processes such as stress signaling, cell cycle progression, differentiation, and cell death. It is known that extensive apoptosis in pre-implantation embryos affects implantation and pregnancy rates. Mammalian embryos release microRNAs and cell-free microRNAs are linked to aneuploidy and implantation in humans. However, information is lacking about the potential use of SCM microRNA analysis for assessing the apoptotic status of pre-implantation embryos and the application of this method for elective single embryo transfer cycles.
Study design, size, duration: Cryopreserved mouse zygotes (N=70) were cultured individually for 80 hours until they reached the blastocyst stage. SCM were collected and further analysed for the presence of miR-294, a key anti-apoptotic mediator in cells. Blastocysts were stained at Day 5 of development to assess the apoptotic extent. MicroRNA levels were compared to the apoptotic percentage to identify possible correlations. The study was carried out in two consecutive repetitions.
Participants/materials, setting, methods: Frozen mouse zygotes (B6C3F-1 x B6D2F-1) were individually cultured at 37°C, 5% CO_2 to the Expanded Blastocyst (ExB) stage. Blastocysts were graded using a standard morphology grading system based on the quality of the trophectoderm and inner cell mass. Media samples (N=59) were collected (20µl) and analysed for miR-294 with the polymerase chain reaction method (PCR). The blastocysts were stained for apoptosis using the TdT-mediated dUTP-X nick end labelling method (TUNEL).
Main results and the role of chance: Blastocyst formation reached 84% (59/70 embryos). Using the scoring data the blastocysts were further categorised in Good, Fair, and Poor morphology groups. For the majority of the blastocysts morphology was Fair (N=37), whereas 6 blastocysts were Poor and 4 were of excellent quality and graded as Good. The apoptotic percentage ranged from 0 to 55% with an average of 15% (N=52). Mean comparisons between the Good, Fair, and Poor groups showed that apoptosis was comparable between the groups ($P>0.05$), meaning that morphological scoring is not valuable for assessing the extent of cellular death in pre-implantation embryos. MiR-294 was detected in 42 SCM samples and was strongly correlated to the apoptotic status of the blastocysts ($P<0.05$). The direction of this association is positive ($rho=0.394$), with higher levels of miR-294 linking to increased apoptotic percentage. According to our findings, it is speculated that embryos with abnormally high number of apoptotic cells express abundant levels of miR-294 in an effort to limit cell death and survive.
Limitations, reasons for caution: The use of cryopreserved embryos is a limitation of this study. These results are limited to mouse embryos and further validation is needed for applications in humans. Consideration should be given when interpreting the results for other species because of the differences in microRNA sequences.
Wider implications of the findings: Mouse embryos release microRNAs in the surrounding microenvironment, similarly to bovine and human embryos. DNA fragmentation in the embryo possibly leads to increased miR-294 in SCM that can be ultimately used as a non-invasive indicator of impaired embryo quality.

Trial registration number: not applicable

P-134 Protein profile of euploid single embryo transfer reveals differential patterns among them.

M. Meseguer Escriva[1], L. Bori[1], R. Del Gallego[1], J. Remohi[1], A. Quinonero[1], F. Dominguez[1]

[1] *Instituto Valenciano de Infertilidad, IVF Laboratory, Valencia, Spain*

Study question: Can we differentiate the implantation potential of euploid single blastocyst transfers using a proteomic profile?

Summary answer: A differential proteomic profile can be observed among all single blastocyst transfered depending on their implantation (yes/no), quality and culture media used.

What is known already: There have been initial attempts to select the best embryo for transfer according to proteomic patterns of developing embryos. Nevertheless, euploid single embryo transfers have never been assessed before. In this study a well-defined population of euploid and good quality blastocyst were singled transferred, and their culture media analyzed in order to determine the secretomic profile and its relation with implantation potential.

Study design, size, duration: 81 euploid single blastocyst transfer (SET) conditioned media (CM) and 8 controls were recruited for the study from September 2017 to March 2018 in our clinic. Morphokinetic and Morphology parameters were also recorded from all embryos using a Time-Lapse monitoring incubator (Embryoscope, Vitrolife).

Participants/materials, setting, methods: Eighty-one patients included in our PGT program were enrolled in this study from which 81 euploid blastocyst were analyzed. A Proximity Extension Assay (PEA) technology was used for analyzing 25 different secreted proteins in all media, including IL-6, IL-8, VEGFA, MCP-1, IL-1, CSF-1, SCF and others. Classical Morphology of blastocyst were evaluated including grade of expansion, inner cell mass (ICM) and trophoectoderm (TE). Additionally morphokinetcis and morphology dynamics were evaluated by using EmbryoVIewer (Vitrolife, Denmark).

Main results and the role of chance: First, we observed a clear protein pattern of consumption and secretion of the blastocyst when we compared with controls in all proteins analyzed. We confirmed a significantly high secretion of IL-6 and IL-8 of growing embryos, highlighting the potential of these molecules during the embryo development.Concerning the differences between implanted and non-implanted embryos only IL-8 seem to have a significant difference between groups. Furthermore, most of the protein concentrations presented a pattern of higher values in full hatched blastocyst and were directly related with ICM and inversely with TE quality.

Limitations, reasons for caution: Although we use the most sensitive system available in the market to measure proteins, the very low amount of some of them make us difficult to asses their implication in the implantation potential of these blastocyst.

Wider implications of the findings: Using a combined biochemical/morphology/morphokinetic approach we may be able to distinguish an embryo with higher implantation potential, compared to those that will have very low chances of implantation.

Trial registration number: Not applicable.

P-135 Distinct roles of cohesin acetyltransferases Esco1 and Esco2 during porcine oocyte maturation

L. Yajuan[1]

[1] *Nanjing Agricultural University, College of Animal Science and Technology, Nanjing, China*

Study question: What are the roles of cohesin acetyltransferases Esco1 and Esco2 during porcine oocyte meiosis?

Summary answer: Here, we document that Esco1 and Esco2 exert distinct functions during oocyte meiosis beyond their canonical roles in chromosome cohesion during mitosis.

What is known already: In mammalian cells, the cohesin acetyltransferase Eco1 evolves into two orthologues Esco1 and Esco2 that acetylate cohesin subunit Smc3 to establish chromosome cohesion. We have previously demonstrated that Esco1 and Esco2 have unique functions during mouse oocyte meiotic maturation beyond their conventional role in cohesion establishment during mitosis.

Study design, size, duration: Porcine oocytes were randomly assigned to control group and knockdown group.Depletion of Esco1 or Esco2 by microinjection of RNAi-mediated gene silencing respectively. The *in vitro* cultured oocytes from each group after treatment were applied to the subsequent analysis.

Participants/materials, setting, methods: Acquisition of oocyte meiotic competence was assessed by the immunostaining, fluorescence intensity quantification and/or immunoblotting analysis to analyze the localization, protein expression at various stages, spindle assembly, chromosome alignment, acetylated α-tubulin levels, acetylated H4K16 levels, spindle assembly checkpoint activity. Interactions between proteins were examined by co-immunoprecipitation assay.

Main results and the role of chance: We find that Esco1 localizes to the spindle apparatus while Esco2 localizes to the chromosomes during porcine oocyte meiotic maturation. Depletion of Esco1 by RNAi-mediated gene silencing causes the meiotic progression arrest($P < 0.001$) and defective spindle/chromosome structure($P < 0.001$). Depletion of Esco2 by RNAi leads to the precocious polar body extrusion($P < 0.001$) and activation of spindle assembly checkpoint($P < 0.001$). Furthermore, we show that Esco1 binds to α-tubulin and is required for its acetylation to ensure the microtubule stability, and that Esco2 binds to histone H4 and acetylates it at lysine 16 to maintain the SAC activity.

Limitations, reasons for caution: We investigated the functions of Esco1 and Esco2 on the oocyte meiotic maturation *in vitro*, but not *in vivo*.

Wider implications of the findings: Our findings not only provide evidence that the meiotic functions to Esco1 and Esco2 beyond their roles in the cohesion establishment are conserved during oocyte meiotic maturation, but also extend to provide an indicator of oocyte quality.

Trial registration number: Not applicable.

P-136 From triggering to ICSI: Optimal timing between triggering, OPU, denudation and ICSI

M. KARAGIANNI[1], E. Taki[2], M. Moysidou[1], N. Christoforidis[3], A. Chatziparasidou[1]

[1] *Embryolab Fertility Clinic, Embryology lab, Thessaloniki, Greece*

[2] *Embryolab Fertility Clinic, Andrology lab, Thessaloniki, Greece*

[3] *Embryolab Fertility Clinic, Medical department, Thessaloniki, Greece*

Study question: Which is the optimal time range between triggering, OPU, denudation and ICSI for optimal reproductive outcomes?

Summary answer: This study suggests that 38.5h between triggering and ICSI increase maturation rates and 2h between OPU and denudation increase fertilization rates without increasing pregnancy rates.

What is known already: In order to achieve successful fertilization, both nuclear and cytoplasmic maturity are required. Some studies support that pre-incubation time before ICSI can be beneficial when it comes to fertilization and pregnancy rates while late fertilization may have negative results due to oocyte ageing. There are also studies supporting that there is no statistically significant difference in fertilization and pregnancy rates when ICSI is performed between 2-5 hours post OPU. When it comes to triptorelin/hcg administration in IVF cycles, it is widely accepted that the best timing for OPU is 34-39 hours after triggering.

Study design, size, duration: This retrospective cohort study included ICSI treatments performed at Embryolab Fertility Clinic, in Thessaloniki, Greece between September 2017 and May 2018. The study group consisted of stimulated cycles with own oocytes fertilized with partner or donor sperm. The embryos transferred were either fresh or frozen, but were always derived from the same stimulation.

Participants/materials, setting, methods: 617 stimulated cycles with similar ovarian stimulation protocols were analyzed as per time range between triggering, OPU, denudation and ICSI. The exact time between the procedures was recorded manually. The results were categorized in classes containing the same number of cycles and were analyzed using Kruskal-Wallis test and scatter plots for maturation and fertilization rates and Mann-WhitneyU test and logistic regression for pregnancy/clinical pregnancy/live birth rates using IBM Statistical Package for the Social Sciences (SPSS).

Main results and the role of chance: The women included in the study were 37.23 ($\pm$4.867) years old with BMI 23.22 ($\pm$9.4). The number of oocytes collected at OPU was 9 ($\pm$7.15) and the mean number of MII was 6.82 ($\pm$5.65).

The mean fertilization rate was 72.24 (±28.13), pregnancy rate was 61.55% and clinical pregnancy rate was 56%.

The 6 categories studied were triggering-OPU (DT1), OPU-denudation (DT2), denudation-ICSI (DT3), triggering-denudation (DT4), triggering-ICSI (DT5) and OPU-ICSI (DT6) and were measured in minutes. Kruskal-Wallis test showed statistically significant differences in DT3 and DT5 categories regarding to maturation rate (31-45 minutes, 85.27% and 2371-2385 minutes, 83.12% respectively) and DT2 with fertilization rate (106-120 minutes, 74.57%). Mann-Whitney U test showed no statistically significant difference in any DT between positive and negative pregnancies or live births.

Ideal maturation rates were observed when OPU was performed 36.5h after triggering (p=0.089), denudation 2-2.25h after OPU (p=0.393) and 38.5-38.75h after triggering (p=0.836) and ICSI 30-45min after denudation (p=0.017), 2.5-2.75h after OPU (p=0.145) and 38.5-38.75h after triggering (p=0.008). Optimal fertilization rates were observed when OPU was performed 36.5h after triggering (p=0.464), denudation 1.5-2h after OPU (p=0.023) and 38h after triggering (p=0.138) and ICSI 2.7-3.5h after denudation (p=0366), 5-5.5h after OPU (p=0.592) and 39.5h after triggering (p=0.114).

Limitations, reasons for caution: Results presented in the abstract are based in existing cycles and time ranges. As a result, some classes were few in some categories due to similar time ranges between procedures. Additionally, as the cases were recent enough not all the results for pregnancy/clinical pregnancy/live birth are available.

Wider implications of the findings: Our results indicate that if all the procedures occur within a specific time range, the number of mature and fertilized oocytes can be higher. A positive outcome, can also be expected higher due to more available embryos for embryotransfer.

Trial registration number: N/A

P-137 Blastulation timing is significantly associated with clinical pregnancy outcomes in day 6 frozen blastocysts

M. Kobayashi[1], H. Watanabe[1], R. Suzuki[1], K. Tsukamoto[1], T. Kyoya[1], A. Kikumoto[1], H. Hasegawa[1], S. Saito[2], J. Kobayashi[2]

[1]Kanagawa Ladies Clinic, Embryology Labolatory, Yokohama, Japan

[2]Kanagawa Ladies Clinic, Department of Gynecology, Yokohama, Japan

Study question: Is the blastulation timing of day 6 blastocysts associated with clinical outcomes in single frozen-thawed embryo transfer (sFET)?

Summary answer: The morphologically good-quality day 6 blastocysts which have not intiaited blastulation on the morning of day 5 have high clinical pregnancy rate in sFET.

What is known already: Many studies have indicated that day 6 blastocysts (D6BL) includes normal ploidy status with pregnancy potential. Based on morphokinetic data from time-lapse monitoring (TLM) in D6BL, our previous study showed that clinical pregnancy groups demonstrated significantly shorter time intervals between the start of blastulation and the expanded blastocyst stage (tEB-tSB) than non-clinical pregnancy groups. This result suggested that we may be able to predict for clinically pregnant D6BL from tEB-tSB analysis. However, morphokinetic analysis is time-consuming and high workload task in the busy IVF laboratory, therefore, in D6BL culture, simple and effective method is needed for clinically potential embryo selection.

Study design, size, duration: This retrospective observational study included 412 expanded blastocysts among 321 couples who underwent IVF/ICSI treatment and sFET cycles between January 2017 and October 2018. Cycles with advanced maternal age (>43 years), not expanded blastocysts (internal diameter of <170 μm) and blastocysts that underwent rescue-ICSI were excluded.

Participants/materials, setting, methods: Embryos were cultured in EmbryoScope+ (Vitrolife, Sweden), and conventional morphological parameters were observed at each fixed time point (on the morning of days 1-6) without morphokinetic analysis. D6BL divided into the two groups according to whether initiated blastulation on the morning of day 5 (D5BL) or not (Non-D5BL) and evaluated morphological grade by Gardner-Schoolcraft method. Then, clinical pregnancy rate (CPR) and pregnancy loss rate (PLR) were analyzed.

Main results and the role of chance: The mean patient age was similar between the two groups (D5BL: 37.4 ± 3.4 vs. Non-D5BL: 37.9 ± 3.3 years). Overall CPR was significantly lower in the D5BL group than Non-D5BL group [D5BL vs. Non-D5BL: 27.3% (95/348) vs. 42.2% (27/64), P=0.0362], whereas PLR was similar between both groups [D5BL vs. Non-D5BL: 24.7% (21/85) vs. 32.0% (8/25)]. In blastocysts with AA, BA or AB, CPR was significantly lower in the D5BL group than Non-D5BL [D5BL vs. Non-D5BL: 30.8% (77/250) vs. 48.8% (20/41), P=0.01], whereas PLR was similar between both groups [D5BL vs. Non-D5BL: 26.5% (18/68) vs. 21.1% (4/19)]. In blastocysts with BB, CPR was significantly lower in the D5BL group than Non-D5BL [D5BL vs. Non-D5BL: 20.3% (16/79) vs. 46.7% (7/15), P=0.049], whereas PLR was higher in the Non-D5BL groups but no significant difference [D5BL vs. Non-D5BL: 20.0% (3/15) vs. 66.7% (4/6)]. In blastocysts with AC, BC, CA or CB, Non-D5BL group had no clinical pregnant cycles [D5BL vs. Non-D5BL: 10.5% (2/19) vs. 0.0% (0/8)].

Limitations, reasons for caution: The main limitation is only the blastocysts that targeted on blastocysts of day 6 with small sample size and CPR and PLR were only analyzed in sFET cycle. Further studies are required to clarify whether the blastulation timing associates with live birth rates in D6BL.

Wider implications of the findings: This study revealed that the fixed time point observation is useful to predict high pregnancy potential in D6BL without using TLM. Combination of blastulation timing and morphological grading may offer a new direction in D6BL selection for pre-implantation genetic testing for aneuploidy or sFET.

Trial registration number: None.

P-138 Embryonic morphokinetics is potentially associated with clinical outcomes of single embryo transfers in preimplantation genetic testing for aneuploidy cycles

C.I. Lee[1,2,3], C.H. Chen[2], C.C. Huang[2], E.H. Cheng[2], S.T. Ho[2], H.H. Chen[2], P.Y. Lin[2,3], M.S. Lee[1,2,3], T.H. Lee[1,2,3]

[1]Department of Obstetrics and Gynecology, Chung Shan Medical University Hospital, Taichung, Taiwan R.O.C.

[2]Division of Infertility, Lee Women's Hospital, Taichung, Taiwan R.O.C.

[3]Institute of Medicine, Chung Shan Medical University, Taichung, Taiwan R.O.C.

Study question: Is morphokinetics of euploid blastocysts evaluated by a generally applicable algorithm associated with clinical outcomes of single embryo transfers (SETs) in patients undergoing preimplantation genetic testing for aneuploidy (PGT-A) cycles?

Summary answer: Morphokinetic grades evaluated by the KIDScore™ D5 algorithm are associated with the clinical outcomes in PGT-A cycles using high-resolution next-generation sequencing (hr-NGS).

What is known already: Using hr-NGS for PGT-A can enable the exclusion of mosaic embryos before embryo transfer and thus improve pregnancy outcomes as compared with PGT-A using array comparative genomic hybridization. To select euploid blastocysts with high implantation potential in advance, several groups have proposed the implementation of morphokinetic algorithms for implantation prediction. However, most of the available morphokinetic algorithms were developed based on clinic-specific settings, raising concerns about their general applicability. Therefore, appropriate external validation is essential before routine clinical use of a specific morphokinetic algorithm in varied clinical settings.

Study design, size, duration: The current study enrolled a total of 108 consecutive patients < 38 years and with more than four mature oocytes undergoing 119 PGT-A cycles in Lee Women's Hospital from January 2017 to August 2018. Morphokinetic data derived from 694 biopsied blastocysts cultured in a time-lapse incubator were retrospectively assessed. Clinical outcomes from 106 euploid blastocyst SETs were included in this study.

Participants/materials, setting, methods: Time-lapse microscopy was used to compare morphokinetic variables between expanded blastocysts derived from PGT-A cycles using hr-NGS. The clinical efficacy of the morphokinetic algorithm KIDScore™ D5 was evaluated after SETs of euploid blastocysts. Statistical analysis was conducted using the Mann–Whitney–Wilcoxon test for morphokinetic parameters and the Fisher's exact test for morphological changes, developmental paces, and clinical outcomes.

Main results and the role of chance: Compared with euploid blastocysts, low-level mosaic blastocysts presented comparable morphokinetic and morphological features. However, high-level mosaic blastocysts exhibited significant delays in t5 (median, 51.9 h post insemination (hpi), P = 0.034) and t8 (median, 58.6 hpi, P = 0.032) accompanied by prolonged CC3 (median, 14.7 h, P = 0.012). A significantly higher incidence of multinucleation indicated the

susceptibility of the high-level mosaic blastocysts to mitotic errors. By contrast, only a delay in tB (median, 106.0 hpi, P = 0.039) was revealed in aneuploid blastocysts, reflecting a reduced capability to form good-quality blastocysts (42.6 vs. 65.7%, P < 0.001). Euploid blastocysts with specific morphokinetic characteristics were graded by the KIDScore™ D5 algorithm. Notably, the grade C euploid embryos not only exhibited a consistent delay during preimplantation stages, but also achieved significantly lower rates of clinical pregnancy, implantation and ongoing pregnancy (25%, 25% and 10%) compared with the grade A (76.2%, 79.4% and 68.3%) or grade B (62.5%, 66.7% and 62.5%) euploid embryos.

Limitations, reasons for caution: Because of the retrospective nature of the study, its major limitation was the lack of randomization, which may have presented a risk of selection bias. In addition, this study included only patients aged < 38 years; hence, the results may not represent all the patients undergoing infertility treatment.

Wider implications of the findings: Although morphokinetic features appear dissimilar in embryos with different diploid–aneuploid mosaic levels, predicting chromosomal abnormalities using morphokinetics alone is insufficient. In combination with hr-NGS, the use of generally applicable morphokinetic algorithms may be practicable in independent clinics to support embryo selection for the purpose of improving clinical outcomes of SETs.

Trial registration number: The study is retrospective hence registration was not required. The study was approved by the local IRB committee.

P-139 Human giant oocytes; - cytoplasmic diameter and chromosomal abnormalities -

H. Kitasaka[1,2,3], Y. Konuma[1,3], M. Tokoro[4], N. Fukunaga[1,2,3,4], Y. Asada[1,2,3,4]

[1]Asada Ladies Clinic, Asada Ladies Kachigawa Clinic, Kasugai, Japan
[2]Asada Ladies Clinic, Asada Ladies Shinagawa Clinic, Tokyo, Japan
[3]Asada Ladies Clinic, Asada Ladies Nagoya Clinic, Nagoya, Japan
[4]Asada Ladies Clinic, Asada Institute for Reproductive Medicine, Kasugai, Japan

Study question: Do Giant Oocytes with large cytoplasmic diameters have chromosomal abnormalities?

Summary answer: Giant oocytes with cytoplasmic diameters ≥ 130 μm have chromosomal abnormalities.

What is known already: The diameter of a human oocyte is approximately 110μm, but larger diameter oocytes have been documented in ART and referred to as Giant Oocytes (GO). GO appear to be a product of the cytoplasmic fusion of two primary oocytes, and there are examples of both ova in which some mitotic spindles may or may not be fused. Accordingly, they have a higher risk of aneuploidy than normal oocytes. However, the identification criteria of GO are not well defined as the classification is often dependent on the experience of the embryologist and it is not definitively known whether they are abnormal.

Study design, size, duration: We examined 49,612 oocytes collected from 6,193 ART cycles which underwent controlled ovarian stimulation. Cytoplasm diameters and centromere numbers of oocytes determined to be larger than normal were measured. 63 MII phase oocytes analyzed had a diameter of ≥130μm and were classified as GO. MII oocytes from conventional IVF cycles in which fertilization did not occur were used as a control group.

Participants/materials, setting, methods: Cytoplasmic diameters of oocytes defined as GO were measured and subjected to fluorescent immunostaining using α-Tubulin antibody and DAPI (4'-6-diamidino-2-phenylindole). Spindles were classified into three groups GO 1 (1 spindle present), GO 2 (2 spindles present) and control oocytes. The size of the spindle was measured. Furthermore, we counted the centromere number of GO using anti - centromere antibody recognizing the part where two homologous chromosomes join.

Main results and the role of chance: GO (n=63) had a mean cytoplasmic diameter of 144.3±10.7μm. After staining of 56 GO, it was possible to analyze 47. Of these, 25 were classified as GO1 and 22 oocytes were GO2. The average equatorial plane diameter of the spindle was 18.0±3.3μm in GO1, 11.7±2.2μm in GO2 and 12.3±1.3μm in control oocytes. The average diameter between the two spindle poles was 19.1±2.2μm in GO1, 14.5±3.2μm in GO2 and 13.2±2.0μm in control oocytes. GO1 were significantly different ($p<0.05$) in all these parameters compared to the other groups. There were 16 GO in which the number of centromeres were analyzed, among which 11 GO had one spindle and 5 GO with two observed. The mean number of centromeres in GO where one spindle was observed was 82.2 ± 9.9. GO, with two spindle bodies, 41.3 ± 3.1 on each spindle.

Limitations, reasons for caution: Whilst the incidence of GO is very low (0.1% of oocytes), a larger sample size would be desirable in order to further validate the association between GO and chromosomal abnormality.

Wider implications of the findings: Normally, the number of centromeres in the normal human oocyte is considered to be 46, so there seems to be some evidence from this study that GO are chromosomally abnormal and should be avoided for use in an ART cycle.

Trial registration number: None.

P-140 New insights into the nature of embryo's aneuploidy, arisen from preimplantation genetic testing for monogenic disorders (PGT-M)?

N. Samara[1], S. Peleg[1], T. Frumkin[1], V. Gold[1], E. Haikin herzberger[1], A. Reches[1], H. Amir[1], D. Ben Yosef[1], F. Azem[1], M. Malcov[1]

[1]lis maternirty hospital- Sourasky medical center.affiliated with the Sackler Faculty of medicine-Tel Aviv University-, Wolf PGD Stem Cell Lab- Racine IVF Unit, Tel Aviv, Israel

Study question: What are the frequencies of early chromosomal errors and the parental origin according to haplotype analysis during PGT-M?

Summary answer: Results demonstrate 12.5 % trisomy versus 87.5% monosomy, and semi-equivalent parental origin of aneuploidy. This counters the dogma of major maternal contribution to total aberrations.

What is known already: It is accepted that the majority of aneuploidies in the early developing embryos are derived from errors occurring during meiosis .These anomalies, as deduced from analyses of miscarriage products, primarily involve trisomies of chromosomes 16,22,21,18,15 and XO, majorly attributed to maternal origin. Haplotype analyses at the earliest stages of embryo development, 3 days after fertilization, can be utilized to identify chromosomes' aneuploidity and to confirm or refute the assumptions concluded from prenatal testing.

Study design, size, duration: This is a retrospective study of PGT-M cycles performed between the years 2008-2017. Data were collected from the genetic analysis of embryos, based on haplotypes of at least 5 informative markers. This study includes 2084 embryos, derived from 210 PGT-M cycles of 113 patients. Patients were already diagnosed as carriers of severe monogenic mutations in various genes located on 9 different chromosomes.

Participants/materials, setting, methods: Prior to PGT-M, polymorphic markers were designed and haplotypes characterized. Diagnosis by mutation testing paralleled to haplotype analysis, was validated in single leucocytes from affected family members. Diagnosis of single blastomeres, biopsied from embryos on their day 3 of development, was performed using multiplex nested single cell PCR technique. While analyzing the embryos for the familial genetic disorder, the numerical chromosomal aberrations and parental attribution of monosomy and trisomy, were determined by informative haplotypes.

Main results and the role of chance: In our study we reviewed and analyzed haplotypes results of 2084 embryos from 210 cycles of 113 different patients. We inspected data of 40 genes located on the following chromosomes: 6, 16, 2, 7, 17, 19, 1, 20, X.

The analyzed embryos were chromosomally distributed as follows: on chromosome 6 203 embryos were tested for 5 genes (locations); 151 embryos for 4 loci on chromosome 16; 118 embryos for 6 loci on chromosome 2; 723 embryos for 5 loci on chromosome 7; 132 embryos for 3 loci on chromosome 17; 331 embryos for 5 loci on chromosome 19; 321 embryos for 8 loci on chromosome 1; 41 embryos for 1 locus on chromosome 20; and 84 embryos for 3 loci on chromosome X.

Out of the 2084 embryos analyzed in 210 PGT-M cycles, 152 (7.3%) embryos presented numerical aberrations in the tested chromosomes. Out of them, 133 (87.5%) displayed monosomy and 19 (12.5%) trisomy. Unexpectedly, 71 (47 %) of all aberrations were of paternal origin and 81 (53%) of maternal origin.

Limitations, reasons for caution: Chromosomes' numbers were determined by haplotypes localized at specific points. Misidentification of trisomy was due to limited ability to identity copies that originated from same allele, and failure to distinguish between trisomy and parental contamination. There is no

way to determine whether aberrancy represents whole embryo or biopsied cell only.

Wider implications of the findings: We add new insights concerning chromosomal aberrations in early developing embryos. We demonstrated higher frequency of monosomy compared to trisomy and a significant paternal contribution. This is in contrast of maternal dominancy described in studies of early miscarriage. The paternal role in IVF failure and chemical pregnancies should be re-evaluated.

P-141 Comparison of outcomes between Piezo-assisted versus conventional intracytoplasmic sperm injection for human oocyte: A prospective RCT study

A. Matsuda[1], K. Furuhashi[1], N. Enatsu[2], Y. Katada[1], T. Sumimoto[1], Y. Matsumoto[2], S. Kokeguchi[2], M. Shiotani[2]

[1]Hanabusa Women's clinic, Embryologist, Kobe, Japan

[2]Hanabusa Women's clinic, Doctor, Kobe, Japan

Study question: Does piezo-assisted intracytoplasmic sperm injection (ICSI) for human oocyte lead to a different outcome from conventional ICSI?

Summary answer: When compared to conventional ICSI, the blastocyst and good-quality blastocyst development rate was positively affected by Piezo-ICSI in patients with age older than 35.

What is known already: In conventional-ICSI, an injection needle penetrates the oolemma through the zona pellucida, which can cause harmful effect to the zona. Piezo-actuated micromanipulation makes the constant vibration to the tip, which makes the smooth puncture of the zona without need for suction of ooplasm, minimizing the damage of oocyte during procedure. Piezo-ICSI is now widespread among the animal laboratory especially mice, because it's plasma membrane has high extendibility and ooplasm has low viscosity. However there are few evidences among human oocyte and no prospective randomized controlled trail (RCT) is reported at this time.

Study design, size, duration: In this study, we performed prospective paired RCT with sibling oocyte retrieved more than two oocytes per women at our institution, between October 2017 and July 2018. Oocytes were randomly allocated to Piezo-ICSI and conventional ICSI for fertilization subsequently to oocyte retrieval, all ICSI procedures were performed by single expert technician.

Participants/materials, setting, methods: Retrieved oocytes were cultured after 3-5 hours of culture and pipetting was conducted to remove cumulus cells. For conventional ICSI, microinjector of NARISHIGE was used, to which gauge of outside diameter 6.0 um and inside diameter 4.7 um needle was attached. A injection tube was connected through a needle holder. For piezo-ICSI, microinjector of outside diameter 6.7 um and inside diameter 4.5 um was connected to the drive unit of piezo-micromanupulator.

Main results and the role of chance: We randomized 957 matured oocytes retrieved from 137 women to conventional-ICSI (472 oocytes) and piezo-ICSI (475 oocytes). The overall outcomes were similar among conventional-ICSI vs piezo-ICSI; fertilization rate 82.0% vs 86.5% p=NS, blastocyst development rate 50.2% vs 54.9% p=NS and good quality blastocyst development rate 51.2% vs 54.9% p=NS respectively. However, subgroup analysis among patient's age > 35 revealed that the oocytes underwent piezo-ICSI showed significantly better outcomes (conventional vs Piezo-ICSI: fertilization rate 79.7% vs 86.3% p<.05, blastocyst development rate 39.6% vs 52.4% p<.05, good-quality blastocyst development rate;50.7% vs 56.0% p<.05). There were no differences among the patients age 35 or younger between two groups.

Limitations, reasons for caution: This study only evaluated fertilization and blastocyst development and there is no data about the pregnancy rate or live birth rate.

Wider implications of the findings: Piezo-ICSI showed more favorable outcomes than conventional-ICSI in case with patient's age was older than 35 years, indicating that flat tip and vibration of the piezo can be more protective to oocyte and cause less damage to the aging oocyte.

Trial registration number: not applicable

P-142 Survivability after vitrification-warming of human embryos following use of different polymeric substances in warming media

H. Tsuji[1], Y. Konuma[2], H. Kitasaka[1,2], N. Fukunaga[1,2,3,4], Y. Asada[1,2,3,4]

[1]Asada Ladies Clinic, Asada Ladies Shinagawa Clinic, Tokyo, Japan

[2]Asada Ladies Clinic, Asada Ladies Kachigawa Clinic, kasugai, Japan

[3]Asada Ladies Clinic, Asada Institute for Reproductive Medicine, Kasugai, Japan

[4]Asada Ladies Clinic, Asada Ladies Nagoya Clinic, Nagoya, Japan

Study question: What is the optimal composition of vitrification-warming medium for human embryos?

Summary answer: Only blastocysts not enclosed by the zona pellucida should be warmed in medium containing serum substitute rather than Hydroxypropylcellulose(HPC).

What is known already: The advancement of vitrification technology including the Cryotop method has facilitated cryopreservation of human embryos. Media including serum substitute is thought to have some disadvantages, such as qualitative fluctuations and risk of contamination by unidentified viruses, so that recently there has been the introduction of artificial serum substitutes. As a candidate for a non-human supplement to vitrification-warming media, HPC maybe a potential replacement for serum substitute. However, information on whether serum substitute or HPC is suitable for vitrification-warming of human embryos is limited.

Study design, size, duration: This was a retrospective study in an experienced ART laboratory. The time period was 60 months (January 2013 to December 2017). Results from vitrified-warmed pronuclear embryos (n=40483), 13255 blastocysts with intact zona pellucida and 45 blastocysts without a zona pellucida were assessed. Statistical tests were applied to determine an effect at the level of $p<0.05$ using the chi-square test.

Participants/materials, setting, methods: Patients were seeking infertility treatment in an IVF clinic. All vitrification-warming cycles were performed using the Cryotop method (Kuwayama et al. 2005). Vitrifified human embryos were warmed in two types of warming media containing serum substitute or HPC. The survival rate of each medium was compared.

Main results and the role of chance: The survival rate of vitrified-warmed pronuclear embryos was 99.0% (27742/28031) with the use of serum substitute and 99.0%(12329/12452) for HPC. For blastocysts with an intact zona pellucida, the survival rate was 99.9% (7678/7684) for the use of serum substitute and 99.8% (5560/5571) for HPC. There was no significant difference in survival rates after vitrification-warming between serum substitute and HPC in these two stages of embryo development. However, in blastocysts without a zona pellucida, the survival rate in the warming medium containing the serum substitute was 100% (21/21), which was significantly higher than that using a warming medium containing HPC (62.5% (15/24); $p<0.01$).

Limitations, reasons for caution: This study only compared elements of the warming medium, the composition of the vitrification medium was not taken into account.

Wider implications of the findings: It's thought that the surfactant action of HPC does not tolerate fragile blastocysts which are free of the zona pellucida as it was observed on such occasions that the blastocyst came to the surface as soon as the Cryotop was immersed in the warming medium.

Trial registration number: None.

P-143 Failure of complete hatching of intracytoplasmic sperm injection-derived vitrified–thawed human blastocyst by cell herniation via small slit and insufficient expansion despite ongoing cell proliferation

T. Inoue[1,2], M. Uemura[3], S. Taguchi[2], K. Hirao[2], Y. Tsujimoto[2], K. Miyazaki[2], Y. Yamashita[2]

[1]Hyogo College of Medicine, Department of Emergency- Disaster and Critical Care Medicine, Nishinomiya, Japan;

[2]Umeda Fertility Clinic, Department of Gynecology, Osaka, Japan

[3]Kobe Gakuin University, Faculty of Rehabilitation, Kobe, Japan

Study question: Does intracytoplasmic sperm injection (ICSI) affect the complete hatching of vitrified–thawed human blastocysts *in vitro*?

Summary answer: ICSI-derived blastocyst displayed cell proliferation, intermittently herniating trophectoderm cell and/or inner cell mass via small slit and insufficient expansion, leading to failure of complete hatching.

What is known already: The hatching pattern is associated with the fertilisation method, and the complete hatching rate of ICSI-derived blastocysts is lower than that of *in vitro* fertilisation (IVF)-derived blastocysts until day 6; however, whether incompletely hatched blastocysts can escape after day 6 remains unclear. Several studies have reported on the effect of zona pellucida thinning by using the assisted hatching (AH) method, but the results of studies on zona pellucida thinning in ICSI-derived blastocyst and pregnancy outcomes are ambiguous. Moreover, few reports have discussed the effects of ICSI and zona pellucida thinning procedures on the embryo hatching process.

Study design, size, duration: Donated cryopreserved blastocysts from patients who had a baby were used for all analyses. Differences in the hatching process between IVF- (n=56) and ICSI-derived (n=56) human blastocysts were observed, and the effect of laser-assisted zona pellucida thinning (IVF and ICSI, n=58 and n=54, respectively) on their hatching was evaluated under time-lapse microscopy (CO_2, 6%; O_2, 5% at 37°C and 80%±20% humidity).

Participants/materials, setting, methods: Vitrified–thawed blastocysts were individually cultured in a time-lapse incubator until degeneration. The spontaneous hatching pattern was categorised (type A: initial penetration of small trophectoderm projections and type B: sudden large rupture of the zona pellucida followed by fast extrusion of the blastocyst). The rates of hatching commencement and completed hatchings were determined. The blastocyst diameter and estimated number of trophectoderm cells were measured at hatching commencement and at maximum expansion.

Main results and the role of chance: No significant difference was found in the hatching commencement rate between the IVF and ICSI groups. However, hatching patterns differed between the IVF and ICSI groups (type A: 25.0% vs. 92.5% and type B: 75.0% vs. 7.5%, P<0.01). The completed hatching rate in the IVF group was significantly higher than that in the ICSI group (67.9% vs. 23.2%, P<0.01). Diameters at hatching commencement and maximum expansion during hatching in the IVF group were greater than that in the ICSI group (P<0.01). The maximum expansion diameters in completely hatched blastocysts were greater than those in incompletely hatched blastocysts of the IVF and ICSI groups (P<0.05). The completed hatching rate significantly increased with AH in both groups (IVF-AH vs. IVF, 89.7% vs. 67.9%, P<0.01 and ICSI-AH vs. ICSI, 77.8% vs. 23.2%, P<0.01). The maximum expansion diameters of the completely hatched blastocysts in the AH groups were significantly smaller than that in the non-AH groups (P<0.01). Moreover, the estimated trophectoderm cell numbers significantly increased in ICSI-derived blastocysts with type A hatching patterns from hatching commencement to their maximum expansion points (P<0.01). The trophectoderm cells and/or inner cell masses were intermittently herniated via small slits until degeneration in the incompletely hatched ICSI-derived blastocysts.

Limitations, reasons for caution: First, the zona pellucida of blastocyst–uterus interactions could not be evaluated during implantation. Second, the contribution of male factors to blastocyst development/hatching process remains unclear. Although our results do not completely explain the hatching process, they should be helpful in elucidating the process.

Wider implications of the findings: ICSI-derived blastocysts do not adequately increase their internal hydrostatic pressure despite ongoing cell proliferation because of presence of a small slit; consequently, blastocysts insufficiently expand, leading to failure of hatching. Laser-assisted zona pellucida thinning leads to complete hatching in the blastocyst stage of less expansion and lower internal hydrostatic pressures.

Trial registration number: Not applicable

P-144 Human oocytes are ready for ultra fast vitrification after two minutes of exposure to cryoprotectant solutions

M. Gallardo[1], S. Jaime[2], J. Gosalvez[3], R. Risco[4]

[1] *Malo Clinic - Ginemed, IVF Laboratory, Lisbon, Portugal*

[2] *Seville Engineering School, Applied physics, Seville, Spain*

[3] *Universidad Autónoma de Madrid, Genetics, Madrid, Spain*

[4] *National Accelerator Centre, Applied physics, Seville, Spain*

Study question: Can the duration of the exposure of human oocytes to cryoprotectant solutions, that is necessary to create the adequate intracellular environment for vitrification, be reduced?

Summary answer: The critical intracellular solute concentration necessary for successful vitrification of human oocytes can be achieved in just two minutes with standard cryoprotectant solutions

What is known already: Despite the cooling and warming of the oocytes is ultra-fast, the procedure of vitrification as a whole is time consuming. The standard preparation protocol to ready the oocytes for vitrification takes from 8 to 15 minutes, most of which consists on a long exposure to a non-vitrifying solution (n-VS) to allow for osmotic equilibration. A reduction in the duration of the protocol is desirable to improve the workflow in the IVF setting and reduce the time of exposure of the oocytes to suboptimal conditions: solutions with high molarity at a low temperature.

Study design, size, duration: We employed biologic material from patients of a private IVF unit, that was donated for research by a signed informed consent form. Human metaphase-II oocytes that did not show fertilization signs 48 hours after being subjected to ICSI were employed for in vivo osmotic behavior assessment and for viability tests. Human zygotes with 3 pronuclei at 17 hours after ICSI were employed for viability tests.

Participants/materials, setting, methods: We developed in MatLab a simulation of the flux of water and solutes through the plasma membrane of the oocyte during its exposure to hypertonic EG, Me2SO and sucrose solutions, using the 2Parameter formalism. The conditions of the simulation were reproduced in vivo using microvolumes of the solutions, and the volumetric excursions of the oocyte were recorded in an inverted microscope. Ultimately, oocytes were subjected to vitrification with a closed carrier after different preparation protocols.

Main results and the role of chance: We compared a standard equilibration protocol (EP) of 10 minutes of exposure to n-VS (7.5% EG, 7.5% Me2SO) followed by 1 minute of exposure to vitrification solution (VS; 15%EG, 15% Me2SO, 0.5M sucrose) with a short dehydration protocol (DP) consisting of 1 minute of exposure to each solution. The intracellular molarity of the oocyte at the end of both protocols was similar (5.40M in EP vs. 5.37M in DP), even though oocytes prepared for vitrification with DP showed a lower normalized water content (26.6% EP vs. 17.7% DP). The final relative volume of oocytes prepared for vitrification with EP (49.9% in silico, 62.5% in vivo) was higher than with DP (39.9% in silico, XXX% in vivo). Unfertilized oocytes survived vitrification in high rates after short dehydration protocols (30/30 DP). And 27/27 threepronuclear zygotes prepared for vitrification with DP survived the process and 24/27 resumed mitosis after 24 hours of culture. A similar proportion (25/27) of mitosis resumption was observed in a fresh control population of human threepronuclear zygotes. These results show that the critical intracellular solute concentration necessary for succesful vitrification of human oocytes and zygotes at currently attainable cooling and warming rates can be achieved in just two minutes.

Limitations, reasons for caution: Potentially deleterious effects of this short, dehydration based protocol should be studied in terms of oocyte ultrastructure, integrity of organelles, functional protein and RNA content, and ultimately and assessment of its effect on embryo development and clinical use in a controlled setting.

Wider implications of the findings: The duration of the phase of preparation of human oocytes to vitrification can be dramatically shortened even using a standard combination of penetrant and non penetrant cryoprotectants. The exposure to suboptimal, potentially deleterious conditions it entails could be minimized and the laboratory workflow improved.

Trial registration number: C.P. VITCOR - C.I. 1123-M1-17

P-145 D3 embryo quality predicts live birth of single vitrified non-top quality rather than top-quality blastocyst transfers

Q. Sun[1], C. Peilin[1], Z. Huixian[1], X. Feng[1], L. Guanggui[1], Y. Zhihong[1], W. Caiyun[1], Z. Yong[1]

[1] *Shenzhen Zhongshan Urological Hospital, Shenzhen Key Laboratory of Reproductive Immunology for Peri-implantation- Fertility Center, Shenzhen- Guangdong, China*

Study question: Whether embryo quality on Day-3 (D3) has predictive values on clinical outcomes after single vitrified-warmed blastocyst transfer (SVBT)?

Summary answer: D3 embryo quality was an independent factor for predicting live birth of single vitrified non-top quality (NTQ) rather than top-quality (TQ) blastocyst transfers.
What is known already: Transferring TQ blastocysts originated from D3 NTQ embryos had lower implantation rate compared with those from D3 TQ embryos, while it had comparable clinical outcomes after transferring TQ blastocysts developed from either D3 TQ or NTQ embryos. Besides, there were still fewer studies about the predictive values of D3 embryo quality on clinical outcomes of neither single TQ nor NTQ blastocyst transfers.
Study design, size, duration: This study retrospectively analyzed the data of 1 121 SVBT cycles from 1 015 patients in single fertility center of Shenzhen zhongshan Urology hospital between April 2015 and December 2017.
Participants/materials, setting, methods: The cycles were divided into four groups according to blastocyst quality and D3 embryo quality: Group A1 (TQ blastocyst from D3 TQ embryos, n=577), Group A2 (TQ blastocyst from D3 NTQ embryos, n=193), Group B1 (NTQ blastocyst from D3 TQ embryos, n=152)and Group B2 (NTQ blastocyst from D3 NTQ embryos, n=199). The clinical outcomes were compared between A1 and A2, B1 and B2. Logistic regression analysis was performed.
Main results and the role of chance: The HCG positive rate (A1 vs. A2: 67.2% vs. 58.5%; B1 vs. B2: 57.9% vs. 37.2%, $P<0.05$) and clinical pregnancy rate (CPR) (A1 vs. A2: 66.3% vs. 54.3%; B1 vs. B2: 46.7% vs. 22.6%, $P<0.05$) of A1 and B1 group was significantly higher than that of A2 and B2 group, respectively. Ongoing pregnancy rate (OPR), early abortion rate (EAR) and live birth rate (LBR) were not statistically different between A1 and A2 group ($P>0.05$). B1 group had higher LBR than B2 group (30.9% vs. 14.6%), while no significant difference was found in OPR and EAR between the two groups. Multivariable analysis demonstrated that D3 embryo quality was not predictive for the CPR [crude OR=0.69 (95% IC 0.50-0.96), adjusted OR=0.79 (95% IC 0.55-1.14), $P>0.05$] and LBR [crude OR=0.75 (95% IC 0.53-1.05), adjusted OR=0.88 (95% IC 0.61-1.28), $P>0.05$] of single TQ blastocyst transfer, however, it was an independent factor for predicting CRP [crude OR=0.33 (95% IC 0.21-0.53), adjusted OR=0.43 (95% IC 0.26-0.70), $P<0.05$] and LBR of single NTQ blastocyst transfer [crude OR=0.38 (95% IC 0.23-0.64), adjusted OR=0.47 (95% IC 0.26-0.84), $P<0.05$].
Limitations, reasons for caution: Retrospective nature, small number sample and the selection bias caused by strategy of blastocyst culture applied in the fertility center were the main limitations.
Wider implications of the findings: D3 embryo quality should be taken into consideration when one NTQ blastocyst rather than TQ blastocyst was selected to transfer.
Trial registration number: Not applicable

P-146 Using the GnRH agonist leuprolide for luteal phase support (LPS) in, in vitro fertilisation (IVF) / intracytoplasmic sperm injection (ICSI) procedures - a randomised trial

R. Dutta[1], K. George[1]
[1]*Bangalore Baptist Hospital, Reproductive Medicine Unit, Bangalore, India*

Study question: Does the addition of leuprolide (GnRH agonist) to standard LPS (vaginal progesterone) improve pregnancy outcomes in patients undergoing IVF/ICSI when studied in a randomised manner?
Summary answer: Addition of leuprolide to standard LPS improves ongoing pregnancy rate at 12 weeks in patients undergoing IVF/ICSI, when compared with patients receiving standard LPS alone.
What is known already: LPS is important for improving pregnancy outcomes. Multiple agents like progesterone, GnRH agonists and hCG have been studied for their roles in LPS. Evidence is divided as to which is the ideal agent of choice. Vaginal progesterone appears to be the most commonly used and the current standard of practice. There is conflicting data about the use of GnRH agonists for LPS. In 2015, a Cochrane meta-analysis (Linden et al) had shown a probable beneficial trend with GnRH agonists in terms of pregnancy outcomes, when used for LPS, albeit with evidence that had been classified as low quality.
Study design, size, duration: This is a single centre randomised open labelled trial with a view to recruit 106 patients each, in the intervention and control arms, initiated in the year 2018. The on-going study is being performed in the Department of Reproductive Medicine, Bangalore Baptist Hospital, which is a tertiary care teaching centre at Bangalore, India. The study was approved by the institutional review board and the ethics committee of the institution.
Participants/materials, setting, methods: Patients undergoing IVF/ICSI, 21-40 years of age, with antagonist protocol, hCG trigger and fresh embryo transfer (day 3) were randomised to standard LPS (vaginal progesterone - control) or standard LPS plus leuprolide (0.5 milligrams subcutaneously single dose, 6th day after oocyte retrieval - intervention). The primary outcome was live birth rate (LBR) and the secondary outcomes were implantation rate (IR), clinical pregnancy rate at 8 weeks (CPR), and ongoing pregnancy beyond 12 weeks (OPR).
Main results and the role of chance: This is an interim analysis of the first 50 patients enrolled in the trial (24 in the intervention and 26 in the control arm). Baseline characteristics were well balanced. Primary infertility was more common in both arms. There were no differences between the arms in the number of oocytes available after stimulation, the number of embryos available or the number of embryos transferred. The LBR was higher at 29.16% in the intervention arm compared to 7.69% in the control arm with a trend towards significance ($p=0.069$). The OPR was statistically higher in the intervention group as compared to the control group (33.33% versus 7.69%, $p=0.035$). CPR (37.5% in intervention, 23.7% in control) and IR (33.33% in intervention, 23.07% in control) were not statistically different between the two arms.

The initial results look promising in that the OPR appears to be better in the intervention arm, and there seems to be a trend towards benefit of the intervention with respect to the primary outcome (LBR). This may achieve statistical significance with higher population numbers on completion of the trial. The overall role of chance is small as the trial is randomised and the baseline characteristics are well balanced.
Limitations, reasons for caution: This is an exploration of the first 50 patients of this trial. The sample analysed is small with limited outcome events. Hence, though the results encourage continuation of the trial and reporting of the data, the final analysis at the end of the trial would be worth looking forward to.
Wider implications of the findings: These results will encourage other centres to test this agent in similar manners in their population to determine whether the effects are reproducible and generalisable. It would also be worth considering the use of other GnRH agonists for LPS and check for class effects of this group of drugs.
Trial registration number: The trial has been registered with the Central Trials Registry - India (CTRI), with the following number: CTRI/2018/07/014958.

P-147 Sibling oocyte study to determine effects of media refreshing on clinical outcomes with the use of a single step media

K. Rennison[1], A. Storey[1], F. Heath[1], S. Evans[1], M.E. Middleton[1], P. Knaggs[1]
[1]*Abertawe Bro Morgannwg University Health Board, Wales Fertility Institute, Cardiff, United Kingdom*

Study question: Does using Sage Single Step (SS) media, without refreshing media on day 3, give the same Key Performance Indicators as refreshing?
Summary answer: Refreshing SS media shows a significant increase in top quality blastocyst formation and number of blastocysts vitrified, indicating a potential increased cumulative chance of pregnancy.
What is known already: With the increasing use of time-lapse embryo culture systems there has been renewed interest in single step culture media. There is debate around whether to refresh this media on day 3 of culture to optimise blastocyst formation and pregnancy rates.
Study design, size, duration: This prospective sibling oocyte study analysed 280 patients that had IVF/ICSI treatment between August 2017 and December 2018. A 2 staged study was used to examine Sage Single Step Media when refreshed (SSr) (day 3), Sage Single Step non refreshed (SSnr) and Sage Sequential media (SQ). The key performance indicators were analysed. The choice of which blastocyst to transfer would be based only on embryo quality and development not on the media in which cultured.
Participants/materials, setting, methods: Patients who had 4> 2PN's from sibling oocytes were included. Stage 1 study divided 2PN's between SSr and SQ. Stage 2 divided 2PN's between SSnr and SQ. Number of blastocysts, top quality blastocyst rate, number vitrified, positive HCG and clinical pregnancy

were the key indicators. To assess a cumulative rate of embryo utilisation any vitrified embryo transfers resulting from the study were analysed and included.
Main results and the role of chance: Blastocyst formation rate in SSr vs SQ was 67.7%, top quality blastocyst rate of 42.5% with 38.4% blastocysts being vitrified for SSr. The SQ group resulted in a 61.2% blastocyst formation rate, 43.1% top quality blastocysts and 39.3% blastocysts being vitrified.

Blastocyst formation rate in SSnr vs SQ group was 67.3% vs 60.6%, top quality blastocyst rate 38.6% vs 55.1% ($p < 0.05$) and 34.5% of blastocysts vitrified for SSnr vs 47.4% ($p < 0.05$) SQ.

SSr vs SQ group; SQ transfers resulted in 63% positive HCG and 52.9% clinical pregnancy rate per embryos transferred. SSr transfers resulted in 57.1% positive HCG and 45.9% clinical pregnancy rate per embryos transferred.

SSnr vs SQ group 50% positive HCG and 40.5% clinical pregnancy per embryos transferred for SQ transfer patients. Patients where SSnr embryos were selected a positive HCG rate of 57.9% and a clinical rate of 41.9% per embryos transferred.

Cumulative utilisation rates (embryos transferred and vitrified); averaged across both stages gave an embryo utilisation rate of 35.7% for SQ cultured embryos, 38% utilisation rate for SSr and 32.3% for SSnr.

Cumulative pregnancy rates per embryos transferred; SQ 42.2%, SSr 44.7% and SSnr 40.8%.
Limitations, reasons for caution: Results for SSnr vitrified embryo transfer date are based on lower numbers compared to SSr vitrified embryo transfers. The SQ media, acting as a control in the sibling oocyte groups, has provided varying results over the 2 groups.
Wider implications of the findings: Sage Single Step media provides comparative pregnancy results to Sequential media that can be of benefit in a time lapse system. By not refreshing we have seen a reduction in top quality blastocyst formation and embryo vitrification. Therefore cumulative pregnancy rates could be reduced from a single treatment cycle.
Trial registration number: not applicable

P-148 Oolemma rupture outside the intracytoplasmic sperm injection needle significantly improves the embryo quality.

C. Sifer[1], C. Herbemont[1], T.L.H. NGuyen[2], I. Cedrin-Durnerin[3], M. Grynberg[3], H. Le[2]
[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-CECOS, Bondy, France
[2]Tam Anh General Hospital, ART Centre, Hanoï, Vietnam
[3]Hôpital Jean Verdier, Medecine de la Reproduction, Bondy, France

Study question: To compare the effect on fertilization, oocyte damage and embryo quality of two different techniques for rupturing the oolemma during ICSI.
Summary answer: Fertilization and degeneration rates were similar irrespective of the technique of oolemma rupture. However, top-quality embryo at days-2/3 and top-quality blastocyst rates were significantly different.
What is known already: Two procedures for rupturing oolemma during ICSI have already been described. The most commonly used in routine practice implies the application of a negative pressure. In this case, the breakage of the membrane is observed inside the injection needle. This leads to different patterns of breakage depending on the degree of suction. In the second technique, the rupture is obtained outside the needle by its stabbing action until the oolemma surrounding the needle recoiled. At present, no study had compared ICSI outcomes following these two techniques of oolemma rupture.
Study design, size, duration: This prospective, interventional, monocentric, auto-controlled study on sibling oocytes was performed from 11/2018 to 01/2019. Thirty-one patients, candidates for ICSI cycles were included when >2 metaphase-2 (M2) oocytes were available. Each M2 oocytes cohort was split into groups-1 and -2 according to the ICSI technique used. All ICSI included in the study were performed by the same senior embryologist.
Participants/materials, setting, methods: Oocytes in group-1 were injected by pushing the needle into the oocyte until the oolemma was observed to break outside the needle. In group-2 the oolemma was aspirated into the needle applying a negative pressure until it ruptured inside the needle. Fertilization (FR), degeneration (DR), top-quality embryo (TQE) at days-2/3 (D2/D3) and top-quality day-5 (D5) blastocyst (TQB) rates were compared, using paired-sample analysis with appropriate statistical test with a $p<0.05$ level of significance.
Main results and the role of chance: Briefly, 31 patients were included during the study period. Patients' mean age was 34.3 years, their mean serum AMH levels and antral follicle count were 2.9 and 19, respectively, and they underwent their 1.4th ICSI cycle. In total, 299 oocytes were retrieved, and 248 of them were M2 oocytes. Twenty-two fresh embryo transfers were performed (and 9 freeze-all due to risk of ovarian hyperstimulation syndrome), resulting in a clinical pregnancy rate of 50.0% (11/22).

When comparing groups-1 and -2 respectively, FR (76.4 *vs.* 78.1%; p=0.79) and DR (0.7 *vs.* 2.3%: p=0.29) were similar. Regarding embryo quality, TQE at D2 (defined as 4 blastomeres and <20% cytoplasmic fragmentation) and D3 (8 blastomeres and <20% fragmentation) were significantly improved in group-1 than those tabulated in group-2 (56.2 *vs.* 36.1% at D2; p=0.02, and 37.6 *vs.* 13.8% at D3; p=0.05, respectively). Among these cycles, 13 extended cultures were performed, resulting in comparable blastulation rates (69.8 *vs.* 57.4%; p=0.20). However, TQB rate at D5 (defined as blastocyst ≥B4BB according to Gardner and Schoolcraft's classification) was significantly greater in group-1 (49.4 *vs.* 22.8%; p=0.05). Finally, the rate of embryos suitable for transfer and/or cryopreservation was also higher in group-1 (69.2 *vs.* 48.4%; p=0.005).
Limitations, reasons for caution: The main weakness of this preliminary work is the low number of analysed cycles. A further prospective randomized study enrolling a larger number of patients is required to confirm these data. Moreover, the analysis of live birth rates among both groups would be relevant.
Wider implications of the findings: Taking those results into account, techniques used to rupture the oolemma during microinjection impact ICSI outcome with a deleterious effect of negative pressure applied onto the oocyte.
Trial registration number: No need.

P-149 Genes for Anti-Müllerian Hormone and Androgen Receptor are under-expressed in human cumulus cells surrounding morphologically highly graded oocytes

S. Dević Pavlić[1], T. Tramišak Milaković[2], L. Panić Horvat[2], K. Čavlović[2], N. Smiljan Severinski[2], A. Radojčić Badovinac[1]
[1]University of Rijeka, Department of biotecnology, Rijeka, Croatia
[2]Clinical Hospital Centre Rijeka, Department of Obstetrics and Gynaecology, Rijeka, Croatia

Study question: Can expression profiles of AMH gene and its respective receptors in cumulus cells be biological markers for the oocyte, zygote or embryo quality?
Summary answer: Morphologically suboptimal oocytes had statistically significantly higher levels of AMH and AR gene expression in their associated cumulus cells.
What is known already: Morphological assessment of the oocyte, commonly used during ART, is not always a good predictor of successful fertilization and the developmental capacity of the ensuing zygote. Identification of specific genes or other biological components of the microenvironment surrounding each oocyte such as cumulus cells (CCs), could potentially enable more accurate distinguishing between high and low quality oocytes. Previous studies have investigated AMH gene expression levels in CCs, along with its correlation with the oocyte quality, but the obtained results were inconsistent and contradictory. A few studies have found connection between gene expression of AR, AMH and FSHR in CCs.
Study design, size, duration: Study design: cross sectional -morphologically highly (N=107) versus poorly (N=22) rated oocytes.

Size: 129 CCs and 35 follicular fluid samples from 58 patients undergoing ART.

Duration: one year.

Sampling procedure: Each follicle from the patients included was aspirated separately and the cumulus-oocyte complex (COC) was isolated. CCs were removed from the oocyte, oocytes were cultivated separately. Follicular fluids were included in the study if the COC was identified.
Participants/materials, setting, methods: Study included 129 CCs and 35 FF samples from 58 patients undergoing ICSI procedure. AMH, AMHR2, FSHR and AR gene expression levels were analysed on a real-time PCR device using TaqMan technology. Concentrations of AMH in FFs were measured by enzyme-linked immunosorbent assay. Morphological assessment of oocytes was conducted immediately before and during the ICSI procedure, Zygotes

and embryos were assessed 16-18 hours and 64-66 hours after fertilization, respectively.

Main results and the role of chance: The results yielded suggest a relationship between AMH, AR and oocyte morphology: AMH and AR gene expression levels in CCs surrounding morphologically optimal oocytes were significantly lower than in CCs surrounding oocytes with suboptimal morphology ($2^{-\Delta\Delta Ct}$(AMH) = 1.703; p = 0.011 and $2^{-\Delta\Delta Ct}$(AR) = 1.530; p = 0.008 respectively).

Statistically significant positive correlation was found between mRNA expression levels of AMH and FSHR ($p < 0.001$), AMH and AR (p = 0.001), AMHR2 and FSHR ($p < 0.001$), AMHR2 and AR ($p < 0.001$), as well as between FSHR and AR ($p < 0.001$).

No significant differences were found in AMHR2 or FSHR mRNA expression levels among different morphological groups of oocytes, zygotes and embryos.

The concentration of FF AMH did not differ significantly between different morphological groups of oocytes, zygotes and embryos (p = 0.082, p = 0.230 and p = 0.486, respectively). There are no correlations between FF AMH concentration and mRNA expression levels of the AMH, AMHR2, FSHR or AR genes in associated CCs (p = 0.195, p = 0.809, p = 0.461 and p = 0.240, respectively).

Limitations, reasons for caution: Due to heterogeneity of the study population regarding age and controlled ovarian stimulation protocol it is possible that some of gene expression differences could be the result of individual patient's characteristics and not of oocyte/zygote/embryo quality itself.

Wider implications of the findings: Research reinforces the importance of the COC and communication between an oocyte and its microenvironment for oocyte development, embryo formation and successful fertilisation. Obtained results suggest that the pursuit for the oocyte quality markers should be focused on its microenvironment.

Trial registration number: Not applicable

P-150 Implementation of a new single-step culture media: a randomized control trial (RCT) on sibling oocytes.

G. Fabozzi[1], L. Albricci[1], D. Cimadomo[1], V. Morgante[1], R. Maggiulli[1], S. Romano[1], F. Sanges[1], L. Dovere[1], M. Stoppa[1], E. Ievoli[1], L. Tacconi[1], M.G. Amendola[1], G. Nastri[1], F.M. Ubaldi[1], L.F. Rienzi[1]

[1]Clinica Valle Giulia, G.en.e.r.a. Centers for Reproductive Medicine, Rome, Italy

Study question: Is the blastulation rate in Geri Medium comparable to well-established culture conditions?

Summary answer: Geri Medium (Gems, Genea-Biomedx) and Continuous Single Culture Medium (CSCM, Irvine) in an undisturbed incubator resulted in different timings of development but similar blastulation rates.

What is known already: It well-known that culture conditions play a key-role in IVF. Currently, the ideal framework is represented by embryo culture conducted in a time-lapse incubator and in single-step media to limit the exposure to sub-optimal environment and unnecessary handling-stress. Several studies to date compared single-step and sequential media, but few authors investigated the performance of different single-step media in the same ideal conditions. A new commercially-available medium has been recently introduced which contains anti-oxidant to limit the damage that might derive from reactive oxygen species. Aiming at a clinical implementation of such tool, we investigated its performance compared to well-established conditions.

Study design, size, duration: Interim analysis of a registered-RCT (April-December2018; 912 oocytes from 129 patient; mean maternal age: 36.7±3.6yr). Inclusion criteria: maternal age≤42yr, 4-8 MII oocytes, ICSI with ejaculated sperm, motile sperm-count>500,000/ml after swim-up, no carriers of single-gene diseases or chromosomal imbalances. Following denudation, the oocytes were randomized in two arms (Geri-Medium or CSCM). The primary outcome was mean blastulation rate per cohort. A sample size of 1182 oocytes (160-200 patients) is required to achieve a 80% statistical power.

Participants/materials, setting, methods: Controlled ovarian stimulation in an antagonist protocol, ICSI, culture to blastocyst in a time-lapse incubator (GERI, Genea Biomedx) at 6%CO_2 and 5%O_2, standard blastocyst morphological assessment and morphodynamic evaluation of preimplantation development (from time of second polar body extrusion to time of blastulation) were performed. In case of developmental arrest, the relative stage was annotated. T-test or Mann-Whitney U tests were performed to assess statistically-significant differences.

Main results and the role of chance: The mean number of oocytes per arm for each patient was 3.5±0.7 (2-4) in Geri-Medium versus 3.6±0.7 (2-4) in CSCM (p=0.5). The mean number of zygotes was 2.6±1.0 (0-4) versus 2.8±0.9 (0-4) (p=0.2). The mean fertilization rate per cohort per patient was 75%±26% versus 78%±22% (p=0.3). The mean number of blastocysts obtained was 1.5±1.1 (0-4) versus 1.4±1.0 (0-4) (p=0.6). The mean blastulation rate per inseminated oocyte per cohort per patient (i.e. primary outcome) was 42.4%±30% versus 40.6%±29% (p=0.56). No difference was reported also if the blastulation was calculated per zygote (54.9%±33.9% versus 52.2%±34.3%, p=0.48). The mean quality of the blastocysts obtained from each cohort was comparable in the two groups (rate of blastocysts ≥4BB according to Gardner and Schoolcraft's classification: 72%±40% versus 81%±34%, p=0.08). Of note, the embryos cultured in Geri-Medium were significantly 2-3 hr slower (p≤0.02) from the 5-cell stage (t5) up to full-blastulation (tB). The developmental arrest rates were similar in both media, but the embryo cultured in CSCM were more prone to arrest in the transition from starting-compaction (tSC) to morula (tM) formation (arrest at tSC n=20/339 zygotes, 5.9% in Geri-Medium versus n=36/357, 10.1% in CSCM, p=0.05; arrest at tM n=8/339, 2.4% versus n=22/357, 6.2%, p=0.01).

Limitations, reasons for caution: This is an interim analysis (77% of the sample size), therefore we did not reach yet the required statistical power. The use of ideal low-tension oxygen conditions might have hindered the benefit of the anti-oxidant compounds contained in Geri Medium .

Wider implications of the findings: Ideal culture conditions are required to define benchmark outcomes expected from the implementation of novel tools in IVF. If our data will be confirmed, Geri-Medium and CSCM might be considered equally-efficient in an undisturbed culture-system. When standard conditions are adopted, a difference cannot yet be excluded and should be investigated.

Trial registration number: ClinicalTrials.gov ID: NCT03497052

P-151 The supraphysiological levels of Oxidation Reduction Potential (ORP) present in the human embryo culture media affects blastocysts formation and ongoing pregnancies in IVF cycles

I. Maldonado Rosas[1], A. Agarwal[2], I. Jimenez Medina[1], F. Solorzano Vazquez[1], L. Gabriela Villar[3], F.M. Perez Bernal[1], M.K. Panner Selvam[2]

[1]Citmer Medicina Reproductiva, Ivf, Mexico City, Mexico

[2]Cleveland Clinic, American Center for Reproductive Medicine- Department of Urology, Cleveland, U.S.A.

[3]Citmer Medicina Reproductiva, Ivf, Monterrey, Mexico

Study question: Does the adjustment of the supraphysiological ORP levels in embryo culture system improves the blastocyst formation, pregnancy and ongoing pregnancy in in vitro fertilization cycles?

Summary answer: The adjustment of the supraphysiological ORP levels in embryo culture to physiological ORP levels found in follicular fluid of oocyte donors improves the clinical outcomes.

What is known already: The oxidative stress in embryos can be induced by means of atmospheric oxygen concentration, culture media, cell manipulation, cryopreservation etc. This results in cell membrane damage, DNA damage, delayed development and reduced their viability. The supraphysiological levels of ORP measured using MiOXSYS system in culture media affects the development of 3PN human embryos. The overall levels of ORP found in follicular fluid from oocyte donor is 250% lower than Hepes media and 175% lower than embryo culture media. Hence ORP is the best indicator of oxidative stress in embryo culture media compared to other parameters.

Study design, size, duration: This prospective cohort study was performed from May to December 2018. 104 patients less than 37 years old with at least one transferred blastocysts or without embryo transfer due to all embryos of the cohort were arrested in embryo development (no blastocysts formation) were selected for this study, 52 cases used adjusted ORP media, Group 1, and other 52 used non adjusted ORP media, Group 2. Each patient was asked to sign an informed consent.

Participants/materials, setting, methods: The ORP levels were determined in culture media (Global total, Life Global Group, USA), and in the Hepes

media. Further, the ORP levels were adjusted to 60 -80 mV using EmbryORPâ (combination of antioxidants). The addition of the EmbryORPâ to both media was done 3 hours before either oocyte collection or the observation of the oocyte fertilization. After fertilization, normal fertilized zygotes were transferred to the ORP adjusted culture media up to blastocyst stage.

Main results and the role of chance: The total blastocyst formation and ongoing pregnancy per each cycle with at least one oocyte with normal fertilization were significantly higher in the group 1 vs group 2. [(63% vs 42%) P (<0.005) and (67% vs 39%) P (0.021)], respectively. The pregnancy rate was comparable between two groups (75% vs. 54%) P (0.0863). In addition no differences were found between groups in terms of mean patient's age (31.96 ±5.7 vs. 33.17±5.76) (p=0.4285), blastocysts formation at day 5 (79% vs. 83%), and at day 6 (21% vs 16%) respectively. The significant difference in the ongoing pregnancy between the two groups suggest that the adjustment of ORP levels in embryo culture media helps in reduced miscarriages in these patients.

Limitations, reasons for caution: Small cohort of patients is a limitation of the study. More studies are necessary to corroborate our findings.

Wider implications of the findings: The result from the current study indicate that the EmbyORP® can be used to scavenge the supraphysiological levels of ORP found in the embryo culture media. Adjustment of ORP levels in human embryo culture media increased the blastocyst formation and ongoing pregnancy rate in IVF cycles.

Trial registration number: Not Applicable

P-152 Clinical outcome of vitrified-warmed blastocyst transfer performed on day 5 and day 6 after LH surge detected by urine tests

M. Reljic[1], V. Kovac[1], V. Gavric Lovrec[1], L. Mlakar[1], P. Kores Testen[1], J. Knez[1], K. Rakic[1], B. Kovacic[2]

[1]University Medical Centre Maribor, Department of Reproductive Medicine and Gynaecological Endocrinology, Maribor, Slovenia

[2]Univerzitetni klinicni center Maribor, Dpt. for Reproductive Medicine & Gynecological Endocrinology, Maribor, Slovenia

Study question: Is clinical outcome of vitrified-warmed blastocyst transfers comparable if they are performed on day 5 or day 6 after LH surge detected by urine tests?

Summary answer: There is no difference in the clinical outcome between vitrified-warmed blastocyst transfers performed on day 5 and days 6 after positive LH urine tests.

What is known already: In true natural cycle (tNC) the timing for vitrified-warmed blastocyst transfers (FET) is determined by investigating the spontaneous LH surge. It is estimated that windows of implantation are opened 7 days after LH surge and last 2–4 days. To achieve synchronization between embryonic and endometrial development, blastocyst transfer on day 6 after LH surge was proposed. Urine LH increases 21 hours after the detection of the blood LH surge and synchronization could also be achieved if FET is performed on day 5 after positive LH urine tests. However, there are currently no studies in the literature covering this topic.

Study design, size, duration: All vitrified-warmed blastocyst transfers performed in tNC between 2013 and 2017, at the Department of Reproductive Medicine, University Medical Centre Maribor, were included in this retrospective study. In women with the regular menstrual cycle (24-35 days), after observing the selection of the leading follicle and thickening of the endometrium on ultrasound, urine LH tests were used twice daily to monitor the LH surge onset. FET was performed on day 5 or 6 after LH surge.

Participants/materials, setting, methods: On day 5, FET was scheduled according to doctor-patient agreement to avoid FET on some days during weekends. [UA1] Progesterone supplementation (400 mg of micronized vaginal progesterone per day) was started after FET. Patients' characteristics and clinical data were collected from our software database. Reproductive outcomes, cycles and patients characteristics between FET on day 5 and on day 6 after LH surge were compared using the Pearson's Chi-squared test, Student's t-test, and Mann–Whitney U-test.

Main results and the role of chance: Among 2041 vitrified-warmed blastocyst transfers, 1631 (79.91%) were performed on day 6 and 410 (20.09%) on day 5 after positive LH urine tests. There were no statistically significant differences between these two groups in the clinical pregnancy rate (37.80 vs. 39.05%), implantation rate (35.08 vs. 33.86%), miscarriage rate (15.13 vs. 19.62%) and delivery rate (29.95 vs. 30.35%). There were also no differences in women's age (33.75 ± 4.18 vs. 34.13 ± 4.13 years), number of previous IVF attempts (1.69 ± 1.30 vs. 1.85 ± 1.99), cause of infertility, proportion of cycles with births after fresh embryo-transfer (19.51 vs. 19.80), proportion of cycles with FET after freeze-all cycle (12.19 vs. 12.38%), average menstrual cycle length (28.23±2.85 vs. 28.17±1.76 days), menstrual cycle variability (3.61±3.55 vs. 3.44±3.08 days), day of LH surge (13.61±2.31 vs. 13.36±2.22), endometrium thickness on the day of FET (10.02±2.11 vs. 9.96±227 mm), endometrial morphology, number of blastocysts transferred (1.21±0.41 vs. 1.25±0.50), proportion of difficult embryo-transfers (7.36 vs. 6.38%), proportion of transferred blastocysts vitrified on day 5 (69.51 vs. 66.09%) and proportion of transfer of morphologically optimal blastocysts (23.17 vs. 25.44%) between cycles with FET on day 5 and FET on day 6 after LH surge detected by urine tests.

Limitations, reasons for caution: This is a single-centre retrospective analysis and despite an acceptable number of included cycles and robust methodological approach, the presence of potential bias cannot be excluded. There is a need for a properly designed prospective randomized study to confirm our findings.

Wider implications of the findings: The main disadvantage of tNC in that there is no flexibility in timing for FET. However, the results of our study suggest that vitrified-warmed blastocyst transfer could be scheduled on day 5 or day 6 after positive LH urine tests without having an impact on the clinical outcome.

Trial registration number: Not applicable.

P-153 Ranking of vitrified blastocysts for frozen transfer based on kinetics and absence of dysmorphisms increases likelihood of implantation- a time lapse (TL) study

N. Desai[1], P. Gill[2], M. Yao[3]

[1]Cleveland Clinic Fertility Center, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Beachwood- OH, U.S.A.

[2]Cleveland Clinic Fertility Center, Obstetrics/Gynecology-Reproductive Endocrinology and Infertility, Beachwood, U.S.A.

[3]Cleveland Clinic, Quantitative Health Sciences, Cleveland, U.S.A.

Study question: Determine if time lapse imaging provides morphokinetic data that can be used to rank vitrified blastocysts according to implantation potential.

Summary answer: Embryos with delayed blastulation should be ranked last for FET, regardless of morphology. Further selection by absence of dysmorphisms can increment viable pregnancies.

What is known already: Ranking and selection of vitrified blastocysts according to implantation potential is critical to shortening time to pregnancy , cost to patients and still transferring only a single blastocyst in the frozen cycle. Morphologic grading alone does not allow sufficient discrimination between blastocysts of similar grades. TL offers a unique set of morphokinetic c markers to potentially aid the selection process. Little is known about the implantation potential of blastocysts arising from embryos with multinucleation or anomalies such as direct uneven cleavage (DUC), reverse cleavage (RC) and irregular chaotic division (ICD) as so often such embryos are deselected in fresh transfers.

Study design, size, duration: Retrospective examination of KID data (Known implantation data) from 427 consecutive frozen embryo transfers (FET) with vitrified warmed blastocysts (n=558). The blastocysts were derived from women undergoing IVF/ICSI (without PGS) between 2014 and 2017. All embryos had been cultured to blastocyst in the EmbryoScope time lapse (TL) incubator. Kinetics of cell division and morphologic features were annotated daily. Good quality blastocysts were vitrified on day 5/6. FET cycles were performed after endometrial priming.

Participants/materials, setting, methods: The primary outcome parameter was embryo implantation (sac). Secondary outcomes monitored were fetal heart, viable pregnancy and live birth rate. Kinetic variables analyzed were vitrification day, time (t) to 2,3,4,5 cells, morula,blastulation, expansion and intervals between cell stages. Implantation potential was compared between embryos with different dysmorphisms and kinetic behaviors. Statistical analysis performed using Pearson's chi-square test and logistic regressions to calculate odds ratio (OR) and 95% confidence interval (95%CI) after controlling for patient age.

Main results and the role of chance: The clinical pregnancy rate was 56.4% with a mean of 1.32 embryos being transferred. Implantation potential of day 5 versus day 6 vitrified blastocysts (BL) was far higher (60.6%, 28.4%, respectively p<0.001). A significantly higher percentage of D6 BL (56%) vs D5 BL (44%) were derived from embryos displaying specific cleavage stage dysmorphisms : MU 47% vs 23%; DUC 8% vs 2%; or a combination of dysmorphism 13% vs 5%. The second cleavage interval cc2 (t3-t2) was observed to be <=5 hrs in 12% D6BL as compared to 6% of D5 blastocysts. This characteristic is often linked to poor developmental potential. After correcting for age, the odds ratio of a day 5 blastocyst with no dysmorphisms implanting with a FH was 1.54 (95% CI 1.042-2.280; p=0.03). OR for D5 MU BL was 0.674 (95% CI 0.432-1.051; p=0.08) and for D5 ICD BL 0.589 (95%CI 0.336-1.031;p=0.06). After adjusting for the presence of two or more dysmorphisms and age, we found that tSB significantly affected implantation potential. Embryos with longer tSB had a decreased probability of resulting in an implantation with a fetal heart. The probability decreases 4% per hour as the tSB prolongs (OR, 0.960; CI 0.940-0.980; P<.001).

Limitations, reasons for caution: The retrospective design of the study did not allow for control of patient-specific variables. Although regression analysis took age into consideration, the chromosomal status of the embryo(s) could not be controlled for. Validating the impact of specific dysmorphisms on implantation rate requires a larger data set with age matched controls.

Wider implications of the findings: In the optimized continuous culture environment of the EmbryoScope time lapse chamber, blastocysts with the highest implantation potential are formed and vitrified within 122 hours of ICSI. Early cell cycle kinetics and observed dysmorphisms provide additional criteria to discriminate among blastocysts and enhance pregnancy outcomes in frozen transfer cycles.

Trial registration number: Not applicable

P-154 Cytological analysis of sperm penetration and arrest of fertilization in mature oocytes that did not form pronuclei following conventional IVF

I. Nagahara[1], K. Yumoto[1], T. Shimura[1], Y. Mio[1]

[1]Mio Fertility Clinic, Reproductive Centre, Yonago, Japan

Study question: Why does fertilization sometimes fail in conventional IVF (c-IVF)?

Summary answer: After c-IVF, most unfertilized oocytes showed no signs of sperm penetration, but some arrested during the fertilization process even after sperm penetration.

What is known already: Unfertilized oocytes after c-IVF may fail to form pronuclei due to lack of sperm penetration. For patients who do not obtain fertilized oocytes by c-IVF, intracytoplasmic sperm injection (ICSI) is the only hope for pregnancy. However, ICSI may not result in fertilization, even though sperm are definitely injected, with research showing: absence of calcium oscillation causes failure of second polar body extrusion; lack of decondensation of sperm nucleus causes unsuccessful pronuclei formation; and sperm centrosomal dysfunction causes developmental arrest at the pronuclear stage. Thus, ICSI has been investigated extensively, but few reports on unfertilized oocytes after c-IVF have been published.

Study design, size, duration: Unfertilized mature oocytes (n=50) without pronuclear formation within 44 hours after insemination by c-IVF were donated by 13 infertile couples. We conducted a cytological analysis of the donated oocytes, using immunofluorescent staining, utilizing anti-pericentrin antibody as a marker of centrosomes to examine sperm penetration. This was based on our previous study on abnormally fertilized oocytes, which revealed that the number of centrosomes matches the number of sperm that penetrate the ooplasm.

Participants/materials, setting, methods: Microtubules and centrosomes of the oocytes were identified using a mouse polyclonal anti-alpha tubulin antibody and a rabbit polyclonal anti-pericentrin antibody, respectively (1:100 dilution for both, Abcam). These primary antibodies were detected by Alexa Fluor 488 goat anti-mouse IgG antibody and Alexa Fluor 568 goat anti-rabbit IgG antibody, respectively (1:250 dilution for both, Life Technologies). DNA in the ooplasm was stained with Hoechst 33342 (Thermo Fisher). Images were obtained using an FV1000 confocal microscope (Olympus).

Main results and the role of chance: Out of the 50 unfertilized mature oocytes, 44 showed a double-positive signal for DNA and alpha tubulin in the ooplasm, which was thought to indicate the metaphase spindle of the second meiotic division (MII spindle). In addition, there was no pericentrin signal in these 44 oocytes, suggesting that sperm penetration did not occur. On the other hand, two oocytes showed pericentrin signals, suggesting that sperm had successfully penetrated these oocytes. One of these two oocytes showed a triple-positive signal for DNA, alpha tubulin and pericentrin, which was thought to be derived from a sperm and the MII spindle, indicating that the fertilization process of this oocyte had arrested during formation of the sperm aster. Interestingly, the other oocyte showed two pericentrin signals at the poles of the assembled spindle. The male and female chromatin in this oocyte may have fused without forming pronuclei, with development thus arrested before the first cleavage. The remaining four oocytes showed two spindles without pericentrin signals in the ooplasm, although the reason for this was unclear.

Limitations, reasons for caution: It is possible that the pericentrin signal was undetectable in some oocytes. In addition, since this was a preliminary study, more detailed investigations are needed to clarify the reasons for fertilization failure in c-IVF oocytes.

Wider implications of the findings: We found that most unfertilized c-IVF oocytes lacked signs of sperm penetration. However, fertilization had begun, but arrested, after sperm penetration in some oocytes. We identified several cytological patterns in the unfertilized oocytes, therefore more detailed analyses using larger numbers of c-IVF oocytes might help determine why fertilization sometimes fails.

Trial registration number: None.

P-155 Effect in sequential medium with or without renewal on day-2 and day-4 during culture for blastocyst transfer

J.E. Lim[1], H.J. Kim[1], E.J. Song[1], S.J. Yoon[1], K.M. Yang[1], S.H. Yoon[2], J.H. Lim[2]

[1]Suji Maria Fertility Clinic, Research center, Yongin, Korea- South

[2]Maria Medical Foundation, Research center, Seoul, Korea- South

Study question: Are there any differences on clinical outcomes following fresh medium renewal on day-2 and day-4 for blastocyst transfer?

Summary answer: Pregnancy rate and implantation rate were statistically significantly higher than those of the non-renewal group, while differences of development were not present.

What is known already: Elective single blastocyst transfer (eSBT) begins to be widely used in assisted reproductive technology and eSBT is also required to avoid multiple gestation pregnancies. For eSBT to be widely used, culture systems should be more improved for recapitulate the in vivo environment. But, embryos are exposed to the risk of accumulating embryo-toxic volatile organic compounds and ammonium during in vitro culture treatments. Change of media would advocate to deplete embryo-toxic substances and to reduce naturally occurring inhibitors. However, some studies have not been detected differences in cultures, whether the culture medium renewed or not.

Study design, size, duration: A retrospective study was performed from January 2018 to December 2018. Total of 86 blastocyst transfer cycles, including 29 cycles with renewal medium and 57 cycles without renewal medium, were carried out. The cycles with genetic diagnosis, poor responder, and advanced maternal age (≥38 years) were excluded.

Participants/materials, setting, methods: The couples were randomly divided into two groups: medium renewed at day-2, day-3, and day-4, respectively and medium not renewed on day-2 and day-4. Three-hundred fifty-nine embryos for renewal medium were transferred into freshly prepared droplets covered with oil. Except for the day-3, 759 embryos were cultured intact without renewal according to our standard protocol with sequential media. All transfers were performed on day-5. Formed blastocysts from surplus embryos were cryopreserved on day-5 and day-6.

Main results and the role of chance: The proportion of good-quality cleavages obtained with the renewal medium protocol (54.0%) was statistically similar to those in the without renewal group (51.0%). Significant differences were not observed in the blastocyst formation (transferred plus frozen; 43.5 vs. 45.6%) and good-quality blastocyst (≥3BB, transferred plus frozen; 67.9 vs. 68.8%) rates. Blastocyst transfers of good quality (≥3BB) in the renewal group were 85.4%, and 86.7% in the without renewal media group. The rates of positive β-hCG tests (69.0 vs. 42.1%, p=0.018), clinical pregnancy (62.1 vs.

38.6%, p=0.039) and implantation (51.2 vs. 31.3%, p=0.025) were statistically significantly higher in the renewal group than the without renewal group.
Limitations, reasons for caution: Further studies will be required to accumulate sufficient data and prospective study with sibling oocytes. And it is the results of single and double blastocyst transfer. Therefore, further studies should be done by only eSBT to determine the accurately analysis on pregnancy.
Wider implications of the findings: Medium renewal on day-2 and day-4 has higher pregnancy outcomes in blastocyst transfer. Our observation suggests that advanced extended culture system could facilitate more successful eSBT and would contribute to reducing the risk of multiple births.
Trial registration number: Not applicable.

P-156 A comprehensive description of the clinical contribution of poor-quality blastocysts to live birth: analysis of 2757 oocyte retrievals with preimplantation genetic testing for aneuploidies.

D. Cimadomo[1], D. Soscia[1], A. Vaiarelli[1], A. Giancani[1], L. Dusi[2], B. Iussig[2], S. Santopaolo[3], A. Capalbo[4], F.M. Ubaldi[1], L. Rienzi[1]
[1]*Clinica Valle Giulia, G.EN.E.R.A. centers for reproductive medicine, Roma, Italy*
[2]*G.EN.E.R.A. Veneto, G.EN.E.R.A. centers for reproductive medicine, Marostica, Italy*
[3]*Clinica Ruesch, G.EN.E.R.A. centers for reproductive medicine, Napoli, Italy*
[4]*Igenomix, Igenomix Italia, Marostica, Italy*

Study question: Which are the clinical benefits and risks of including poor-quality blastocysts (PQBs) in the cohort of biopsied embryos during an IVF cycle with preimplantation-genetic-testing-for-aneuploidies (PGT-A)?
Summary answer: Including PQBs involves higher implantation-failure and miscarriage rates after euploid transfer, but also an overall ~2.5%-increase in the number of live births (LBs) after PGT-A.
What is known already: PQBs (<BB according to Gardner and Schoolcraft's classification) are generally disregarded for clinical use and/or research purposes. Therefore limited data exist in literature to estimate the benefits and risks deriving from the transfer of a PQB. In Italy, the Law imposes the transfer or the vitrification of all embryos, unless proven not viable. This regulation involved a consistent amount of data produced regarding poor-quality embryos. Previous reports outlined a lower chance of euploidy and implantation for PQBs. Yet, a comprehensive picture of their real clinical contribution is missing.
Study design, size, duration: Observational cohort study including 2757 oocyte retrievals for PGT-A (mean maternal age: 39.6±3.3yr) conducted at a private IVF center between April-2013 and May-2018. 1497 PQBs were obtained and their embryological, chromosomal and clinical features were compared to 5250 non-PQBs (≥BB according to Gardner and Schoolcraft's classification). Once defined the overall increase in LBs due to PQBs, we outlined the population of patients that might benefit the most from their clinical use.
Participants/materials, setting, methods: IVF cycles after controlled-ovarian-stimulation (antagonist protocol), blastocyst culture, trophectoderm biopsy, vitrification, comprehensive chromosome testing by qPCR (until October-2017) or NGS (afterward) and warmed euploid single embryo transfers (SETs) were conducted. Overall analyses and sub-analyses in populations of patients clustered according to maternal age at retrieval and size of the cohort of sibling non-PQBs were performed. Lastly, the risk of miscarriage and the chance of LB per biopsied PQB and non-PQB were estimated.
Main results and the role of chance: PQBs involved a 12.4%-increase in the cycles where ≥1 blastocyst was biopsied (n=2217 versus n=1973 if accounting only non-PQBs). To date, we reported a concurrent 2.5%-increase in the cycles resulting in ≥1 LB (n=724 versus n=708) and a 13.8%-increase in the cycles where no LB was achieved but cryopreserved euploid blastocysts are left to transfer (n=206 versus n=181).

On average 0.7±0.9(range:0-9) PQBs were obtained per cycle to biopsy, and 0.2±0.4(range:0-5) euploid PQBs. No patient/cycle feature associated with higher/lower chance of producing them. However, the 18 women achieving their only LB thanks to PQBs clustered among patients with a limited cohort of sibling non-PQBs produced (1.1±1.1,range:0-3).

The 1497 PQBs compared to the 5250 non-PQBs showed slower developmental (day5:10.1% versus 43.9%, day6:60.5% versus 50.8%, day7:29.4% versus 5.2%;p<0.01) and lower euploidy rates (23.5% versus 51%;p<0.01). Among the 195 and 1697 transferred euploid PQBs and non-PQBs, the former involved a lower implantation (16.9% versus 52.3%;p<0.01), and higher miscarriage (36.4% versus 13.9%;p<0.01), therefore resulting in a lower LB-rate (LBR:10.8% versus 44.6%;p<0.01). Based on these rates, we estimated an overall 1.4% risk of miscarriage and 2.5% chance of LB after euploid vitrified-warmed SET per each biopsied PQB. The same estimates for non-PQBs were 3.7% and 22.8%.
Limitations, reasons for caution: The clinical benefit of PQBs is under-estimated since they are the last option for transfer and this analysis entailed only the first LB. Specifically, 42 women never pregnant and 90 that already delivered still have euploid PQBs left. Lastly, cost-benefit analysis is required in a prospective non-selection fashion.
Wider implications of the findings: PQBs show higher aneuploidy rates. If included, PGT-A is recommended. When selecting against aneuploid-PQBs, euploid ones could still involve higher implantation-failure and miscarriage rates; yet, their LBR is not negligible. Women should be acknowledged that implantation potential is not defined by a poor-morphology, but PQBs might entail more clinical risks.
Trial registration number: None.

P-157 The ART score: a score time independent able to predict frozen embryo transfer (FET) outcome.

M. Benchaib[1], E. Labrune[1], S. Giscard d'Estaing[1], G. Soignon[1], B. Salle[1], J. Lornage[1]
[1]*Hôpital Femme Mere Enfant, Biology of Reproduction, Bron cedex, France*

Study question: The ART score (Labrune et al, 2018) could be used as predictive score of FET outcome after a failed in vitro fertilization procedure.
Summary answer: The ART score issued from fresh ART procedure, from which are derived the frozen embryo, was able to predict FET outcome and was time independent.
What is known already: The factors linked to the FET outcome were multiple. The percentage of remaining blastomers after the thawing procedure, the number of ART procedure carried out previously were important factors to obtain childbirth. However, the appreciation of the anteriority of the ART procedure by their only rank, although interesting, does not apprehend the history of the ART procedure in its entirety. The ART score synthesizes an ART procedure into a single note, higher is the ART score, higher is the delivery chance. The ART score could be used to predict the FET outcome according its fresh ART procedure.
Study design, size, duration: A retrospective cohort study was conducted in the department of reproductive medicine at the Hôpital Femme Mere Enfant (Lyon, France). Couples performing an ART procedure during the study period were included according to the following exclusion criteria: delivery during the ART procedure from whom the freezed embryos originated, freeze all procedure, oocytes donation, none embryo freezed during the ART procedure. 1500 couples with 2508 FET procedures were included, from January 2010 to December 2016.
Participants/materials, setting, methods: Embryos were frozen at early stage (D2 or D3) with slow freezing process; or at blastocyst stage, in this case slow freezing process or vitrification process were used. Only embryos classified as "top embryos" were freezed or vitrified. The endometrial preparation was performed with substitution protocol or gonadotropin protocol. Monovariate and multivariate regression logistics analysis were performed to study the link between predictive parameters and FET outcome.
Main results and the role of chance: At the FET time, the women mean age was 33.4 ± 4.3 years. The mean number of transferred cryopreserved embryos was 1.52±0.62. The overall delivery rate was 18.0% (452/2508). The FET delivery rate varies significantly over time, starting at 5.9% (3/51) in the first semester of 2010 to 14.2% (26/183) in the fourth semester of the year 2016 (p<0.001). The following parameters were tested for FET outcome prediction: ART score, woman age, number of embryo transferred, number of performed FET (rank), stage of embryo transfer, the freezing procedure, and the endometrial preparation protocol. With the multivariate logistic analysis, the chance of FET delivery increases according to ART score (OR=1.43, p<0.05), and number of transferred embryo (OR=1.78 for two embryos transferred with p<0.001). The chance of delivery decreases according to FET rank (OR=0.22 after the first FET cycle, p<0.001), woman aged above 40 years (OR=0.51, p<0.05). However, among all these parameters, only the ART score

was independent of the time in which the FET was performed (p = 0.094). In conclusion, with this study conducted over a 7-year period, among the factors that influence the delivery rate, only the ART score was time independent and related to the birth rate.
Limitations, reasons for caution: The limitations of this study were: - the non-inclusion of the blastocyst grade at the time of cryopreservation; however, our cryopreserving policy would limited this variable effect, - the study was monocentric, however the ART score has been shown to be reproducible in other ART center (Labrune et al, 2018).
Wider implications of the findings: It seems even if the cryopreserved embryos were classified as good, the ART procedure from where they were originated have an in influence on their destiny. An embryo classification based on its morphology and its history should be elaborated.
Trial registration number: not applicable

P-158 A novel system of imaging mammalian zygotes to track pronuclear migration in 3D

J. Uraji[1], K. Scheffler[1], M. Schuh[1]
[1]*Max Planck Institute for Biophysical Chemistry, Department of Meiosis, Göttingen, Germany*

Study question: Establishing a method to track pronuclear migration using confocal live-cell imaging and 3D Image analysis in mouse zygotes fertilized through IVF.
Summary answer: Successfully established the tools to quantitively track maternal and paternal pronuclei in high spatiotemporal resolution, allowing first observations of the dynamics of their migration.
What is known already: Live cell imaging systems have been established for meiotic progression of mouse (Schuh and Ellenberg, 2008) and human (Holubcova *et al.*, 2015) oocytes, but not zygotes. Previous studies investigating mechanisms of pronuclear migration in mouse zygotes used either immunofluorescence imaging of fixed cells over time, or spinning-disk images of live cells with very low temporal resolution (i.e. images taken at start and end of pronuclear migration) (Schatten, 1994; Chaigne *et al.*, 2016). Therefore, no spatiotemporal analysis of pronuclear migration over the full time course from fertilization to the nuclear envelope breakdown had been established.
Study design, size, duration: Mouse zygotes were imaged on confocal microscopes every 3-15 minutes over the course of 4-17 hours. Experiments were of observational nature in order to quantify the dynamics of pronuclear migration and other proteins or structures of interest. Each type of experiment was repeated at least 3 times, and each repetition was done with at least three, and up to 20 zygotes per group, depending on the nature of the experiment.
Participants/materials, setting, methods: Experiments were conducted in a basic research laboratory setting. MII oocytes were collected from the oviducts of superovulated C57BL/J x CBA/J F1 mice. The oocytes were subsequently injected with mRNA encoding for fluorescently labelled proteins and structures of interest, such as DNA, cell membrane, or vesicles. The oocytes were fertilized with capacitated sperm from male C57BL/J x CBA/J F1 mice, imaged using confocal microscopy and analysed using IMARIS 3D imaging software.
Main results and the role of chance: We successfully established a method to culture and image mouse zygotes expressing fluorescently tagged proteins of interest from fertilization until nuclear envelope breakdown and subsequent first mitotic division. By injecting the zygotes with mRNA encoding for different fluorescently tagged proteins, we were able to conduct a series of experiments to further our understanding of pronuclear migration in mammals. First of all, by labelling DNA and cell membrane and imaging a z-stack of the zygotes every 15 minutes, IMARIS could subsequently be used to reconstruct pronuclei and zygote in 3D. Using this approach, we could quantify the distance of each pronucleus (maternal and paternal) from the zygote centre over time. Furthermore, we were able to image other structures of interest in high spatial and temporal resolution; for example, we were able to image actin vesicles with an interval of 3 minutes zoomed into smaller parts of the cell, allowing us to analyse the dynamics of these structures over time.
Limitations, reasons for caution: The zygotes were fertilized and cultured in vitro, which may affect observations. Also, we have not tested this method in zygotes from other species, and thus whether the method works or similar dynamics exist in e.g. human zygotes is not known.
Wider implications of the findings: Correct pronuclear migration is required for successful early embryogenesis. This method allows us to systematically test the function of various cytoskeletal components in mouse pronuclear migration, and may be applied to other model systems in the future, to help us understand the mechanisms of this process.
Trial registration number: not applicable

P-159 The impact of reproductive ageing on the human oocyte transcriptome during the GV to MII transition

P. Ntostis[1], G. Kokkali[2], D. Iles[1], J. Huntriss[1], T. Vaxevanoglou[2], K. Pantos[2], H. Picton[1]
[1]*LICAMM Institute, Discovery and Translational Science, Leeds, United Kingdom*
[2]*Genesis Athens clinic, Reproductive Medicine Unit, Athens, Greece*

Study question: What are the differences in gene expression between human germinal vesicles (GV) to metaphase II (MII) stage transition during reproductive ageing?
Summary answer: A decrease in mitochondrial-related transcripts from GV to MII oocytes was observed, with a much greater reduction in the MII with advance age.
What is known already: Early embryonic development is governed by maternal transcripts stored within the oocyte during oogenesis. Transcriptional activity of the oocyte ultimately dictates its developmental potential and may be influenced by maternal age, resulting in reduced competence of older oocytes compared with young. Others performed gene expression studies in human and animal oocytes, using qRT-PCR and array-CGH based techniques. An RNA sequencing (RNA-Seq) study showed energy-related transcript reduction during the GV to MII transition in bovine oocytes. In the current study, RNA-Seq was used for transcriptome profiling of human GV and MII oocytes of young and advanced maternal age women.
Study design, size, duration: Fifteen patients treated for infertility in a single IVF unit agreed to participate in this study. Five GV and 6 MII oocytes from eight 21-26 yo women (young group) and 5 GV and 6 MII oocytes from seven 41-44yo women (old group) were donated for this research (Ref. No.: 19964/04-09-2014) by women undergoing IVF treatment. The samples were collected within 3 months. RNA was isolated and deep sequenced at the single cell level.
Participants/materials, setting, methods: Cumulus dissection from donated oocytes was performed 38 hours after hCG injection and oocytes were frozen at -80°C in lysis buffer supplemented with RNase inhibitor. RNA from GV and MII oocytes underwent deep RNA sequencing using the SMART-Seq v4 Ultra Low Input RNA protocol (Takara-Clontech, USA) and Nextera XT DNA library preparation kit (Illumina, USA). Data processing, quality assessment and bioinformatics analysis were performed using source-software, including FastQC, HISAT2, StringTie, edgeR and DAVID.
Main results and the role of chance: Following deep single-cell RNA-Seq of GV and MII oocytes, hundreds of transcripts were significantly differentially expressed between young and old groups, with the most significant biological processes relating to mitochondrial reserves. The GV to MII transition shares common biological processes between young and old groups, however, some genes involved in mitochondria function were altered during ageing. A decrease in mitochondrial-related transcripts was also observed in the GV to MII transition. However, there was a much greater reduction of mitochondrial-related transcripts in MII oocytes with advanced age. This observation was confirmed when young MII oocytes were compared with the old MII group with mitochondrial-related transcripts being significantly higher expressed in the young group, including biological processes such as mitochondrial electron transport and ATP biosynthetic process (FDR 7.7E-12 to 1.5E-3). These results indicate a higher energy potential in young MII oocytes that is decreased with age. Other biological processes that were significantly higher in the young MII group include transcripts involved in the regulation of ubiquitin-dependent degradation. Lack of these transcripts could lead to a non-appropriate removal of oogenesis remnants following fertilisation in the old MII group.
Limitations, reasons for caution: The different stimulation treatments among the recruited patients/donors could be a reason for caution. However, the RNA-Seq results cluster quite closely with low intra-group variation. Furthermore, 5-6 biological replicates were derived from at least 3 different donors per group, minimising the potential impact of chance on the findings.

Wider implications of the findings: Understanding reproductive ageing effects at the RNA level in human oocytes may reveal differences in the mechanisms regulating the GV to MII transition that impact on oocyte quality in young and old patients. Further investigations of the up-/down-regulated transcripts during ageing could guide and improved IVF outcomes for older patients.
Trial registration number: Not applicable

P-160 Three-dimensional biodynamic imaging: a novel approach to assessing oocyte maturity in an intact cumulus-oocyte complex to enhance in-vitro maturation yield

B. Levine[1], R. Krisher[2], Z. Machaty[3], R. An[4], G. Narayanan[5], T. Morgan[6]
[1]*CCRM New York, Administration, New York, U.S.A.*
[2]*CCRM, Research, Denver, U.S.A.*
[3]*Purdue University, Animal Sciences, West Lafayette, U.S.A.*
[4]*Animated Dynamics- Inc., Technology, Indianapolis, U.S.A.*
[5]*Animated Dynamics- Inc., Research, Indianapolis, U.S.A.*
[6]*Animated Dynamics- Inc., Administration, Indianapolis, U.S.A.*

Study question: Is it possible to assess oocyte maturity without removal of cumulus cells utilizing biodynamic imaging?
Summary answer: Oocyte maturity can be accurately assessed with non-invasive imaging techniques.
What is known already: Clinicians and patients share the common goals of increased success rates and reduced dependence on hormone support of the in-vitro fertilization ("IVF") workflow. Both goals are currently hindered by the absence of suitable means to perform non-destructive assessment of harvested oocyte maturity while preserving the prospect of in-vitro maturation ("IVM") for immature oocytes. Current practices accept a very high loss rate among harvested eggs given the requirement to denude the cumulus oocyte complex ("COC") to accommodate optical microscopy, rendering immature oocytes non-viable. An assessment method that circumvents denuding would greatly improve IVF outcomes.
Study design, size, duration: This study aimed to establish the feasibility of a novel interferometry technique combining near-infrared light, advanced optics, and proprietary bioinformatic analysis to produce a three-dimensional computer visualization of fresh oocytes within the intact COC. Safety and efficacy of polar body detection was assessed in two experimental models: murine oocytes (672), and porcine oocytes (147).
Participants/materials, setting, methods: This research was conducted in collaboration with animal facilities at Indiana University and Purdue University. Safety testing involved imaging 331 test COCs for approximately 30 seconds, while holding 341 matched controls under otherwise identical conditions prior to completing routine IVF protocols. Efficacy was established by subjectively scoring interferometry images of fresh porcine oocytes as either mature or immature, after which they were denuded and blindly re-scored by an experienced embryologist using conventional methods.
Main results and the role of chance: Our safety experiments demonstrated a difference in mean fertilization rates between test and control cohorts of 0.96% (90% CI: -5.19% to 7.11%). Day 6 blastocyst yield differed by 1.42% (90% CI: -4.50% to 7.35%). The data support statistical equivalence of test and control groups for both study endpoints (equivalence limit +/- 0.075; fertilization rate p=.0399; day 6 blastocyst yield p=.0456). These favorable results are not unexpected given that exposure of biological samples to near-infra red light is generally regarded as being safer than visible and ultra-violet light due to its far lower single photon energy. To our knowledge, however, this is the first study of near-infrared light in the IVF setting.

Among 147 COCs evaluated using the technique, 135 (91.8%) were correctly predicted to contain mature or immature oocytes as subsequently confirmed by conventional microscopy. Technician evaluations yielded only 7 (4.8%) false-negative and 5 (3.4%) false-positive reads (sensitivity=89.7%, specificity=93.7%, $p<0.001$). With practice, the imaging procedure and subsequent interpretation demonstrated high efficiency and repeatability among two independent technicians and were deemed generally amenable to a high throughput embryology laboratory environment. These findings imply that the proposed imaging technique holds promise for safe and effective use in clinical practice.
Limitations, reasons for caution: Results of these porcine and murine studies may not generalize to human subjects. Further research is warranted to independently reproduce safety and accuracy results in additional animal models, followed by human trials subject to satisfactory results of expanded animal studies.
Wider implications of the findings: These promising preliminary results offer the potential to dramatically improve the IVF process both by increasing viable oocyte yield per harvest and reducing dependence on hormone support. Continued research and development should be a high priority given the unmet need for technologies that enable expanded adoption of IVM.
Trial registration number: not applicable

P-161 the negative effect of bisphenol A on preimplantation embryos via the induction of oxidative stress

J. Guo[1], G.N. Huang[1]
[1]*Chongqing Reproductive and Genetics Institute, Chongqing Key Laboratory of Human Embryo Engineering, Chongqing, China*

Study question: we investigated whether BPA negative effects on early embryonic development is associated the oxidative stress
Summary answer: our results indicate that BPA displays an adverse effect on porcine early embryonic development because of the excessive accumulation of ROS
What is known already: BPA is an environmental contaminant widely used in the plastic industry, and has been detected in good and water consumed by animals and humans. BPA has been demonstrated to be an endocrine disruptor and has an adverse effect on the embryonic development of mammals. However, the mechanism of action of BPA is limited. Because of the porcine germ cells that has been shown to be more similar to human than others, the pig was used as the animal model in this study.
Study design, size, duration: Ovaries from prepubertal gilts were obtained from a local slaughterhouse. Follicles that were 3–6 mm in diameter were aspirated. The oocytes were maturated *iv vitro* and activated of parthenogenesis. For BPA treatment, the porcine parthenotes were randomly assigned to four groups. The adverse effects on the embryos were detected after treatment with BPA at a concentration of 100μM for 5 days
Participants/materials, setting, methods: The porcine parthenotes were randomly assigned to four groups: control, 50μM, 100μM, 200μM. The developmental rate was observed at different stage. 100μM was used in this study. The embryos were analyzed for ROS, and ROS related effects with immunofuorescence and RT-PCR
Main results and the role of chance: We found that blastocyst formation was impaired and the parthenotes were arrested at the 4-cell stage after treatment with 100μM BPA. Second, ROS increased following the addition of BPA, which further caused mitochondrial damage, and cytochrome c was released from the mitochondria to induce apoptosis. The adaptive response was demonstrated through LC3 immunofluorescence staining and by assessing autophagy-related gene expression. In addition, BPA caused DNA damage through the p53-p21 signaling pathway.
Limitations, reasons for caution: Because of the ethical limitations, the pig was used as animal model in this study. This justifies was adopted to human embryos need to be further investigated
Wider implications of the findings: These results will help us understand the reason that BPA cause the arrest of pre-implantation embryonic development. Therefore, the BPA toxicity observed in this study may contributed to understanding the reduced development potential in human oocytes.
Trial registration number: not applicable

P-162 Effect of Dynamic Oxygen Concentration on Mouse Preimplantation Embryos Development and Apoptosis with the Double Channel Gas Supply Incubator System

S. Lee[1], H. Seo[1], J. Lee[2,3], J. Jinhyun[2,3], K. Choi[1]
[1]*CNC biotech, Research center, Suwon-si, Korea- South*
[2]*Eulji University, Biomedical Laboratory Science, Seongnam=si, Korea- South*

[3]Eulji University, 3Department of Biomedical Laboratory Science- Graduate School, Seongnam=si, Korea- South

Study question: Is a reduction of the oxygen concentration from 5% to 2% during in vitro culture of mouse preimplantation embryos beneficial for developmental competence?
Summary answer: A reduction of oxygen concentration after day-3 could improve blastocyst quality and peri-implantation embryonic developmental competence.
What is known already: The various oxygen concentrations have effects on embryonic development rates and quality of in vitro culture. The majority of modern IVF labs have accepted the 5% or 20% of oxygen concentration. Recently, a new debate has emerged regarding whether a further reduction of oxygen concentration on day-3 after fertilization on development represents more similar in vivo physiological condition. This new approach is based on the premise that oxygen concentration is actually lower in the uterus than in the oviduct. There were several studies that in vitro culture of pre-implantation embryos using less than 5% of oxygen concentration.
Study design, size, duration: We examined the effect of different oxygen conditions of 20% (high O_2), 5% (low O_2) and 5% to 2% (dynamic O_2). In dynamic O_2 group, mouse embryos were cultured from the 1-cell to morula stage under 5% O_2 (for 3 days), followed by cultured under 2% O_2 concentration to the blastocyst stage. The other high O_2 and low O_2 group were cultured 1-cell to blastocyst stage under 20% and 5% oxygen concentration, respectively.
Participants/materials, setting, methods: We used a novel double channel gas supply incubator (DCGS, CNC biotech, Korea) to provide dynamic oxygen concentration environment. Embryos were cultured in 5% O_2 until day-3 and automatically changed 2% O_2 concentration in the DCGS incubator. Cleavage, blastocyst formation rate and TUNEL assay were performed to assess the embryo quality. Outgrowth assay for in vitro model of implantation was performed to evaluate the developmental potential of peri-implantation embryos.
Main results and the role of chance: Cleavage rates to 2-cell stage were similar in high, low, and dynamic O_2 group as 86.9 ± 5.8%, 87.9 ± 3.5%, and 90.1 ± 2.0%, respectively. However, blastocyst formation rate was significantly increased in low O_2 (75.7 ± 2.2%) and dynamic O_2 (75.6 ± 4.6%) group compared with high O_2 (54.0 ± 2.3%) group. Total cell number was significantly increased in dynamic O_2 (128.9 ± 3.3) group compared with low O_2 (115.4 ± 3.6) and high O_2 (87.5 ± 2.5) group, also, apoptotic index was significantly reduced in low O_2 (4.47 ± 0.49%) and dynamic O_2 (4.15 ± 0.35%) group compared with high O_2 (8.67 ± 0.82%) group. Outgrowth rates of blastocyst on day-8 after fertilization were increased in low O_2 (58.32 ± 2.26%) and dynamic O_2 (66.67 ± 11.11) group compared with high O_2 (43.41 ± 5.23) group, but, there was no significant differences. Mean area of TE were significantly increased low O_2 (1.05 ± 0.05 mm^2) and dynamic O_2 (1.11 ± 0.07 mm^2) group compared with high O_2 (0.70 ± 0.07 mm^2) group.
Limitations, reasons for caution: We could not clearly demonstrate dynamic oxygen concentration was superior to 5% static culture condition in terms of embryo development. Also, extra oxidative stress caused by inappropriate culture condition is not fully investigated. Moreover, embryo transfer is also required to fully investigate the implantation potential of in vitro cultured embryos.
Wider implications of the findings: Our results showed that slight benefits of dynamic oxygen concentration from 5 to 2% on day-3. It may be related to the physiological condition for pre-implantation embryos in uterus. Dynamical optimization of oxygen concentration with the novel DCGS incubator could improve embryo developmental competence in human IVF-ET program.
Trial registration number: This work (Grants No. 17-05) was supported by Business for Cooperative R&D between Industry, Academy, and Research Institute funded Korea SMBA in 2018.

P-163 The combination of embryo morphokinetics, blastocyst morphodynamics and classical morphology grading by using last generation time-lapse incubators improve embryo selection

L. Romany Sevilla[1], L. Bori[1], L. Alegre[1], R. Del Gallego[1], J. Remohi[2], M. Meseguer[1]

[1]Ivirma Global, IVF lab, Valencia, Spain
[2]Ivirma Global, gynecology department. IVI president, Valencia, Spain

Study question: Can the blastocyst expanded diameter (BD) be useful to determine the embryo implantation potential?
Summary answer: A combination of BD with two well-known parameters: blastocyst quality (ASEBIR criteria, 2015) and s3 (t8-t5), can predict the implantation potential of the embryos.
What is known already: In recent years, several authors have found different morphokinetic variables that could be predictors of implantation potential. The relevance of s3 predicting blastocyst development have been shown (Motato et al., 2016) and the success of the ASEBIR criteria to assess blastocyst quality is checked in many IVF laboratories daily. However, although a correlation between BD and implantation rate was found by our research group, BD had never been described as embryo selection criterion. In this study, a precise morphokinetic evaluation was conducted to identify the appropriate variables to generate a predictive algorithm.
Study design, size, duration: A retrospective analysis including 578 women undergoing single embryo transfer from 03/2017 to 08/2018 was performed. Embryos were cultured to the blastocyst stage in a Time-lapse monitored incubator (Embryoscope Plus®, Vitrolife, Denmark) in groups up to 8 embryos per slide.
Participants/materials, setting, methods: 578-SET embryos from younger than 38-year-old women were evaluated with the Embryoviewer®. Timings of the main events of embryo development including the transition of 5 to 8-blastomere embryos and the blastocyst morphology dynamics including the expanded diameter were annotated. A ratio between BD and the timing of this measurement was conducted to normalize data. Blastocyst quality was evaluated with ASEBIR blastocyst assessment classification. ANOVA, Chi-square-analysis and logistic regression method were conducted in SPSS as appropriate.
Main results and the role of chance: A detailed analysis of morphokinetic parameters showed that many of them were significantly correlated with subsequent implantation**.** We identified three variables most relevant: blastocyst quality (ASEBIR), blastocyst expanded diameter and time between division to 5 cells and division to 8 cells (s3). Optimal ranges were established for each relevant parameter: ASEBIR - A (**65.70%** implantation rate for A vs. **53.27%** for B+C)*, BD ≥ 159 µm (**61.8%** vs. **44.50%** for BD < 159 µm)** and s3 ≤ 14.5 h after ICSI (**61.30%** vs.**43.80%** for s3 > 14.5)*. Based on these results we elaborated a good discriminatory algorithm that classified embryos from A to C according to implantation potential. When the embryo parameters were inside the optimal range (A quality, BD ≥ 159 µm and s3 ≤ 14.5 h) embryos were classified as A, according to the algorithm, (**66.40%** implantation rate); if some of three parameters were outside the optimal range embryos were classified as B (**58.9%**); if three parameters were outside the optimal range embryos were classified as C (**37.4%**)*.
Note: *(p=.000) **(p=.001)
Limitations, reasons for caution: This analysis is limited by its retrospective nature as well as the subjectivity of blastocyst morphology evaluation. A larger retrospective sample size maybe necessary and a prospective trial would be important to validate our algorithm.
Wider implications of the findings: The combination of morphology with morphology dynamics of the blastocyst and morphokinetics could be used as a powerful non-invasive tool to select embryos to transfer. The subjectivity associated with the blastocyst evaluation can be overcome by the measurement of blastocyst features in a time-dependent fashion.
Trial registration number: Not applicable

P-164 Assessment of embryo implantation potential with a cloud-based automatic software

L. Alegre[1], R. Del Gallego[1], L. Bori[1], N. Basile[2], K. Loewke[3], M. Mahnaz[3], B. Aparicio-Ruiz[1], A. Palma-Govea[4], J. Marcos[5], M. Meseguer[1]

[1]IVIRMA Valencia, In Vitro Fertilization, Valencia, Spain
[2]IVIRMA Madrid, In Vitro Fertilization, Madrid, Spain
[3]Cellogy, Research, California, U.S.A.
[4]IVIRMA Panama, In Vitro Fertilization, Panama, Panama

[5]IVIRMA Murcia, In Vitro Fertilization, Murcia, Spain

Study question: ¿Does the embryo selection made by the DANA system correlate with a good implantation rate in patients undergoing IVF treatments?

Summary answer: DANA system selects embryos with high implantation potential from an automatically parameter (UAD) based on the morphokinetic characteristics of those embryos that have implanted.

What is known already: Selecting the best embryo for transfer is crucial to achieve the final goal of in vitro fertilization treatments. Time-lapse technology has made possible to perform a deep and accurate analysis for optimal embryo selection. The usefulness of time-lapse monitoring greatly depends on the creation of predictive algorithms that could be effective in different clinical settings and after distinct IVF procedures.

Study design, size, duration: This is a multi-centred retrospective study designed in three phases for the validation of the DANA system. The patients were recruited from July 2015 to January 2018 in three IVI Clinic's centres. A total of 1312 IVF cycles and 5343 analysed embryos were included in this three-phase trial. A new parameter was developed to estimate embryo score: the average distance of each embryo to the centre of the cloud of KID embryos (UAD).

Participants/materials, setting, methods: Phase 1: Creation of the data cloud of KID (Known Implantation Data) embryos from 1676 transferred embryos. Timings of embryo cleavage and cell cycle lengths up to the 5-cell stage were included in the DANA software; Phase 2: embryo selection based on the DANA system and confronted with the embryologist manual annotations (389 transferred embryos); Phase 3: Validation of DANA automatic embryo selection, without embryologist's intervention (147 transferred embryos).

Main results and the role of chance: The implantation rate of the 1021 KID embryos from phase 1 were distributed as follows: grade A 34%, grade B 25%, grade C 24%, and grade D 19%. In phase 2, a classification ranking according to the unit average distance (UAD) values was established: High (UAD $<$ 0.447), Medium (UAD = 0.447 – 0.998) and Low (UAD $>$ 0.998) implantation potential. The pregnancy rates for these groups were 55%, 45%, and 33%, respectively ($p < 0.001$). In phase 3, the 147 transferred embryos were classified according to their UAD values as grade A (UAD $<$ 0.50), grade B (UAD = 0.50 – 0.66), grade C (UAD = 0.67 – 1.03), and grade D (UAD $>$ 1.03); most implanted embryos were found in Groups A, B, and C (UAD $\leq$ 1.03), whereas the implantation rate in Group D (UAD $>$ 1.03) was significantly lower: 46% vs. 25%, respectively ($P = 0.037$).

Limitations, reasons for caution: External and prospective validations are required to confirm the reproducibility and generalizability of this automated system.

Wider implications of the findings: The model can analyse data obtained in different settings, and therefore is supposedly applicable to any clinic, standardizing the interpretation of embryo development. The great innovation of DANA is that the system learns as the database grows with each new patient cycle, becoming more and more accurate (machine learning).

Trial registration number: not applicable

P-165 Trophectoderm cell cycle, inner cell mass area, blastocyst expanded diameter and pronuclei migration associated with implantation potential: description of novel embryo parameters through time-lapse technology.

L. Bori Arnal[1], L. Alegre[2], R. Del Gallego[1], J. Remohi[3], T. Viloria[2], M. Meseguer[2]

[1]IVIRMA Valencia, Research laboratory, Valencia, Spain
[2]IVIRMA Valencia, In Vitro Fertilization, Valencia, Spain
[3]IVIRMA Valencia, Ginecology, Valencia, Spain

Study question: Can we improve the outcomes of the *in vitro* fertilization (IVF) cycle by studying new embryo development variables through time-lapse technology?

Summary answer: Novel analyzed variables showed a clear influence over the implantation rate. Optimal value ranges have been established for each variable, based on the implantation potential.

What is known already: Time-lapse technology allows consecutive observation of embryo development and provides morphological and morphokinetic information. Several studies have shown that timing of the most relevant events in embryo development are correlated with embryo preimplantation development and subsequent implantation rates. However, not all seemingly good quality embryos lead to implantation, raising the need to define new selection variables. Trophectoderm cell cycle length, inner cell mass area, blastocyst expanded diameter and pronuclei migration have already been assessed with the time-lapse incubator Embryoscope Plus® in a preliminary study performed by our research group. Currently, we have doubled the sample size reaching stronger results.

Study design, size, duration: A retrospective analysis, including 541 patients, was conducted. 765 embryos transferred were evaluated out of 2540 viable embryos. Single embryo transfer (SET) was performed for 476 of them. All of them were cultured in a time-lapse incubator (Embryoscope Plus®, Vitrolife, Denmark).

Participants/materials, setting, methods: 476 transferred embryos from younger than 38-year-old women were evaluated with the Embryoviewer®. Morphokinetic parameters were annotated during the embryo development by senior embryologists and the drawing tools were used to measure new variables, including: speed of the pronuclei migration, blastocyst expanded diameter, inner cell mass (ICM) area and trophectoderm cell cycle length. Data obtained was assessed in terms of clinical outcome and statistically analyzed with ANOVA test and Chi-squared test (SPSS 21 software).

Main results and the role of chance: This extensive analysis of morphokinetic parameters already known showed the optimal range for each variable, which give the embryos the highest implantation rate. Events associated with the late-stage embryo development are the most significant **t8**($<$62.83h), **tM**($<$93.15h), **tSB**($<$102.4 h) and **tB**($<$108.12h). New variables analyzed also showed values associated with different clinical outcomes. Implantation rate improved significantly ($p<.05$) as the blastocyst expanded diameter increased (**44,5%**for $<$158 µm vs. **52,3%**for 159-173 µm vs. **63,1%**for 174-187µm vs. **69.6%**for $>$188 µm). According to our data, embryos with ICM area larger than 2716µm^2 achieved better implantation rates than smaller ones (**60.20%**for $>$2716 µm^{2}vs **57.20%**for $<$2716 µm^2). In terms of speed of pronuclear migration, values from 0.21 µm/h to 3.32 µm/h were found, being the fastest ones, which displayed highest implantation rates. Trophectoderm cell cycle length was shorter than blastomere cell cycle. Moreover, the shorter the trophectoderm cell cycle the better (**64.4%**implantation rate for $<$8.66 h vs. **58.15%** for $>$8.66h).

Limitations, reasons for caution: Impact of each variable over the implantation rate has been individually assessed so far. In addition, although we used a high quality time-lapse system supplied with different plans, the embryonic three-dimensional morphology made the evaluation of some events difficult, mainly those which are related to pronuclei appearance and fading.

Wider implications of the findings: Analysis of the interaction among variables would be necessary to confirm the relevance of each parameter. A possible subsequent consolidation of the novel variables in embryo selection could lead to the development of new algorithms improving the selection of the best quality embryo.

Trial registration number: Not applicable

P-166 Impact of embryo replacement position (ERP) on euploid frozen embryo transfer (FET) outcomes

A. Bayram[1], N. De Munck[1], I. Elkhatib[1], A. Arnanz[1], A. El-Damen[1], A. Abdala[1], L. Melado[2], B. Lawrenz[2], H. Fatemi[2]

[1]IVI Middle East Fertility Clinic LLC, IVF Lab, Abu Dhabi, United Arab Emirates
[2]IVI Middle East Fertility Clinic LLC, Clinic, Abu Dhabi, United Arab Emirates

Study question: Does the position of the euploid blastocyst, measured as distance from the fundus (DFF) of the uterine cavity (mm) affect the implantation potential?

Summary answer: There is a negative correlation between the DFF and the probability of pregnancy and implantation, while no effect was seen on the miscarriage rate.

What is known already: The optimal ERP of a euploid blastocyst is one of the last hurdles of an ART treatment. However, the ideal location within the uterine cavity is still being debated. While it has been claimed that the transfer site does not affect the implantation potential, most of the studies found that the highest

pregnancy rates are obtained when the embryo is placed in the upper or middle area of the uterine cavity. Unfortunately, due to heterogeneity of parameters between different studies in which embryos with unknown ploidy state were transferred, objective assessment on the real effect of the ERP is difficult.

Study design, size, duration: This single center retrospective cohort study included a total of 455 single/double euploid FET cycles between March 2017 and November 2018. Trophectoderm biopsy samples were subjected to Next Generation Sequencing to screen the ploidy state. Vitrification and warming were performed using the Cryotop method (Kitazato, Biopharma). The longitudinal distance between the fundal endometrial surface and the air bubble after transfer with a K-soft COOK catheter was measured and pregnancy, implantation and miscarriage rates were recorded.

Participants/materials, setting, methods: The following explanatory variables were analyzed: age, Anti Müllerian hormone (AMH), body mass index (BMI), endometrial thickness, quality of the trophectoderm, difficulty of the transfer (requirement of additional instrumentation), presence of mucus or blood, day 5 or day 6 biopsy, single (SET) or double (DET) embryo transfer, cycle preparation (natural cycle - NC or hormone replacement therapy - HRT). The primary aim was to detect if the implantation potential is affected by the DFF.

Main results and the role of chance: The patients were on average 33.5 years old. The FET was performed in a NC (n=137) or HRT cycle (n=318). Of the 455 transfers, 325 (71.4%) resulted in a pregnancy and 262 (57.6%) in a clinical pregnancy leading to an implantation rate of 61.6%. Initially, we performed bivariate basic comparison tests between all explanatory variables and the pregnancy, implantation and miscarriage outcomes. When comparing the cycle preparation, number of embryos transferred and the quality of the embryos, the pregnancy and implantation rates were significantly higher in NC (p=0.0117 and p=0.0077), after DET (p=0.0049; and p=0.0026) and for high quality embryos (p=0.0039 and p=0.0072).

After performing a multivariate logistic regression analysis to consider the effect of all explanatory variables on the DFF, a negative effect between DFF and pregnancy (p=0.0084) and implantation (p=0.0065) was found. When all variables remained constant, the increase of one mm of DFF increases the odds ratio of pregnancy by 0.902 and of implantation by 0.903, implying that the probability of pregnancy and implantation decreases as the fundus distance increases. No statistical significance of DFF was found for the miscarriage outcome (p=0.2166), however, the presence of only 38 miscarriage cases is insufficient to make an adequate evaluation.

Limitations, reasons for caution: Besides the retrospective design of the study, superiorly the full length of the cavity should have been measured to estimate the exact position within different uterine sizes. Also, a higher number of miscarriages is needed to find a possible effect of the distance from the fundus on this parameter.

Wider implications of the findings: The depth of embryo replacement inside the uterine cavity may influence the pregnancy and implantation rates and should be considered as an important factor to improve the success of IVF cycles.

Trial registration number: NA

P-167 Impact of equilibration duration during oocyte vitrification protocol: preliminary results of a prospective observational study.

C. Herbemont[1], S. Sarandi[1], B. Dagher-Hayeck[2], M. Comtet[2], C. Vinolas[2], J. Calvo[2], F. Krief[2], I. Cedrin-Durnerin[2], M. Grynberg[2], C. Sifer[1]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-Biologie de la Reproduction-CECOS, Bondy, France

[2]Hôpital Jean Verdier, Médecine de la Reproduction, Bondy, France

Study question: Does the duration of equilibration step during oocyte vitrification protocol influence survival rate and biological outcomes after oocyte warming and micro-injection?

Summary answer: The equilibration duration during oocyte vitrification protocol might influence survival rates after warming but does not impact further embryo development of surviving oocytes.

What is known already: Oocyte cryopreservation is a valuable technique in the field of female fertility preservation (FP) as well as oocyte donation programs. Numerous studies have already analyzed biological and clinical outcomes following oocyte vitrification. Regarding technical aspects, open versus closed carriers have mainly been investigated. However, oocyte vitrification protocols commercially available do describe various durations of the equilibration step (ranging from 6 to 10 minutes (min)). To date, a potential influence of this variability on the outcomes after oocyte warming has never been investigated.

Study design, size, duration: This prospective-observational-monocentric study has been in progress since 2014, including all oocyte cryopreservation cycles. Vitrification/warming (n=64) were performed using commercialized media (Kitazato, Japan). During equilibration done according to the manufacturer's procedure, nine oocytes maximum were deposited by three in three drops of equilibration solution (ES). After 6min, the vitrification step was initiated for the first three oocytes (duration 1min), and the following oocytes straw-by-straw were vitrified immediately thereafter, respectively after 7 and 8min of equilibration.

Participants/materials, setting, methods:

Oocyte vitrification/warming required patients' written informed consent. To date, 64 couples underwent the whole procedure of warming and ICSI. The allocation of oocytes per straw depended on the total number of mature oocytes available, explaining the variable number of oocytes in groups 6/7/8min. Survival, fertilization, embryo quality at Day-2 and suitability for transfer/cryopreservation were assessed for each oocyte and compared according to the duration of equilibration (6/7/8min).

Main results and the role of chance: Briefly, the included patients were on average 36 years of age and underwent their 1.8th ICSI cycle. Indications for oocyte cryopreservation were: oocyte accumulation program (46%); oocyte donation (33%); FP prior to cancer treatment (3%), for endometriosis (10%) or poor ovarian reserve (1%); and absence of spermatozoa on the day of ICSI (7%). Overall, 388 oocytes were warmed, and 329 of them survived (survival rate (SR)=84.8%). The analysis according to the equilibration step duration showed a slight difference in terms of SR: 82.5% (188/228) in group "6min" *vs.* 85.6% (101/118) in group "7min" *vs.*95.2% (40/42) in group "8min" (global p-value=0.06). Interestingly, SR after 8min of equilibration was significantly or close to significantly higher than after respectively 6min (p=0.02) and 7min (p=0.07). Regarding biological outcomes after ICSI of the surviving oocytes, fertilization rate (68.1 *vs.*74.5 *vs.* 60.6%, p=0.29), Day-2 top-quality (28.9 *vs.*37.1 *vs.*19.0%, p=0.23) and good-quality embryo rates (43.0 *vs.*47.1 *vs.*33.3%, p=0.52) and rates of embryos suitable for transfer/cryopreservation (70.3 *vs.*67.1 *vs.*52.4%, p=0.28) were statistically similar whatever the duration of the equilibration phase.

Limitations, reasons for caution: Further investigation on a higher number of cycles and particularly on a higher number of oocytes in group "8min" is needed to clarify a potential impact of the equilibration duration on biological outcomes after oocyte warming. Furthermore, clinical outcomes should be analyzed.

Wider implications of the findings: If the duration of equilibration had a confirmed impact on oocyte survival, larger investigations should be performed on the different vitrification media commercially available. Then, manufacturers' recommendations on vitrification protocol should be amended accordingly.

Trial registration number: Not applicable

P-168 Comparative analysis of different nuclear transfer techniques to prevent the transmission of mitochondrial DNA variants

M. Tang[1], R. Reddy[1], Y. Gansemans[2], M. Van der Jeught[1], A. Boel[1], P. Stamatiadis[1], R. Van Coster[3], D. Deforce[2], F. Van Nieuwerburgh[2], P. De Sutter[1], B. Heindryckx[1]

[1]Ghent University Hospital Ghent Fertility and Stem cell Team, Department for Reproductive Medicine, Gent, Belgium

[2]Laboratory of Pharmaceutical Biotechnology- Ghent University- Ottergemsesteenweg 460- Ghent 9000- Belgium, Laboratory of Pharmaceutical Biotechnology, Gent, Belgium

[3]Department of Pediatric Neurology and Metabolism- Ghent University Hospital-Corneel Heymanslaan 10- Ghent 9000- Belgium, Department of Pediatric Neurology and Metabolism, Gent, Belgium

Study question: What is the efficiency of different types of germline nuclear transfer (NT) to prevent the transmission of mitochondrial DNA (mtDNA) variants in a mouse model?
Summary answer: First/second polar body transfer (PB1/2T) outperforms both maternal spindle transfer (ST) and pronuclear transfer (PNT) in reducing the transmission of mtDNA variants.
What is known already: Eliminating mtDNA disease's transmission may nowadays be possible by using NT in the germline. However, scientific evidence to compare different NT techniques to overcome mtDNA diseases within the same study is lacking. Recent studies have demonstrated the feasibility of ST, PNT and PB1T in humans, but conventional PB2T remains challenging due to difficulty of identifying the female pronucleus in human zygotes.
Study design, size, duration: We performed four types of NT (PB1/2T, ST and PNT) between B6D2F1 mice (n=91) (intra-strain NT) and between NZB/OlaHsd (n=52) and B6D2F1 (n=47) mice (inter-strain NT). We evaluated the efficiency based on embryonic development potential and the level of mtDNA carry-over. Moreover, using mouse MII (n=334) and human *in vitro* matured (IVM) (n=216) oocytes, we explored two novel protocols (PB2T-a and PB2T-b) to optimize PB2T procedures, and compared their efficiency with conventional PB2T.
Participants/materials, setting, methods: We conducted PB1T, ST and PNT by transferring nucleus from oocytes/zygotes into enucleated counterparts. PB2 was transplanted into half-enucleated zygotes (conventional PB2T), and into enucleated oocytes (PB2T-a), and into single-pronucleus zygotes (PB2T-b). The reconstructed embryos were cultured to assess embryonic development. Some reconstructed oocytes were examined for spindle formation using polarized microscopy, and for spindle morphology by confocal analysis. Polymerase chain reaction (PCR) followed by next generation sequencing (NGS) was performed to measure mtDNA heteroplasmy.
Main results and the role of chance: Polarized and confocal analysis revealed that the majority of PB1T and ST oocytes re-formed MII-like spindles, most of which exhibited normal spindle-chromosomal structures (90.1% and 89.7%, respectively). Following ICSI, both PB1T (89.0%) and ST (87.3%) yielded high blastocyst rates similar to an ICSI control (88.4%). Additionally, PB2T-b showed promising result with a blastocyst rate of 86.5%, which was higher than conventional PB2T (70.7%) ($P < 0.05$); in contrast, PB2T-a failed to form blastocysts probably owing to a high abnormal spindle rate (28.0%) ($P < 0.05$). PNT zygotes (92.0%) exhibited comparable blastocyst formation rates to those of PB1T, PB2T-b and ST embryos. Comparing intra-strain NT to inter-strain NT, we found no significant reduction in embryonic development. By analyzing artificial mixtures of mtDNA with different molar ratios, we confirmed that NGS had a high sensitivity in detecting mtDNA heteroplasmy with a detection threshold of ~0.5%. Analysis of NT-generated blastocysts using NGS revealed that both PB1T (0.6182%) and PB2T-b (0.9089%) had significant lower levels of mtDNA carry-over than those of ST (3.565%) and PNT (4.132%) ($P < 0.01$). Finally, extrapolation of novel PB2T-b to human IVM oocytes resulted in 12.9% of reconstituted embryos successfully developing to blastocysts similar to control ICSI embryos (20.5%).
Limitations, reasons for caution: Our findings in the mouse model should be verified in human patients with known mtDNA diseases. In addition, invasive micromanipulation of human oocytes or zygotes may cause chromosomal or epigenetic abnormalities. Further study to ensure the safety of different NT technologies is therefore required.
Wider implications of the findings: Our study reveals that PB1/2T results in minimal mtDNA carry-over without compromising embryonic development, indicating that PB1/2T has potential to reduce risk of transmitting diseased mtDNA. Since PBs are normally discarded, PB1/2T could be applied in combination with ST or PNT to improve the efficiency and number of available embryos.
Trial registration number: Not applicable.

P-169 Evaluation of the effects produced by Styrene (volatile organic compound- VOC) over the human pre- embryo development.

V. Vásquez Cubillos[1], F. Capuano[2], D. Beltran[1], P. Buendia[1], F. Insua[1], V. Garcia[1], A. Galan[1], M.J. De Los Santos[1]
[1]*IVIRMA Valencia, IVF Laboratory, Valencia, Spain*
[2]*IVIRMA, Research Laboratory, Valencia, Spain*

Study question: Can specific concentrations of Styrene, a very common IVF VOC, affect the human embryo development and ploidy?
Summary answer: Embryos cultured along with IVF- ambient air- related concentrations of Styrene have worst survival rates and morphology score when evaluated at blastocyst stage (day 6).
What is known already: Polystyrene, a synthetic aromatic hydrocarbon polymer made from the monomer styrene is present in the plastic-ware used in IVF laboratories. Styrene may persist even after the process of devolatilization, and its presence is known to affect the embryo development in animal models but no specific effects on humans have been described yet. Previous analysis have demonstrated that there are negative effects over human embryo development when exposing embryos to Benzene and Limonene,. Specific threshold levels at which most of the common pollutants in the IVF's ambient air can cause harm to cultured human embryos, have not been determined either.
Study design, size, duration: Prospective study with 115 day-3 (D3) human embryos. These have been allocated in four experimental groups; a. 40 embryos were cultured in the control (C) culture media. At the same time, 75 embryos were cultured and exposed to three Styrene concentrations based on previous IVF's environmental characterizations: b. Exterior (SE: 165,8∗10^-5ppm), c. Laboratory (SL: 981∗10-^5ppm) and d. Double Laboratory (SDL: 1962∗10^-5ppm). All embryos were cultured till day-6 (D6) so they could reach the blastocyst stage.
Participants/materials, setting, methods: This developmental toxicity test includes D3 embryos, with 6 to 10 cells and less of 25% of fragmentation, which have been exposed by contaminating the blastocyst culture medium with three doses of Styrene (under 1% of the occupational limit value, OLV). After thawing, 25 embryos were exposed to each dose up to D6 of development, when embryo morphology was evaluated. Then biopsy of trophectoderm (TE) was performed for ploidy analysis of expanded blastocysts through NGS.
Main results and the role of chance: A total of 115 D3 human embryos were donated for this VOCs research. In general, 66,7% of embryos developed to blastocyst stage after being exposed to Styrene while 90% of the embryos developed in C group (p= 0.006). Individually, all three doses of Styrene affected similarly the development: SE and SL 68% (p= 0.0460) and SDL 64% (p= 0.0228).

53,3% of embryos exposed reached the expanded- hatched blastocyst stage compared to 75% of the C group (p= 0.028). SDL doses affected significantly the expansion of the embryos: 48% (p= 0.0350).

Inner cell mass (ICM) and trophectoderm (TE) good quality scores (A-A, A-B, B-A, B-B) were only registered on 26,7% of Styrene embryos group compared to 40% of the control group, not being significant (p= 0.2048). A-A score embryos were obtained in both groups.

A total of 55 embryos that reached expanded- hatched state were analyzed for aneuploidies. Aneuploidy rates were not significant between Styrene (n=35) and Control (n=20) groups (28,6% vs. 25% respectively); however when analyzing the effects of specific doses, the embryos that were exposed to the to the highest dose of styrene (SDL) reached up to 40% of aneuploidies compared to 25% of the C group. (p= 0.4311).
Limitations, reasons for caution: Developmental and ploidy rates were obtained by direct contamination of the culture medium with VOCs, specifically Styrene in this experiment. For this reason the results do not represent the exact conditions of an IVF laboratory.
Wider implications of the findings: The association of the specific morphologic and chromosomal effects produced by common IVF VOCs, over the human pre- embryos will allow to establish a database with regulatory institutions, with accurate occupational limit values for human embryo culture.
Trial registration number: Not applicable

P-170 ICSI outcome of infertile men with round-headed sperm: is ICSI effective?

M. Sabbaghian[1], K. Kakavand[1], M.A. Sadighi-Gilani[1]
[1]*Royan Infertility Center, Andrology, Tehran, Iran*

Study question: is ICSI an effective treatment for infertile male with round-headed sperm syndrome?

Summary answer: based on current knowledge, ICSI consider as main therapeutic procedure for these patients.

What is known already: patients with round-headed spermatozoa are infertile due the lack of acrosome in sperm structure, so acrosome reaction which is necessary for sperm entering to oocyte, do not take in part. More than 20 years studies showed that with ICSI, it could be possible to overcome infertility for about 25% of patients with this certain pathology worldwide. However, approximately all these studies, except one, applied on few numbers of patients. Reports showed a 24.3% fertilization rate, 22.1% pregnancy rate, and 12.2% delivery rate after ICSI cycles of these patients.

Study design, size, duration: in this study, we followed-up ICSI outcome of infertile round-headed sperm men who referred to Royan institute, Tehran, Iran, between years 2008 and 2016. This study, to date, is the largest one in assessing treatment of round-headed sperm patients.

Participants/materials, setting, methods: This is a retrospective study on ICSI outcome of 163 infertile couples which male partner has more than 50% round head spermatozoa, referring to Royan institute (Tehran, Iran) between years 2008 and 2016.

Main results and the role of chance: from all 163 couples, 53 underwent 66 ICSI cycles, achieving 38% fertilization rate. Afterward, 43 couples had a total number of 60 embryo transfers consists of transferring 41 fresh embryo and 19 frozen embryo. The chemical pregnancy rate was 27% (18 pregnancies out of 66 cycles; 11 from fresh and 6 from frozen embryos,), and clinical pregnancy rate showed a value of 24% (16 out of 66 cycles; 9 from fresh and 6 from frozen embryo transfers). Finally, 16 successful deliveries achieved from clinical pregnancies, which means a 24% delivery rate, with total 21 normal live births, 15 boys and 6 girls. notably, 3 patients with successful deliveries, have more than 90% round-headed sperm in their spermogram, may indicate that even patients with severe round-headed sperm syndrome could have benefit from ICSI procedure.

Limitations, reasons for caution:

Genetics evaluations of round-headed sperm syndrome, revealed that *DPY19L2* alterations, even the gene deletion, is the main genetics feature of this syndrome; however, we did not have access to patients to see whether they have this disorder or not, specially in those who have successful pregnancy and delivery.

Wider implications of the findings: These results, means that it could be hope for round-headed sperm patients to enjoy being parents. Also, some studies reported that ICSI along with assisted activated oocyte (AOA) could be more effective than ICSI alone, but the side effects of AOA should be considered.

Trial registration number: none

P-171 NOVEL APPROACH IN CRYOPRESERVATION OF HUMAN EMBRYOS AT THE MORULA STAGE WITH INCOMPLETE COMPACTION

M. Petrushko[1], V. Piniaiev[2], T. Yurchuk[3], N. Buderatska[4]

[1]ART Clinic of Reproductive Medicine, Embryology, Kharkiv, Ukraine
[2]ART Clinic of Reproductive Medicine, Gynecology, Kharkiv, Ukraine
[3]Institute for Problems of Cryobiology and Cryomedicine of the National Academy of Sciences of Ukraine, Cryobiology of reproductive system, Kharkiv, Ukraine
[4]IGR Medical Center, Embryology, Kyev, Ukraine

Study question: Is it possible to obtain a high survival rate after cryopreservation not fully compacted morulae?

Summary answer: Removing of excluded cell and fragmentation can increase the survival rate of not fully compacted morulae after cryopreservation.

What is known already: It has been shown that mosaic embryos may form partially compacted morulae in order to exclude aneuploid cells, which subsequently undergo apoptosis. Cryopreservation of embryos at the morula stage which had fragmentation more than 20% have led to significantly lower post-thaw survival rate compering with fully compacted morulae. These excluded fragments could be subject to major damage than compacted part by cryopreservation factor. The necrotic factor released from these injury cells may impact the survival rate of embryo and their further development.

Study design, size, duration: The investigation was performed in the ART-clinic of reproductive medicine since January 2015 to November 2018. The study involved 352 morulae with different compaction degree obtained in ICSI cycle from 70 patients with mean age 313 ± 4.2 years. 189 morulae were cryopreserved by conventional vitrification procedure (group I) and 163 morulae were underwent removing of excluded cells were prior to vitrification according with a written consent of patients (group II).

Participants/materials, setting, methods: All the morulae were graded into five groups by two embryologist independently: 1 – fully compacted morulae, 2–4 – incomplete compacted morulae (compaction were about 75, 50, 25 % of whole embryo respectively) and 5 –morulae with no compaction. The osmotic reaction in cryoprotectant media during equilibration time in vitrification procedure of all morulae groups, their survival and blastocyst formation rates after cryopreservation were evaluated taking into account embryo compaction degree.

Main results and the role of chance: The excluded fragments of morulae with not full compaction has been shown to have a low osmotic response to cryoprotactant solutions during equilibration time whereas the compacted part of embryo responds to the changes of osmotic pressure as a single whole. The survival rate of vitrified morulae of grades 1-5 were (98 ± 6.2), (85 ± 4.1), (38.2 ± 4.4), (50 ± 5.8) and (22.2 ± 4.4)% respectively. The blastocyst formation rate of morulae after warming positively correlated with their compaction degree ($r = 0.32$). Removal of excluded cells and fragments of morulae prior to cryopreservation led to an increase of their post-thawing survival rate up to (93.1 ± 4.1) and (75 ± 8.8)% and blastocyst formation rate up to (85.2 ± 10.4), (59.4 ± 5.2)%, $p<0.05$ in grades 2 and 3 respectively.

Limitations, reasons for caution: Limited number of cases of the study group. Further studies are recommended.

Wider implications of the findings: This study revealed that removing of excluded cells and fragmentation from morulae with incomplete compaction prior cryopreservation can increase the survival and blastocyst formation rates and as result improve the cumulative pregnancy rate.

Trial registration number: not applicable

P-172 Adverse results in oocyte donation cycles using cryo-banked eggs

C. De la Cruz Rodrigo[1], M. Solé[1], I. González[1], E. Clua[1], S. García[2], M. Boada[1], P.N. Barri[1], A. Veiga[1,3]

[1]Reproductive Medicine Service, Dexeus Mujer - Dexeus University Hospital, Barcelona, Spain
[2]Unit of Biostatistics, Dexeus Mujer - Dexeus University Hospital, Barcelona, Spain
[3]Barcelona Stem Cell Bank, Center of Regenerative Medicine, Barcelona, Spain

Study question: Is the oocyte survival rate an adequate prognostic factor of good outcome in oocyte donation cycles?

Summary answer: Low oocyte survival rates after warming lead to worse clinical outcomes in oocyte donation cycles.

What is known already: Oocyte vitrification is performed routinely and successfully in IVF and oocyte donation programs. The cryotop vitrification method for human oocytes described by Kuwayama et al. (2005) had reported a 91% survival rate. Other authors supported this finding (Cobo et al. 2010, Solé et al. 2014) but, in some cycles, it has been observed that this percentage is significantly diminished without any apparent explanation.

Study design, size, duration: This is a retrospective study including 535 oocyte donation cycles in which 6 or more eggs were warmed between December 2014 and December 2017. We compared vitrification/warming cycles with good survival rates (>60%), the high survival group, with cycles with low survival rates (≤60%), the low survival group.

Participants/materials, setting, methods: The participants were consenting donors and recipient couples from the oocyte donation program. Primary end-points were clinical pregnancy rate, miscarriage rate and live birth rate. Additionally, donor demographic baseline characteristics, donor ovarian stimulation parameters, type of ovarian stimulation treatment and embryo developmental characteristics were analysed.

Main results and the role of chance: 476 cycles (89%) were included in the high survival group and 59 cycles (11%) in the low survival group. There were no differences between the two groups in terms of donor demographic baseline characteristics and in donor ovarian stimulation parameters except for E2 on day of triggering (2188.58±1259.62 vs 2890.91±1504.71 p=0.004). No differences were observed regarding the type of ovarian stimulation treatment.

No differences were observed in laboratory outcomes: fertilization rate 76% (95% CI:74.5-77.6) vs 71.2% (95% CI:65.9-76.4), ongoing embryo rate 52.3% (95% CI:50.2-54.4) vs 53.3% (95% CI:46.1-60.6) and top-quality embryo rate 28.6% (95% CI:26.5-30.8) vs 22.1% (95% CI:15.9-28.2) in high survival group and low survival group respectively.

In general terms, 97.9% cycles had ongoing embryos, with a 44.7% clinical pregnancy rate, 20.9% miscarriage rate and 34.2% live birth rate.

When analyzing the clinical results per cycle, significant differences were observed regarding clinical pregnancy rate (46.4% vs 30.5% p=0.020) and live birth rate (35.9% vs 20.3% p=0.017), but not in miscarriage rate (21.2% vs 25% p=0.753) between groups. When comparing the data per embryo-transfer, not statistically significant differences were found regarding clinical pregnancy rate (48.7% vs 34.6% p=0.054); only the live birth rate showed significant differences (37.7% vs 23.1% p=0.038).

Limitations, reasons for caution: This is a retrospective study. A larger sample would probably be required to further strengthen the differences.

Wider implications of the findings: The results of this study suggest that the group of vitrification/warming oocyte donation cycles with low survival rate display similar laboratory outcomes but worse clinical results than cycles with survival rate >60%. New data are needed to ascertain the reasons for low survival rates after oocyte vitrification.

Trial registration number: Not Applicable

P-173 Success rates of hatching/hatched blastocyst transfer in frozen embryo transfer (FET) cycles.

Y.J. Cho, M.Sc.[1], E.A. Park[1], H.S. Kim[1], J.W. Park[1], B.Y. Kim[1], W.Y. Jo[2], H.Y. Lee[2], J.H. Lee[3,4], K.A. Lee[3], E.J. Yu[5], R. Kim[5], Y.B. Lee[5], Y.S. Kim[5], M.K. Koong[5], I.S. Kang[5]

[1] *CHA Fertility Center Seoul Station, Fertility laboratory, Seoul, Korea- South*

[2] *CHA Fertility Center Seoul Station, Nursing, Seoul, Korea- South*

[3] *CHA University, Department of Biomedical Science- College of Life Science, Pocheon, Korea- South*

[4] *CHA Fertility Center Seoul Station, Research, Seoul, Korea- South*

[5] *CHA Fertility Center Seoul Station, Department of Obstetrics and Gynecology, Seoul, Korea- South*

Study question: Is spontaneously hatching-blastocyst transfer more beneficial than hatched-blastocyst transfer in FET cycles?

Summary answer: Hatched-blastocyst transfer is more beneficial compared to hatching-blastocyst transfer in FET cycles. Hatched-blastocyst transfer in FET cycles can be considered as a superior method.

What is known already: Blastocyst stage embryo transfer has become a preferred practice in recent years. However, there is only limited amount of data available on cryopreservation of hatching and hatched-blastocysts.

Study design, size, duration: A total of 2,320 frozen-thawed blastocyst transfer cycles between 2016 and 2018 in CHA Fertility Center Seoul station, Seoul, Korea, was evaluated. All of the frozen and thawed blastocysts that were hatching or hatched were included in this retrospective cohort study.

Participants/materials, setting, methods: Day5 or day6 blastocysts were frozen and thawed using 2-step vitrification and 4-step warming protocols with EG and DMSO as cryoprotectants. Blastocyst survival post thaw was defined as more than 50% of ICM and TE cells remaining intact and re-expansion after culture for 3-4 hours before transfer. IR and PR were evaluated and compared between subgroups by ≤37 vs. >38 years old, the gradeA vs. B and the number of transferred embryos SET vs. DET.

Main results and the role of chance: SET cycles of Grade-A embryo, PR and IR were significantly higher in hatched-blastocysts compared to hatching-blastocysts in the group of ≤37 years old, PR 70.59% vs. 63.02%, p=0.019, and IR 66.34% vs. 56.61%, p=0.0035. In the group of >38 years old, PR was significantly higher in hatched-blastocyst transfer (58.70% vs. 41.75%, p=0.017), while there was no significance in IR for both groups. SET cycles of Grade-B embryo, only IR was significantly higher in hatched-blastocysts (54.10% vs. 38.87%, p=0.029). In the group of >38years old, PR and IR were significantly higher in hatched-blastocysts compared to hatching-blastocysts, 52.94% vs. 29.76%, p=0.066, and 47.06% vs. 17.86%, p=0.069, respectively. DET cycles of Grade-A embryo, there was a trend of higher PR and IR in ≤37 years group (83.78% vs. 77.35%, p=NS; 59.46% vs. 50.29%, p=NS). In >38years group, PR was significantly higher in hatched-blastocyst compared to hatching-blastocyst (84.21% vs. 36.96%, p=0.00009), and no significance in IR. DET cycles of Grade-B, PR and IR were significantly higher in hatched-blastocysts compared to hatching-blastocysts in both age groups; PR 78.13% vs. 56.94%, p=0.0039, IR 50.0% vs. 26.39%, p=0.00009 in ≤37 years group; PR 100% vs. 31.17%, p=0.04, IR 100% vs. 20.83%, p=0.00001 in >38 years group.

Limitations, reasons for caution: Due to small number of patients in the age group of >38 years old, a larger study is needed to fully support our results.

Wider implications of the findings: This study suggests that the transfer of hatched-blastocysts is more beneficial compared to hatching-blastocysts in FET cycles. Further study is needed with larger number of patients, especially in older age group.

Trial registration number: Not applicable.

P-174 The blastocyst score: a strong predictor of frozen euploid blastocyst transfer outcome

Q. Zhan, E.L.D.- M.D.- Ph.D.[1], J.E. Malmsten[1], Z. Rosenwaks[1], N. Zaninovic[1]

[1] *Weill Cornell Medicine, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.*

Study question: What is the relationship between the blastocyst score, which integrates a blastocyst's morphologic grade with its rate of development, and frozen euploid blastocyst transfer outcome.

Summary answer: The blastocyst score is a predictor of frozen euploid blastocyst transfer outcome.

What is known already: With advanced genetic molecular technology and improved culture conditions, current trends in IVF practice are shifting to an increase in the use of blastocyst culture, preimplantation genetic testing for aneuploidy (PGT-A), and freeze-all cycles. However, the role of blastocyst morphology and day of blastocyst development in PGT-A embryo selection is controversial.

Study design, size, duration: This is a retrospective cohort study of 2,193 euploid frozen blastocyst transfer (FET) cycles performed between October 2013 and October 2018. We developed the blastocyst score, a numeric ranking system, by integrating a numerical score for the blastocyst morphologic grade (based on expansion, ICM, and TE) with the day of blastocyst development (D5 or D6).

Participants/materials, setting, methods: This study includes 2,193 FET cycles (1,901 SET, 291 TET, and 1 triple ET) from 1,462 patients (age 36.4±4.2). On days 5 or 6, blastocysts were biopsied and tested using aCGH/SNP/NGS. They were vitrified and transferred in programmed or natural cycles. The average blastocyst score was calculated for each transferred blastocyst. Clinical pregnancy and pregnancy loss rates were measured. Odds ratio and logistic regression analysis were used for statistical analysis.

Main results and the role of chance: The average transfer number of BL was 1.1±0.3, with an average blastocyst score of 7.4±2.6. Overall, the clinical pregnancy rate was 56.6% (1,241/2,193), with a pregnancy loss rate of 22.5% (340/1,512). Logistic regression analysis showed that the average blastocyst score was the strongest predictor of clinical pregnancy (p<0.00000), followed by the number of BL transferred (p=0.00011). The method of fertilization (ICSI/IVF), oocyte age and source (donor/autologous; fresh/frozen), sperm source (ejaculate/donor/surgical), transfer day, and type of FET cycle (programmed/natural) were not correlated with pregnancy. Interestingly, for pregnancy loss, the FET transfer protocol was the strongest predictor (programmed/natural OR=5.22; 95%CI 4.01-6.83), followed by the average blastocyst score (Unit OR=1.17; 95% CI 1.11-1.24).

Limitations, reasons for caution: The study is limited by its retrospective nature.

Wider implications of the findings: The blastocyst score is a predictor of euploid blastocyst pregnancy outcome. It can serve as a simple ranking tool to improve embryo selection by quantitatively assessing blastocyst quality. It also has potential applications in the personalization of ART treatment, particularly in the new era of artificial intelligence.

Trial registration number: None

P-175 Ideal strategy of trophectoderm biopsy for preimplantation genetic testing for aneuploidies (PGT-A) cycle.

J.Y. Lee[1], E.A. Park[1], E.B. Joe[1], J.W. Park[1], S.Y. Moon[1], Y.J. Cho[1], H.S. Kim[1], K.H. Choi[1], H.S. Choi[1], H.Y. Lee[2], E.J. Yu[3], Y.S. Kim[3], Y.S. Kim[3], M.K. Koong[3], T.K. Yoon[3]

[1]CHA Fertility Center Seoul Station, Fertility laboratory, Seoul, Korea- South
[2]CHA Fertility Center Seoul Station, Nursing, Seoul, Korea- South
[3]CHA Fertility Center Seoul Station, Department of Obstetrics and Gynecology, Seoul, Korea- South

Study question: Is the timing of trophectoderm biopsy associated with successful pregnancy after the embryo transfer of blastocyst subjected to preimplantation genetic testing for aneuploidies (PGT-A)?
Summary answer: Trophectoderm biopsy(PGT-A) before or after the cryopreservation may be the optimal strategy for better clinical outcomes compared to the fresh trophectoderm biopsy without cryopreservation.
What is known already: Embryo biopsy and fresh embryo transfer are traditionally performed in the PGT-A cycle. However, before embryo transfer, the time allowed for genetic analysis of the specimens is restricted, particularly after blastocyst biopsy. Cryopreservation of blastocysts after biopsy instead of fresh transfer permits more sufficient time for performance of molecular diagnosis. The effect of cryopreservation and warming procedures on clinical outcomes in PGT-A cycle has not been effectively studied.
Study design, size, duration: This retrospective study included women that underwent IVF with PGT-A from January 2016 to October2018. 2098 blastocyst from cycles were subjected to trophectoderm biopsy for performing array comparative genomic hybridization (CGH) test. Embryos were cultured to expanded blastocyst stage and underwent trophectoderm biopsy on day 5 to day 6 of embryo development. Cycles with complete PGT-A diagnosis were 349, 178 of which had embryo transfer. The performance of different groups of PGT-A patients was evaluated.
Participants/materials, setting, methods: The groups were divided into three; first group (n=80 transfer/310 cases) contained fresh blastocysts that biopsied for PGT-A without cryopreservation followed by embryo transfer. In the second group (n= 175 transfer/ 176 cases),the blastocysts were initially biopsied then proceeded with vitrification and warming before the embryo transfer. The last group (n=94 transfer/126 cases), the cryopreserved blastocysts were warmed and biopsied prior to ET.
Main results and the role of chance: The total pregnancy and implantation rates of fresh blastocyst biopsied group was 43.8% (35/80), 37.9%(39/103); the cryopreserved-warmed-biopsied blastocyst group showed 53.7% (94/175), 47.3% (107/226); and finally biopsied and cryopreserved-warmed group showed 52.1% (49/94), 46.5% (59/127); respectively. Second group and third group are significant higher pregnancy rate than first group, (p=0.022). Also, The second(biopsied and cryopreserved-warmed) group and third (cryopreserved-warmed–biopsied)group showed higher numerical implantation rate than the first group.
Limitations, reasons for caution: In the case of biopsy after warming, it is difficult to determine the number of warming embryos and re-cryopreservation of surplus euploid embryo could increase embryo damage.
Wider implications of the findings: Using recently available data, when faced with the option of fresh embryos, before or after trophectoderm biopsy for PGT-A, our result supported performing the biopsy before or after embryo cryopreservation and warming.
Trial registration number: Not applicable.

P-176 Finding an optimal algorithm for predicting human embryo development using deep learning and high-resolution time-lapse cinematography (hR-TLC)

M. Mimura[1], R. Tamoto[1], M. Sato[2], T. Shimura[2], K. Yumoto[2], Y. Mio[2]

[1]Nikon Corporation, Mathematical Sciences Research Laboratory, Yokohama-city, Japan
[2]Mio Fertility Clinic, Reproductive Centre, Yonago-city, Japan

Study question: What kind of algorithm is most suitable for predicting human embryo development using deep learning?
Summary answer: Analyzing hR-TLC of human embryos by deep learning with an algorithm using time-series images achieved 86% prediction accuracy, a 12% improvement versus using individual images.
What is known already: Predicting the development of good-quality embryos is essential for human assisted reproductive technologies such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), therefore analysis of the dynamic morphology of embryos using time-lapse imaging has become widespread. In particular, deep learning has been one of the major methods of analysis, but the optimal algorithm for such use of deep learning is still unclear.
Study design, size, duration: From April 2003 to November 2008, 100 normally fertilized embryos from conventional IVF and ICSI were cultured at 37°C at pH 7.35 ± 0.02. For both types of embryos, 40 hours of images of the embryos in culture were taken, starting from the time of second polar body extrusion, by hR-TLC using an inverted microscope with differential interference contrast. Approximately 2,000 photographs were taken every 2 minutes, and these were used for deep learning.
Participants/materials, setting, methods: Embryo quality was evaluated at the four-cell stage using modified Veeck's criteria. 100 embryos (50 good quality, 50 poor quality) were used to verify prediction accuracy (45 for training and 5 for validation per quality group). Two types of deep learning prediction algorithms were applied: a non-time-series model (convolutional neural network [CNN]), and a time-series model (long short-term memory [LSTM]). Cross-validation was repeated 10 times and the average rate of prediction accuracy was calculated.
Main results and the role of chance: First, when time-lapse images for 31 hours from second polar body extrusion were applied, the average rate of prediction accuracy was 72% for the CNN model (mean sensitivity, 0.72; mean specificity, 0.72) and 68% for the LSTM model (mean sensitivity, 0.78; mean specificity, 0.58). Second, when time-lapse images for 25 hours from pronuclear formation were applied, the average rate of prediction accuracy was 71% for the CNN model (mean sensitivity, 0.74; mean specificity, 0.68) and 72% for the LSTM model (mean sensitivity, 0.71; mean specificity, 0.74). Finally, when images for 5 hours from pronuclear disappearance (syngamy) were applied, the average rate of prediction accuracy was 77% for the CNN model (mean sensitivity, 0.76; mean specificity, 0.78) and 86% for the LSTM model (mean sensitivity, 0.84; mean specificity, 0.86). Therefore, the algorithm method using the LSTM model applied to the time-lapse images for 5 hours after syngamy was the most suitable for predicting embryo quality by deep learning, and increased prediction accuracy by approximately 12% when compared with the method using the CNN model.
Limitations, reasons for caution: The accuracy of our findings is limited because of the small number of embryos and images that we used. The optimal time and period used to predict human embryo development by deep learning analysis might be different if the numbers of embryos and the amount of training were increased.
Wider implications of the findings: The accuracy of prediction of good-quality embryos could be improved by updating deep learning and increasing the number of embryos applied to the LSTM model. Furthermore, in the future it may be possible to predict embryo quality at early embryonic stages before syngamy.
Trial registration number: Not applicable.

P-177 Comparison of clinical outcomes between day 5 early-middle expanding blastocysts (E-MB) versus day 6 fully expanded-hatched blastocysts (F-HB) transfer in vitrified-warmed cycles

S.K. Lee[1], J.H. Cha[1], S.H. Shin[1], Y.J. Kim[1], J.H. Kim[1], D.H. Kim[1], H.Y. Kim[1], J.H. Ahn[1], H.Y. Kim[1], K.A. Pak[1], J.S. Yoon[1], S.Y. Park[1]

[1]Agaon Fertility Clinic, IVF center, Seoul, Korea- South

Study question: The aim of this study is to compare clinical outcomes between day 5 E-MB and day 6 F-HB transfer in vitrified-warmed cycles.
Summary answer: Day 5 E-MB transfer showed a significant increase in the rates of biochemical pregnancy, clinical pregnancy, and implantation compared with those of day 6 F-HB.
What is known already: Improved embryo culture system now makes more feasible the possibility of obtaining blastocysts after in-vitro fertilization. It is

known that fully expanded blastocysts represent a higher pregnancy rate than early blastocysts on day 5. Therefore, it is recommended that day 5 early blastocysts are additionally cultured as a strategy to increase pregnancy rates. However, little is known whether day 6 F-HB is also superior to day 5 E-MB in vitrified-warmed cycles.

Study design, size, duration: A retrospective cohort study of 308 cycles was performed from January 2014 to march 2017. The cycles with advanced maternal age (≥40 years) and poor quality blastocysts (grade CC) were excluded. We compared the rates of biochemical pregnancy, clinical pregnancy, ongoing pregnancy, and implantation between day 5 E-MB and day 6 F-HB transfer in vitrified-warmed cycles

Participants/materials, setting, methods: The quality of vitrified blastocysts was evaluated by Gardner and Schoolcraft's classification. The cycles were divided into two groups based on the expansion grade of the blastocysts on day 5 and day 6 (Day 5 E-MB: expansion grades 2 and 3, n = 123 vs. Day 6 F-HB: expansion grades 4, 5 and 6, n = 185).

Main results and the role of chance: Characteristics of the cycles had no statistical differences in maternal age at ovum pick-up, maternal age at blastocysts transferred, infertility diagnosis, and number of blastocysts transferred.

Rates of biochemical pregnancy, clinical pregnancy, and implantation in day 5 E-MB were significantly increased than those of day 6 F-HB transfer (Table 1). In addition, ongoing pregnancy rate was showed that day 5 E-MB tends to be higher than day 6 F-HB transfer (Table 1).

Table 1 Comparison of clinical outcomes between day 5 E-MB and day 6 F-HB

	Day 5 E-MB	Day 6 F-HB	p-value
Cycles (n)	123	185	
Biochemical pregnancy (%)	43.1 (53/123)	31.9 (59/185)	0.045
Clinical pregnancy (%)	33.3 (41/123)	22.7 (42/185)	0.039
Ongoing pregnancy (%)	25.2 (31/123)	17.3 (32/185)	0.092
Implantation (%)	38.2 (47/123)	24.3 (45/185)	0.009

Limitations, reasons for caution: This study has a limitation. Cycles were divided into only two groups, because of its small sample size. Therefore, further study with larger sample size is needed to confirm pregnancy rates according to the degree of expansion of blastocysts (grades 1, 2, 3, 4, 5, and 6, respectively).

Wider implications of the findings: The day of vitrification rather than the degree of expansion is considered more important factor related to pregnancy rate in vitrified-warmed cycles. Therefore, we recommend vitrifying day 5 E-MB rather than additional culture to day 6 in vitrified-warmed cycles.

Trial registration number: Not applicable

P-178 To what extent does the survival rate of blastocysts following freeze and thaw affect the likelihood of pregnancy?

A.M.L. Gambaro[1,2], M. Kanani[1], M. Weybury[1], C. Kleanthis[1], Y. Kopeika[1]

[1]Guy's and St Thomas' NHS Foundation Trust, Assisted Conception Unit, London, United Kingdom

[2]Department of Experimental Medicine, Sapienza University of Roma, 00100 Roma, Italy

Study question: To assess whether the blastocyst survival rate after freeze and thaw affects the likelihood of pregnancy

Summary answer: High blastocyst survival rate in a frozen embryo transfer (FET) cycle is positively correlated with an increased clinical pregnancy rate.

What is known already: The embryo freezing and thawing during IVF is well established process. Studies on embryos at the cleavage stage showed that the percentage of survival of the embryo after freeze and thaw process has an impact on a clinical pregnancy rate. However, to the best of our knowledge there is no published evidence in literature studying the impact of blastocyst survival rate on IVF outcome.

Study design, size, duration: Retrospective study conducted on over 800 embryo transfers performed in a Tertiary Assisted Conception Unit in 2018. Inclusion criteria were: top grade blastocyst (Gardner grading 3CC and above), single embryo transfer (SET), embryos surviving at least 50% and showing signs of re-expansion within 2 hours after thaw. All cycles from preimplantation genetic diagnosis, egg donation and egg freezing cycles were excluded.

Participants/materials, setting, methods: The total number of 356 frozen cycles was analysed. No patients had more than one cycle included. Female patient age ranged between 24 and 45 (mean age: 33.7+/-3.8) at the time of embryo freeze. Embryo survival rate was stratified into following groups: 50-59%, 60-69%, 70-79%, 80-89%, 90-99% and 100%. Clinical pregnancy rate (CPR) was then also adjusted to female age.

Main results and the role of chance: The result shows that there was a strong correlation between CPR and blastocyst survival rate. If the survival rate was under 80%, in spite of presence of re-expansion, the overall CPR was only 11%, whereas CPR was as high as 47% with embryos showing survival of 80% and above. These results were consistent when the data was adjusted by female age at freeze. The sample size is relatively large, however the proportion of embryos with survival below 80% was smaller.

Limitations, reasons for caution: The study was retrospective and some unadjusted variables could be a cause of bias. However, to the best of our knowledge, this is the biggest data set reported until today on this topic.

Wider implications of the findings: This data does suggest that survival of the blastocyst embryo under 80% results in significantly lower chance of pregnancy. This information should be discussed with the patient and option of double embryo transfer could be considered, when clinically appropriate

Trial registration number: not applicable

P-179 Application of PLCZ for patients with repeated unfertilization after ICSI.

T. Yamaguchi[1], A. Tanaka[1], M. Nagayoshi[1], T. Ichiyama[1], M. Ohno[1], K. Kuroda[2], M. Ito[3]

[1]Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan

[2]Sugiyama Clinic Shinjuku, Department of Obstetrics and Gynecology, Tokyo, Japan

[3]Hamamatsu University School of Medicine, Department of Infectious Diseases, Hamamatsu, Japan

Study question: How to decrease the unfertilization rate of ICSI oocytes?

Summary answer: PLCZ injection seems to rescue the ICSI oocytes lacking activation potency and is beneficial for improving clinical outcome of fertilization failure.

What is known already: Most fertilization failures can be resolved by ICSI, however following ICSI fertilization failure still occurs in 20-30%. Fertilization failure in ICSI results mainly from oocyte activation deficiency. Assisted oocyte activation (AOA) can induce transient Ca2+ increase in the oocyte. AOA is an efficient procedure for infertile couples with a history of low or failed fertilization after ICSI treatment. Various AOA have been reported including mechanical, electrical and chemical activation. The most popular assisted activation agents in human eggs include electrical pulses and calcium ionophores, however there is still not an established AOA.

Study design, size, duration: We performed this retrospective study to investigate the usefulness of PLCZ injection for fertilization failure patients from 2014 December to 2016 August. We conducted the study to know the optimal PLCZ concentration incubation period from oocyte pickup to PLCZ injection (1) and cleavage rate among the PLCZ, IM, ES in parthenogenesis and ICSI (2).

Participants/materials, setting, methods: 1) To find a optimal PLCZ1 mRNA concentrations, parthenogenetic activation was examined with cleavage rate or monitoring of intra-cellular calcium oscillation.

2) 67 oocytes from 29 patients were used to compare the parthenogenetic cleavage between PLCZ1 and electrical stimulation (ES) or Ionomycin (IM). The three methods were applied to the ICSI oocytes from 38 patients (< 35 years old) who had repeated severe fertilization failure (less than 10%) more than two times.

Main results and the role of chance: 1) Parthenogenetic activation rate was very low (0-23%) in the concentrations of 0.01 to 10 ng/μl. At the optimal concentration of 100 ng/μl, the activation rate was raised to 66.7% (n=18) and the pattern of Ca2+ oscillations by PLCZ injection was similar to that of normal ICSI.

2) In parthenogenesis, no significant difference in PN formation was found among the three methods. However, cleavage rate was the highest in the PLCZ1 group (Table 1).

3) PLCZ was more effective on the development of male pronucleus in the ICSI oocytes than other methods (Table 2), suggesting that appropriate Ca2+ oscillation is required for normal fertilization. The pregnancy and miscarriage rates did not differ among the PLCZ1, IM and ES (25.0% and 0%, 6.7% and 100%, 18.2% and 50.0% respectively) because of the small sample size.

Table 1 Comparison of clinical outcomes between day 5 E-MB and day 6 F-HB

Parthenogenesis	No. of oocytes	Day 1 (1PN+2nd PB)	Day3 (>= 7 cell)
PLCZ1	35	65.7% (23)	60.1% (14/23)
IM	15	66.7% (10)	40.0% (4/10)
ES	17	52.9% (9)	44.4% (4/9)

Table 2 Comparison of clinical outcomes between day 5 E-MB and day 6 F-HB

ICSI	No. of oocytes	Day 1 (2PN+2nd PB)	Day3 (>= 7 cell)
PLCZ1	87	60.9% (53)	60.9% (53)
IM	78	29.5% (23)	24.4% (19)
ES	56	30.4% (17)	26.8% (15)

Limitations, reasons for caution: Birth of healthy offspring and reproduction of healthy second generation from mouse oocytes activated by PLCZ was reported in 2008. However, human births have not been reported after using this method. The safety of PLCZ injection to human health should be further examined for future clinical applications.

Wider implications of the findings: Current poor clinical outcome of ROSI is likely to de derived from insufficient oocyte activation. Application of PLCZ to oocyte is a more physiological activation than that electrical oocyte stimulation and it will be beneficial to improve the clinical outcome of ROSI.

Trial registration number: UMIN Clinical Trials Registry: UMIN000020860

P-180 The effect of high humidity culture conditions over embryo development: a continuous embryo monitoring assessment

J.M. DE LOS SANTOS MOLINA[1], C. Albert[1], N. González[2], J. Marcos[2], L. Alegre[1], B. Aparicio[1], M. Meseguer[1]

[1] *IVI Valencia, IVF Lab, Valencia, Spain*

[2] *IVI Bilbao, IVF lab, Leioa, Spain*

Study question: Since in vivo culture, culture conditions are humid. Our aim was to know how high humidity might affect embryo development comparing to dry conditions by using single step culture media in a continiuous embryo monitoring incubator (CEM)

Summary answer: Our results suggested that culture conditions with high humidity atmosphere did not affect embryo development but increase the pregnancy and implantation rate

What is known already: Oil overlay has supported successful use of a dry incubator for culture human embryos, preventing changes in the pH, temperature. However, dry conditions may affect the osmolality due to the evaporation of culture media. Therefore, the use of humid conditions avoid osmolality changes. In a previous study we found statistical differences in terms of blastocyst rate. Pregnancy and implantation rate was affected but remained not significantly.

Study design, size, duration: A total of 7544 embryos from 1043 patients, from ovum donation programme and own oocytes and that were culture on a time lapse incubator system (Geri genea biomedix, Australia) were included in a retrospective and multicentric study (three IVF units and 5 CEM incubators) from 2016 to 2018

Participants/materials, setting, methods: This CEM incubator has 6 separated small incubators. Three of them works in a dry atmosphere (DC) and the other 3 in humid conditions (HC). In the dry chambers, the embryos from 478 patients were cultured and under HC a total of 558. Retrospectively, blastocyst, good morphology blastocyst rate, pregnancy, implantation and miscarriage rate were evaluated.

Main results and the role of chance: In a previous study we found that culture conditions with high humidity atmosphere promoted embryo development and reproductive outcome. This time, with increased sample size, we didn´t found any differences in embryo development. By performing an stratified analysis, humid conditions were equaly distributed by clinic and treatment (mulivariable analisis). We had very similar blastocyst rate when the embryos were culture under high HC; 71.3% vs 71.0% DC). Also the proportion of blastocyst with good morphology was very similar 38.1 % in HC vs 37.7 % and DC. The ongoing pregnancy rate (OPR) was higher in HC vs DC (52.5 % vs 47.7% respectively), additionally the implantation rate slightly better in HC 54.85 vs 52.7 but but remained not significant.

Limitations, reasons for caution: The retrospective nature of the study may limit the conclusion although sample size is remarcable. A prospective reandomize study may solve the remaining questions surrounded this topic.

Wider implications of the findings: Our results would suggest that HC may increase the reproductive outcome of our patients when using single step media in CEM incubators although effects are limited and still need to be confirmed with a larger sample and improved designs.

Trial registration number: NA

P-181 Day of vitrification, blastocyst developmental stage and trophectoderm quality are strongly associated with survival and implantation in vitrified blastocyst cycles: analysis of 12064 warmed blastocysts

A. Coello[1], M.J. De los Santos[1], M. Meseguer[1], M. Nohales[1], J. Remohí[2], A. Galan[1], A.C. Cobo[1]

[1] *IVIRMA Valencia, IVF laboratory, Valencia, Spain*

[2] *IVIRMA Valencia, OB/Gyn, Valencia, Spain*

Study question: Which fresh-embryo blastocysts parameters are related to survival and implantation rates following vitrification and warming?

Summary answer: Day of vitrification, developmental stage and trophectoderm (TE) quality are parameters directly related to survival and implantation of warmed blastocysts.

What is known already: Due to the relatively recent but exponential increase in blastocysts cryo-transfers, a clearer guide of the factors affecting the outcome is needed. Blastocyst morphology is associated with clinical outcomes in fresh and vitrified cycles. Additionally, fresh blastocysts developed on day 5 of culture give rise to higher pregnancy rates than embryos reaching the blastocyst stage on day 6. However, it is not clear if delayed blastulation and embryo morphological quality can impact the final outcome in vitrified cycles. This study aimed to evaluate the effect of the fresh embryo parameters on survival and implantation in cryo-transfers of vitrified/warmed blastocysts.

Study design, size, duration: This was a multicentric retrospective study including 12064 vitrified-warmed blastocysts transferred from January 2017 to December 2018. No PGT-A cycles were included.

Participants/materials, setting, methods: Blastocysts were allocated to different categories according to: i) day of vitrification (5 and 6); ii) blastocyst expansion degree: cavitated (BC), fully expanded (BE) and hatching out of zona (BHi); iii) TE quality (A, B, and C); and iv) oocyte origin (donor and autologous). Survival and clinical outcomes were compared between groups using chi-square test and 95% confident intervals were calculated.

Main results and the role of chance: General survival rate was significantly lower in blastocysts vitrified on **day 6 *vs.* day 5**: 90.3% (95%CI: 94.9 – 95.8) *vs.* 95.4% (95%CI: 89.1 – 91.5). After analyzing in the different morphological categories, these differences were maintained in the following groups: BE B, 92.5% (95%CI: 90.6 – 94.4) *vs.* 95.3% (95%CI: 94.6 – 95.9); BE C, 87.5% (95%CI: 84.7 – 90.3) *vs.* 94.0% (95%CI: 92.4 – 95.6) and BHi B, 90.2% (95%CI: 87.5 – 92.9) *vs.* 95.2% (95%CI: 94.1 – 96.3). In the same way, implantation rate was significantly lower in blastocysts vitrified on day 6 *vs.* day 5 both in donor oocyte cycles: 31.9% (95%CI: 29.1 – 34.7) *vs.* 47.2% (95%CI: 45.8 – 48.6) and in autologous oocyte cycles: 26.2% (95%CI: 23.1 – 29.2) *vs.* 49.7% (95%CI: 47.9 – 51.5). A greater degree of expansion decreases the survival rate: BC survival was significantly higher than that of BE and BHi (when TE was B or C). Although, implantation was lower for BC compared to BE and BHi (when TE was B or C). Regarding **TE quality,** both survival and implantation were significantly decreased in blastocysts with TE catalogued as C. Finally, the **oocyte origin** had no impact on survival.

Limitations, reasons for caution: The retrospective nature of this study and the subjectivity of the morphological evaluation may be a limitation, although the magnitude of the sample size may counteract this limitation.

Wider implications of the findings: Survival and implantation were impaired in delayed embryos. Warming day-5 should be prioritized. Furthermore, the degree of expansion when vitrifying is closely related to success: BC embryos show higher survival but lower implantation rates and should be cultured after warming to allow them to expand prior to the embryo transfer.

Trial registration number: Not applicable

P-182 The higher the number of times follicular flushing is repeated, the lower the probability of oocyte maturation, without an effect on fertilization and embryo cleavage.

A. Makris[1], G. Lainas[1], T. Lainas[1], I. Sfontouris[1], M. Apergi[1], I. Zorzovilis[1], C. Venetis[2], E. Kolibianakis[3]

[1]EUGONIA, EUGONIA Assisted Reproduction Unit, Athens, Greece

[2]University of New South Wales, School of Women's and Children's Health UNSW Medicine, Sydney, Australia

[3]Aristotle University of Thessaloniki Medical School, Unit for Human Reproduction - 1st Dept of Obstetrics and Gynecology, Thessaloniki, Greece

Study question: Is the probability of oocyte maturation, fertilization and cleavage associated with the number of times follicular flushing is repeated during oocyte retrieval?

Summary answer: The higher the number of times follicular flushing is repeated, the lower the probability of oocyte maturation, without an effect on fertilization and embryo cleavage.

What is known already: Although follicular flushing has not been shown to increase oocyte retrieval rate compared to no flushing, it is still a procedure performed in many IVF centers. Currently, it is not clear whether there is an association between the number of times follicular flushing is repeated per follicle and the probability of oocyte maturation, fertilization and cleavage.

Study design, size, duration: A retrospective observational study was conducted from November 2017 until December 2018. Ninety women undergoing ovarian stimulation with GnRH antagonists and gonadotrophins for intracytoplasmic sperm injection (ICSI) were recruited and contributed 563 oocytes. Oocyte donation or PGD cases were excluded.

Participants/materials, setting, methods: Oocyte retrieval was performed 36hrs after hCG by using double-lumen needle. Follicular flushing was performed up to 5 times when no oocyte was retrieved in the initial aspirate. Oocytes were categorized into two groups depending on the number of times follicular flushing was repeated (Group A: 1-2 times, Group B: 3-5 times). Values are expressed as mean (SD) or median (95% CI) depending on their distribution. Due to multiple comparisons, p-level was set at 0.01.

Main results and the role of chance: The number of COCs retrieved per patient without flushing, in Group A and in Group B was 2 (95%CI: 2-3), 3 (95%CI: 2-4) and 1 (95%CI: 1-2), respectively. Overall 4 COCs (95%CI: 3-6) were retrieved.

The number of MII-oocytes retrieved per patient without flushing, in Group A and Group B was 2 (95%CI:2-2.6),2 (95%CI:2-3.3) and 1 (95%CI:0.3-1), respectively. Overall 3 (95%CI:2-5) MII-oocytes were retrieved.

Maturation rate of oocytes retrieved per patient without flushing, in Group A and Group B was 100% (95%CI:100-100), 100% (95%CI:82.9-100) and 58.3 (95%CI:7.3-100), respectively. Overall maturation rate was 96.5% (95%CI:85.7-100.0).

Generalized linear model (GLM) showed no difference in the probability of an oocyte being mature comparing no flushing vs group A (p=0.068). However, a significant decrease in the probability of an oocyte being mature was present comparing no flushing with group B(p=0.001),and groups A and B (p=0.007).

Moreover, GLM showed no difference in the probability of fertilization comparing no flushing vs group A(p=0.88) or group B(p=0.55), as well as group A vs group B(p=0.60),and no difference in the probability of cleavage comparing no flushing vs group A (p=0.20) or group B (p=0.32), as well as group A vs group B (p=0.03).

Limitations, reasons for caution: This is a retrospective observational study with oocytes retrieved after repeated follicular flushing and thus the further outcome of embryos blastulation or implantation and pregnancy could not be reliably examined.

Wider implications of the findings: Although oocyte maturation rate is significantly lower when follicular flushing is repeated 3-5 times as compared to 1-2, mature oocytes can still be retrieved with similar probabilities of fertilization and cleavage. Nevertheless, the clinical significance of repeated flushing for the achievement of pregnancy needs to be further evaluated.

Trial registration number: not applicable

P-183 Rescue in vitro maturation of oocytes shows potential to improve IVF outcome for patients under 39 years of age

M. Jagiello[1], M. Rusin[1], J. Liss[2], K. Lukaszuk[3,4,5]

[1]INVICTA Fertility and Reproductive Center Gdansk- Warsaw- Wroclaw- Poland, Lab IVF, Wroclaw, Poland

[2]INVICTA Fertility and Reproductive Center Gdansk- Warsaw- Wroclaw- Poland, Lab IVF, Gdansk, Poland

[3]INVICTA Fertility and Reproductive Center Gdansk- Warsaw- Wroclaw- Poland, Fertility and Reproductive Center, Gdansk, Poland

[4]Medical University of Warsaw, Department of Gynecological Endocrinology, Warsaw, Poland

[5]Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing- Faculty of Health Sciences, Gdansk, Poland

Study question: Can IVM-Rescue improve IVF outcome for patients with more than 50% of immature oocytes obtained at retrieval?

Summary answer: The IVM-R can help increase the number of blastocysts available for transfer only for patients under 39 years old. For elder there were no advantages.

What is known already: Rescue in vitro maturation (IVM-R) is currently not a routine procedure in IVF treatment. For patients with low ovarian reserve or advanced maternal age the oocyte retrieval a large often results in a large portion of immature ones (MI and GV stage) which are routinely discarded. Most oocytes released from the follicular environment are able to undergo meiotic maturation to metaphase II spontaneously when placed in a suitable culture medium. They can provide an additional pool of cells to increase the chances of obtaining transferable embryos.

Study design, size, duration: It was a retrospective study that included data for 88 patients (median age 36 years, range 28-46) with diagnosis of infertility who were undergoing IVF treatment between January 2018 and December 2018 at INVICTA Fertility Centre, Poland with at least 50% of immature oocytes obtained at retrieval.

Participants/materials, setting, methods: Oocytes were obtained from patients with standard pick-up procedure. Immature oocytes were divided into two groups: MI (168) and GV (215) and cultured 24-48 h in standard IVF medium. When they reached MII stadium they were fertilized by ICSI. Presence of 2 pronuclei was estimated 18 hour after ICSI procedure. Blastocysts were vitrified on day 5 or 6 day after they become MII.

Main results and the role of chance: The study group included 60 patients under 39 years old and 28 who were 39 or older. There were 145 MI and 155 GV oocytes in the younger group and 23 MI and 56 GV in the older group. In the younger group 104 MI (71.1%) and 67 GV (43.2%) successfully matured into MII and 17 MI (73.9%) and 22 GV (39.3%) in the older group. Blastocysts were obtained only in the younger group.

Considering patients under 39 in the MI subgroup there were 14 blastocysts (22.9% of fertilized and 13.5% of matured oocytes) and in the GV subgroup there were 4 blastocysts (21.1% of fertilized and 6.0% of matured oocytes).

It is also worth noting that 7 patients who obtained blastocyst from IVM-R had no blastocysts from matured oocytes from the same cycle (including 3 who had only immature oocytes retrieved). In 2 cases patients only obtained blastocysts from GV oocytes.

Additionally 6 blastocysts from matured oocytes were transferred and in 2 cases resulted in an ongoing pregnancy.

Limitations, reasons for caution: The study is limited by sample size. A higher sample size could be used in future studies to corroborate the current findings.

Wider implications of the findings: IVM-R seems promising for patients under 39 and shows potential of significantly affecting results of their treatment by increasing the number of blastocysts. Further studies with larger study groups are required to confirm the results and determine if IVM-R could be included as part of the standard treatment process.

Trial registration number: not applicable

P-184 The correlation between re-compaction post de-compaction (RCPDC) of embryos and implantation (IR) and live birth rate (LBR) in fresh embryo transfers.

K. Andreou[1], S. Montgomery[1], A. Campbell[2]

[1] *Care Fertility Manchester, Embryology, Manchester, United Kingdom*

[2] *Care Fertility Group, Embryology, Nottingham, United Kingdom*

Study question: Does the occurrence of RCPDC influence clinical outcomes?

Summary answer: Implantation and live birth rate, but not miscarriage rate (MR), significantly correlate with the exhibition of RCPDC of embryos observed at the morula stage.

What is known already: No previous studies have been conducted examining the possible association between RCPDC of human embryos and clinical outcome. Extracellular calcium is known to be necessary during embryonic development for its role in cell-cell adhesion, whereas intracellular free calcium ($[Ca^{2+}]i$) has been shown to be essential for embryos undergoing compaction. However, causative factors for RCPDC at the morula stage are currently unknown. A study conducted in mouse embryos reported that during experimental decompaction, $[Ca^{2+}]i$ concentration increases and simultaneously cytoskeleton-related proteins E-cadherin, fodrin, and calmodulin relocate. The study suggested $[Ca^{2+}]i$ acts on the cytoskeleton achieving maintenance of the compacted status.

Study design, size, duration: This is a retrospective study conducted between June 2011 and September 2017. Transferred Day 4/5 embryos of known implantation outcome were included, all fresh treatments, cultured in EmbryoScope® (Vitrolife). There were 2474 embryo transfers (ETs): 103 RCPDC ETs (97 single-, 6 double-ETs), and 2371 non-RCPDC ETs (1244 single-, 1088 double-, 39 triple-ETs). Embryos were divided according to compaction degree: fully compacted (M1), and partially compacted (M2). IR, MR, LBR was compared between groups (RCPDC/non-RCPDC, M1/M2).

Participants/materials, setting, methods: Patient treatment included conventional insemination or intracytoplasmic sperm injection. No statistical significance was found in demographics between the RCPDC and non-RCPDC groups (mean female age of oocyte provider 34.5±5.8 vs. 35.0±3.9 years, p=0.1532, and mean number of oocytes 10.6±4.1 vs. 10.3±4.6, p=0.8005).Environmental culture conditions were consistent throughout for RCPDC and non-RCPDC groups, whereas culture media heterogeneity was reflected in both groups. Statistical analyses were conducted using Fisher's exact test (two-tailed) and t-test.

Main results and the role of chance: IR was significantly increased in the RCPDC group compared with the non-RCPDC group, regardless of the compaction degree at morula (67/109 (61.4%) vs. 1365/3537 (38.6%); p=0.0154). Odds ratio was 2.54, 95% CI: 1.7158-3.7553, p<0.0001. The LBR was also significantly higher in the RCPDC group than the non-RCPDC group (48/109 (44.0%) vs. 958/3537 (27.1%); p=0.0261. Odds ratio was calculated to 2.12, 95% CI: 1.4409-3.1143, p=0.0001. No statistically significant difference (p=0.7807) for MR was found between RCPDC (31.7%), non-RCPDC (30.4%) cases. Moreover, no statistical difference was found between M1 embryos of RCPDC and non-RCPDC groups for IR (63.4% vs. 46.7%, p=0.2320), LBR (45.1% vs. 35.8%, p=0.5511), and MR (27.1% vs. 23.3%, p=0.5959). Furthermore, no statistical difference was found between M2 embryos for IR (55.6% vs. 32.4%, p=0.2385), LBR (40.8% vs. 20.5%, p=0.1220) and MR (36.6% vs. 38.2%, p=0.4298) for RCPDC and non-RCPDC groups. The lack of statistical significance is likely due to the small number of cases for each category.

Limitations, reasons for caution: The main limitation of the study is the small sample size of the RCPDC transferred embryos. Additionally, the study is limited to its retrospective design and the heterogeneity of culture conditions.

Wider implications of the findings: Our data shows an association of embryos exhibiting RCPDC to implantation potential and live birth, without a higher miscarriage rate. The identification of a positively correlated time-lapse marker to clinical outcome could be possibly routinely introduced in practice and utilised upon considering embryo selection for fresh transfers.

Trial registration number: Not applicable.

P-185 Dynamics of embryo multinucleation as an early predictor of euploid status following PGT-A -morphokinetic analysis

R. Ahmed-Odia[1], X. Vinals-Gonzalez[1], C. Heath[1], O. Ozturk[1], W. Saab[2], V. Seshadri[2], P. Serhal[2]

[1] *The Centre for Reproductive and Genetic Health, Embryology, London, United Kingdom*

[2] *The Centre for Reproductive and Genetic Health, Clinician, London, United Kingdom*

Study question: Do embryos with multinucleated cells (MNC) have a self-correction mechanism that possibly results in euploid embryos?

Summary answer: Multinucleated embryos are prone to chromosomal aberrations. This feature self-corrects before 4-cell stage resulting in higher euploidy rates, when compared to embryos showing persistent MNC.

What is known already: Blastomere multinucleation is commonly observed in early embryo development. This characteristic seen in embryos have been associated with diminished embryo potential, reduced blastocyst development, significantly lower implantation and higher miscarriage rate. The presence of multinucleation in early human embryo development during the first and second mitotic division are generally considered as abnormal. Some studies using FISH and arrayCGH have shown that 50-100% of MN embryos are aneuploid, complex aneuploid or mosaic. However, resent studies using advanced chromosomal screening have shown that re-analysing on D5 the D3 embryos considered as abnormal due to MNC observed reduction in aneuploidy in these embryos.

Study design, size, duration: A retrospective morphokinetical analysis of 166 known PGT-A (NGS) blastocysts was performed. Presence of MNC was annotated from the 2-cell to morula stage. Analysis consisted of comparing the stages of appearance of multinucleation, number of cells with MN and the stage at which MN disappears in conjunction with chromosomal outcome of the MN blastocysts. The mean female age was 38.51 ± 3.8(SD 3.8) years

Participants/materials, setting, methods: Patients undergoing PGT-A cycles due to advanced maternal age, previous miscarriage, recurrent failed attempts or previous aneuploid pregnancy in a single IVF centre. IVF Inseminated or Intracytoplasmic sperm injected oocytes were cultured in the Time Lapse monitoring incubator. Embryos were annotated from D1 until D5/6 of development. Only embryos reaching the blastocysts stage were biopsied for PGT-A screening. Data were analysed by chi-square statistic using SPSS v23 statistics software

Main results and the role of chance: Analysis was performed based on 166 blastocysts; of which 106 (63.4%) displayed MNC during their early development and 60 (36.6%) embryos did not present this feature. Of the embryos presenting MNC: 25/106 (23.58%) were euploid, 78/106 (73.5%) aneuploid and 3% did not produce a conclusive result. Blastocysts with no MNC: 24/60 (40%) euploid, 34/60 (56.6%) aneuploid and 3.4% no result. Comparison of both groups highlighted the correlation between MNC and ploidy status (p 0.0249). Furthermore, euploidy was analysed considering the disappearance stage of MNC. Euploidy rates were the highest when MNC self-corrected at the 2-4 cell stage, progressively decreasing the longer MNC are observed falling to nearly 0% when MNC persisted past the 10-cell stage. Hence, the later the embryo becomes mononucleated, the higher the odds for it to be chromosomally abnormal (OR 8.54 (CI 5.6-12.7), p<0.0001).

Limitations, reasons for caution: The sample size was small involing a few number of biopsied blastocysts. Larger studies are required for the morphokinetic analysis.
Wider implications of the findings: Multinucleation,embryos have been shown to be chromosomally normal using NGS. Perhaps, the disappearance of these MNB at an early stage could be an indication of cellular repair mechanism or sperm and eggs spindle packaged separately which should converge during the next mitotic division. These embryo/s should be considered for Transfer.
Trial registration number: N/A

P-186 A novel predictive model to estimate the number of oocytes required for obtaining at least one euploid blastocyst for transfer: The ART Calculator

S. Esteves[1], J. Carvalho[2], F. Bento[1], J. Santos[3]
[1]*ANDROFERT, Andrology & Human Reproduction Clinic, Campinas, Brazil*
[2]*Statistika Consulting, Statistics, Campinas, Brazil*
[3]*Clinisys- Tecnologia e Sistemas de Saúde, Department of Development, Campinas, Brazil*

Study question: Is it possible to develop a predictive model to estimate the number of oocytes required to obtain at least one euploid blastocyst for transfer in infertile couples undergoing IVF/ICSI?
Summary answer: Our novel predictive model estimates the minimum number of mature oocytes needed to achieve at least one euploid blastocyst for transfer.
What is known already: The POSEIDON group (**P**atient-**O**riented **S**trategies **E**ncompassing **I**ndividualize**D** **O**ocyte **N**umber) has introduced 'the ability to retrieve the number of oocytes needed to achieve at least one euploid embryo for transfer' as an intermediate marker of successful outcome in IVF/ICSI cycles. A clinical predictive model to estimate the POSEIDON's marker -and that provides a revised estimate of the probability of achieving this outcome when fewer than the predicted number of oocytes are obtained after one or more oocyte retrieval cycles- would be invaluable for both patient counseling and establishment of a working plan with a clear goal for management.
Study design, size, duration: We analyzed clinical and embryonic data of 347 infertile couples who underwent IVF/ICSI with the intention to have trophectoderm biopsy for preimplantation genetic testing for aneuploidy (PGT-A) from February 2016 to June 2017. A total of 2,520 mature oocytes were injected, resulting in 882 blastocysts that were subjected to PGT-A. PGT-A was mainly used for reasons of advanced maternal age, repeated implantation failure, and for patients concerned about the euploidy status of their embryos.
Participants/materials, setting, methods: Participants were consecutive couples undergoing their first treatment cycle. We only included patients with a complete IVF/ICSI record. Included patients had at least one metaphase II oocyte (MII) retrieved. The oocytes were inseminated for own use and all resulting viable blastocysts were biopsied and analyzed by next-generation sequencing (NGS). We used the negative binomial distribution to model the number of euploid blastocysts and adaptive LASSO (Least Absolute Shrinkage and Selection Operator) method for variable selection.
Main results and the role of chance: The fitted model selected female age, sperm source, and number of mature (metaphase II) oocytes as predictors ($p<0.0001$). Female age was the most important factor for predicting the probability of a blastocyst being euploid given each mature oocyte (loglikelihood of age [adjusted for sperm source]: 30.9; df=2; $p<0.0001$). The final model was developed using logistic regression analysis and internally validated by the holdout method. Its predictive ability assessed by the area under the ROC curve was 0.715. Using the final model and mathematical equations, we calculated the individualized probability of blastocyst euploidy per mature retrieved oocyte and the minimum number of mature oocytes required to obtain at least one euploid blastocyst —with their 95% confidence interval [CI]— for different probabilities of success. The predicted probabilities of a mature oocyte turn into a euploid blastocyst decreased progressively with female age and was negatively modulated overall by use of testicular sperm from men with non-obstructive azoospermia across age ($p<0.001$). A calculator was developed to make two types of predictions automatically, namely (1) the minimum number of mature oocytes for at least one euploid blastocyst, and (2) the chances of having a euploid blastocyst based on the actual number of mature oocytes collected/accumulated.
Limitations, reasons for caution: There is a need to validate its prediction ability externally to confirm generalizability. Our estimations cannot be generalized to patients undergoing cleavage-stage embryo transfer as the study was based on blastocyst biopsies and NGS analysis. The model should be used with caution to decide whether a patient should undergo treatment.
Wider implications of the findings: This tool can help healthcare providers to counsel infertility patients about the individualized oocyte number needed to optimize the chances of having a euploid blastocyst for transfer, thus shaping patients' expectations. Also, it may guide clinicians on a risk-shared decision about ART treatment options aimed at achieving the oocyte number.
Trial registration number: Not applicable

P-187 A comparison of Primovision and EmbryoScope+ time-lapse imaging systems on laboratory performance indicators.

H. Smith[1], L. Zujovic[1], J. Hopkisson[2], N. Raine-Fenning[2]
[1]*Nurture, Embryology, Nottingham, United Kingdom*
[2]*Nurture, Consultant, Nottingham, United Kingdom*

Study question: Is there a difference in laboratory performance indicators between Primovision and EmbryoScope+ time-lapse systems?
Summary answer: Cleavage rate and embryos developmentally on target on d3 and d5 was significantly higher with EmbryoScope+, and rates of embryo transfer cancellation were significantly lower.
What is known already: Many IVF centres now employ time-lapse imaging systems to monitor embryo development and to help predict the most viable embryo for transfer. There are a number of time-lapse imaging systems which have been developed including closed systems such as EmbryoScope+, or Primovision which can be fitted into the laboratories existing incubators. Within our laboratory, Primovision is fitted within a Heraeus Cytoperm 2 incubator. It is thought that EmbryoScope+ is at least comparable to other standard incubation methods with regards to laboratory performance indicators.
Study design, size, duration: A prospective cohort study, collecting data on fresh treatment cycles utilising Primovision or EmbryoScope+ time-lapse systems from d1 to d6 of culture between July 2017 and Aug 2018. Each time-lapse system was used on alternating days. Cycles utilising donor oocytes were excluded. The Primovision group included 157 cycles and 1007 embryos, whereas the EmbryoScope+ group included 246 cycles and 1718 embryos. Pregnancies were followed up until 7 weeks gestation when an ultrasound scan was performed.
Participants/materials, setting, methods: Cycle data collected included: female age, AMH, endometrial thickness, cycle number, insemination method, number fertilised, cleavage rate, embryo development rate on d3 (defined as >6c) and d5 (defined as cavitating and blastocyst formation), good blastocyst development rate, embryo transfer cancellation rate (due to no suitable embryos available), freeze all rate, number of embryos transferred, utilisation rate, implantation rate (IR), clinical pregnancy rate (CPR), multiple pregnancy rate (MPR) and pre-clinical miscarriage rate.
Main results and the role of chance: Patient age (36.53 vs. 36.18, $P>0.05$), cycle number (2.1 vs. 2.06, $P>0.05$), AMH (17.95 vs. 17.90, $P>0.05$) and endometrial thickness (10.65mm vs. 10.68mm, $P>0.05$) were comparable for the EmbryoScope+ and Primovision groups respectively. The number of embryos (6.98 vs. 6.41, $P>0.05$), embryos transferred (1.59 vs. 1.64, $P>0.05$), and the proportion of IVF/ICSI/split cases (113/246, 131/246, 2/246 53.25/45.93/0.81% vs. 75/157, 81/157, 1/157 51.59/47.77/0.64%, $P>0.05$) also did not vary significantly between the EmbryoScope+ and Primovision groups, respectively.

The embryo transfer cancellation rate (17/157, 10.83% vs. 5/246, 2.03%, $P<0.01$) was significantly lower with EmbryoScope+, compared to Primovision respectively. The cleavage rate (987/1007, 98.01% vs. 1706/1718, 99.30%, $P<0.01$) and embryo development rate on day 3 (739/1007, 74.87% vs. 1347/1718, 78.96%, $P<0.05$) and day 5 (507/1007, 51.37% vs. 979/1718, 57.39%, $P<0.01$) was significantly higher with EmbryoScope+, compared to Primovision respectively.

No difference in good blastocyst development rate (326/1718, 18.98% vs. 166/1007, 16.48%), utilisation rate (687/1706, 40.27% vs. 369/987, 37.39%,

P>0.05), IR (118/357, 33.05% vs. 89/225, 39.56% P>0.05), MPR (17/89, 19.10% vs. 16/68, 23.53%, P>0.05), pre-clinical miscarriage rate (28/117, 23.93% vs. 19/87, 21.84%, P>0.05) or CPR/treatment cycle (excluding freeze-alls) (89/229, 38.86% vs. 68/154, 44.16%, P>0.05) was observed between the EmbryoScope+ and Primovision groups, respectively.

Limitations, reasons for caution: Live birth rates should be followed up when the data is available to see if there is a difference in the final outcome between the Primovision and EmbryoScope+ groups. Furthermore, large randomised controlled trials are needed to confirm the results of this study.

Wider implications of the findings: Our findings support other studies that suggest EmbryoScope+ is at least comparable to other standard incubation methods, and may promote improved laboratory performance indicators. This may be due to a more stable culture environment with the use of EmbryoScope+.

Trial registration number: Not applicable

P-188 An improvement in blastocyst quality using temperature variation treatments during in vitro embryo culture

D. Ferreira Moriyama[1], G. Ferrante Alves de Moraes[1], M. De Oliveira Pinheiro[1], W. Maalouf[2], E. Guimaraes Lo Turco[1]

[1]*Sao Paulo Federal University- Medical School, Department of Surgery- Division of Urology- Human Reproduction Section, Sao Paulo, Brazil*

[2]*The University of Nottingham- Faculty of Medicine and Health Sciences, Division of Obstetrics and Gynaecology, Nottingham, United Kingdom*

Study question: Does temperature variation treatments during *in vitro* culture improve blastocyst quality?

Summary answer: Temperature variation treatments improve blastocyst quality and enhance blastocyst rate.

What is known already: It is known that temperature, among other factors, can affect a variety of aspects in the oocyte and embryo function, particularly meiotic spindle stability and embryo metabolism. Basal body temperature (BBT) is the lowest temperature reached by the human body during rest. Even though BBT has been associated with natural family planning and timing of ovulation, the effects of BBT variation during day and night on embryo development is unknown. Moreover, studies have demonstrated a gradient of temperature in the female reproductive tract of several mammalian species.

Study design, size, duration: Fresh mouse zygotes (N=854, 6 repetitions) were cultured for 96 hours in continuous culture media incubated at 37°C in control group (C group), in Treatment 1 group (T1 group) at 37°C during the day and 35.5°C during the night and Treatment 2 group (T2 group) at 38.5°C during the day and 37°C during night, 90% humidity and 6% CO_2. Number of blastocysts and the assessment of embryo quality were analyzed on day 5 of development.

Participants/materials, setting, methods: Female mouse C57BL/6J were superovulated with PMSG and ECG. Males and females were placed to mate for natural fertilization. Zygotes were collected from the tubes and then cultivated (15 embryos/droplet) for 96 hours in continuous culture media and incubated under the 3 temperature variation treatments (Control, T1 and T2 group). Blastocyst rate (N=459) and the assessment of embryo quality, through Morphological Assessment (N=444) and TUNEL Test (N=181) were analyzed on day 5 of embryo development.

Main results and the role of chance: T2 group (38.5°C/37°C) presented a significant (p=0.0001) higher blastocyst rate (63.30%), when compared to T1 group (48.12%) and C group (49.14%). Additionally, considering the TUNEL test, T2 group presented a significant (p=0.0001) lower apoptotic rate (0.04+0.03) when compared to T1 group (0.10+0.08) and C group (0.06+0.04). Regarding the total number of cells of the blastocysts, which is the reference for the TUNEL analysis T2 group also presented a significant (p=0.0001) higher number of total cells (133.24+36.17) when compared to T1 group (83.42+37.37) and C group (116.61+41.93). Considering the Morphological Assessment (SART criteria), T2 group presented blastocysts with a significant (p=0.0001) higher grade (2.21+0.68) when compared to T1 group and a similar grade when compared to C group (2.28+0.70). In summary, blastocysts from T2 group showed better results in all assessments: blastocyst rate, TUNEL test and Morphological Criteria, indicating that with a temperature variation treatment of 38.5°C for 12 hours and 37°C for the next 12 hours not only more embryos reached the blastocyst stage but also, the blastocysts showed enhanced quality.

Limitations, reasons for caution: This study was only carried out in the mouse model, so further investigations are needed on embryos of larger mammalian species.

Wider implications of the findings: More studies are necessary to elucidate the effects of temperature variation treatments on embryo development *in vivo* and *in vitro,* which could lead to novel, safer methods of mammalian embryo culture *in vitro*.

Trial registration number: N/A

P-189 Trophoblast plugs: How do they stay together and why do they break up?

J. James[1], G. Bogle[2], R. Sagian[2], A. Clark[2]

[1]*University of Auckland Faculty of Medical and Health Sciences, Obstetrics and Gynaecology, Auckland, New Zealand*

[2]*University of Auckland, Auckland Bioengineering Institute, Auckland, New Zealand*

Study question: How do the mechanical influences of blood flow impact trophoblast plugging and unplugging of the spiral arteries in early pregnancy?

Summary answer: High cell-cell interaction forces maintain trophoblasts in cohesive plugs, but any asymmetries/weak points produce high flow channels that lead to a cycle of plug disintegration.

What is known already: During early pregnancy trophoblasts colonise and remodel maternal spiral arteries, ensuring adequate delivery of oxygen-rich blood to the placenta later in pregnancy. During this process, trophoblasts form plugs that occlude spiral arteries, preventing maternal blood flow to the placenta until the late first trimester. Inadequacies in these processes are associated with pregnancy disorders. We have shown that trophoblast plugs play crucial roles in spiral artery remodelling by creating a low shear stress environment that promotes trophoblast migration (driven by chemotactic signals). However, our understanding of the cellular interactions involved in maintaining trophoblast plugs, and how/why they disintegrate/dislodge is almost non-existent.

Study design, size, duration: A 3D agent-based computational model of trophoblast migration within plugged spiral arteries was developed, and used to simulate trophoblast behaviour within plugs in response to fluid shear stress and chemotactic signals. Shear stress conditions were informed by our previously published model of haemodynamics in these vessels. In the model, blood flow acts in the opposite direction to chemotactic force, meaning that the flow acts to reduce the speed of trophoblast migration along the artery.

Participants/materials, setting, methods: The net force experienced by each cell/agent in the model was defined as the sum of F_{random} (cell movement in the absence of stimuli), F_{social} (interactions with other cells) and $F_{environment}$ (the force of environmental influences such as arterial walls, chemotaxis, and shear stress). Each force was parameterised using both stochastic data from *in vitro* imaging of trophoblast migration under fluid shear stress, and previous studies investigating mechanical interactions between cells in close proximity.

Main results and the role of chance: How do plugs stay together? When cell-cell interaction forces are high, trophoblasts in plugs remained tightly clustered and little cell movement out of plugs occurs. Decreasing cell-cell interaction forces increases cell migration out of plugs along the vessel wall. Thus, for trophoblast plugs to remain intact (as occurs *in vivo*), cell-cell interaction forces must be relatively high.

How/why do plugs break up? When cell-cell interaction forces are low, plugs progressively open from the centre as cells migrate towards and along the vessel wall. Conversely, when cell-cell interaction forces are high, cells remain in cohesive plugs. If a plug region becomes cell-free (here due to asymmetry in migration, *in vivo* also potentially due to cell death), flow in that region increases, forming channels similar to those reported histologically. Once channels are evident, local increases in flow stimulate further trophoblast migration away from the channels, further increasing flow and reinforcing the cycle of plug breakdown. In this scenario, flow drives plug dispersion, and if total volumetric blood flow increases, as is expected as the larger arcuate/radial arteries remodel late in the first trimester, plug break-up occurs more rapidly. Thus, increases in blood flow may act as a stimulus to induce plug dispersal.

Limitations, reasons for caution: The model was parameterised using in vitro data that is not able to simultaneously capture the influence of all the

factors involved in regulating trophoblast behaviour in vivo (e.g. shear stress, chemotaxis, 3D cell-cell interaction forces).
Wider implications of the findings: This model enabled us to simulate trophoblast behaviour and visualise potential scenarios leading to plug dispersal. These data provide a physiological mechanism by which the channels observed in trophoblast plugs *in vivo* may contribute to their dispersal in the late first trimester.
Trial registration number: Not applicable

P-190 Morphokinetic characteristics of embryos originating from extremely small follicles: a prospective study.

S. Avraham[1], Y. Kalma[2], F. Azem[1], L. Zakar[1], H. Amir[1], R. Rahav[2], L. Barzilay[1], M. Dviri[1], B. Almog[1]
[1]*Lis Maternity Hospital- Tel Aviv Sourasky Medical Center, Racine IVF Unit, tel aviv, Israel*
[2]*Lis Maternity Hospital- Tel Aviv Sourasky Medical Center, Prenatal Diagnosis Unit-Genetic Institute, Tel Aviv, Israel*

Study question: Is the developmental potential of oocytes and embryos derived from extremely small follicles (<10mm) different from those originated in larger follicles?
Summary answer: Embryos originated from small follicles are not different than embryos from larger follicles, as assessed by morphokinetic parameters in time lapse system.
What is known already: There is no data concerning morphkinetic parameters of embryos developed from oocytes derived from very small follicles.
Study design, size, duration: Prospective study, A university affiliated tertiary hospital, IVF unit, PGD referral center.
Participants/materials, setting, methods: We documented follicle aspirations of 98 patients. Aspiration of follicles larger and smaller than 10 mm was undertaken separately and the development of embryos was followed up using different wells for each embryo. We recorded: oocytes retrieved, maturation, fertilization rate, cleavage rate, morphokinetic parameters, transfers, embryo freezing, oocyte freezing and biopsy rate for preimplantation genetic diagnosis (PGD).

Quality was evaluated using time-lapse imaging technology. Day 3 KIDScore was calculated and comparison was made between groups.
Main results and the role of chance: Small follicles compared to large follicles displayed lower recovery rate (45% vs. 74%, P<0.0001), fewer matured oocytes (37.5% vs. 61.7%, P<0.0001), higher rates of GV oocytes (20.7% vs., 3.7%, P< 0.0001), and lower fertilization rate (43.7% vs. 63.3%, P<0.0001. However, morphokinetic variables were similar between embryos that originated from either small or large follicles. Median KIDscores were identical for embryos from small or large follicle origin.
Limitations, reasons for caution: assessment was limited to day 3 embryos.
Wider implications of the findings: In view of our findings, physicians should bear in mind that small follicle aspiration might yield good quality embryos.
Trial registration number: not applicable

P-191 The EGFL7/NOTCH pathway: a novel regulator of the endometrium-blastocyst dialog

L. Campagnolo[1], V. Lacconi[1], F. La Civita[1], D. Antonaci[2], C. Meneghini[2], M. Massimiani[3], C. Ticconi[4], R. Rago[2]
[1]*University of Rome "Tor Vergata", Biomedicine and Prevention, Roma, Italy*
[2]*Ospedale Sandro Pertini- ASL Roma2, UOSD Fisiopatologia della Riproduzione e Andrologia, Roma, Italy*
[3]*University of Rome "Tor Vergata", Biomedicine and Prevention, Rome, Italy*
[4]*University of Rome "Tor Vergata" and Policlinico Tor Vergata, Surgical Sciences, Roma, Italy*

Study question: Is the EGFL7/NOTCH pathway involved in the regulation of endometrial receptivity and embryo implantation, influencing fertility?
Summary answer: EGFL7, NOTCH1, NOTCH-target genes are reduced in the endometrium of patients experiencing unexplained recurrent miscarriages-(uRM) and recurrent implantation failure-(RIF). EGFL7-overexpressing trophoblast spheroids demonstrate increased adhesion
What is known already: Several NOTCH family members have been identified in the endometrium, where they regulate cellular events involved in feto-maternal communication. Reduced expression of Notch1 in endometrial stromal cells inhibits decidualization, and its aberrant activation in the mouse uterus downregulates the expression of progesterone receptor, leading to infertility. The secreted factor Epidermal Growth Factor Like Domain 7 (EGFL7) has been recently demonstrated as a novel regulator of the NOTCH pathway. We previously demonstrated that EGFL7 is expressed by mouse blastocyst and by mouse and human trophoblast cells, and that it regulates their migration and invasion ability by activating NOTCH1
Study design, size, duration: The presented work is a translational study which so far enrolled 60 women stratified into 3 experimental groups: controls, uRM, RIF. Endometrial biopsies have been collected to compare the activation of the EGFL7/NOTCH pathway. From part of these samples, endometrial cell cultures have been obtained and used to determine the ability of recombinant EGFL7 to activate NOTCH signaling. Spheroids of EGFL7-expressing trophoblast cells have been used to study the role of EGFL7/NOTCH crosstalk in implantation
Participants/materials, setting, methods: Women 42 years of age or younger were enrolled. Endometrial biopsies were obtained, and partly processed to characterize the EGFL7/NOTCH pathway expression by both qRT-PCR and immunofluorescence (IF); part of the samples were processed for the preparation of cell cultures used for functional studies. The human trophoblast cell line HTR8 was induced to over-express EGFL7 (HTR8-E7), and spheroids (to resemble the human blastocyst) were obtained to elucidate the contribution of the EGFL7/NOTCH pathway in implantation
Main results and the role of chance: Our qRT-PCR results demonstrate that the expression of EGFL7 is significantly reduced in both RIF and uRM endometrial samples compared to controls. A parallel reduction is also observed for NOTCH1 and the NOTCH target genes HEY1 and HES1, suggesting a correlation between the downregulation of the EGFL7/NOTCH1 pathway and implantation defects. Immunofluorescence analysis of control samples demonstrates that EGFL7 is expressed by endothelial and glandular epithelial cells, and consistent with the qRT-PCR results, in RIF and uRM such expression is strongly reduced. Supplementation of endometrial cultures with hrEGFL7 up-regulates the expression of the NOTCH target genes HES1 and HEY2 in a time dependent manner, indicating an EGFL7-mediated, time-dependent activation of the NOTCH signaling in endometrial cells. Trophoblast spheroids over-expressing EGFL7 show a higher ability to adhere and spread on gelatin and on endometrial cells than control spheroids, suggesting that trophoblast derived EGFL7 may play a role in regulating implantation. In order to avoid serendipitous findings, we have performed our analyses on a sufficiently large number of samples and repeated each experiment at least three times; in all experiments we have also always included the appropriate controls
Limitations, reasons for caution: The reported results may have some limitations: - *in vitro* cultures might per-se influence gene expression, not faithfully representing the *in vivo*; -for ethical reasons no human blastocysts could be used to prove trophoectoderm-expression of EGFL7; -trophoblast spheroids may be a too simplified model of the blastocyst, not including ICM
Wider implications of the findings: Our results provide new insights into the etiopathology of implantation defects and pregnancy complication by identifying alteration in EGFL7 expression and secretion and dysregulation of NOTCH signaling as leading causes of RIF and uRM. Our results might have therapeutic relevance, with EGFL7/NOTCH pathway being target for medical intervention
Trial registration number: Not Applicable

P-192 Evaluation of the intracytoplasmic sperm injection (ICSI) results in recurrent total fertilization failure (TFF)

T. Irez[1], O. Guralp[2], S. Kahraman[3]
[1]*Biruni University Faculty of Medicine, Histology&Embryology, Istanbul, Turkey*
[2]*Oldenburg University, GYn&Obst, Oldenburg, Germany*
[3]*Sisli Memorial Hospital, IVF Center, Istanbul, Turkey*

Study question: Are there any differences regarding parameters of in-vitro-fertilization (IVF) treatment process, semen analyses and sperm functions between cases with recurrent TFF versus fertile pairs?

Summary answer: TFF is associated with the male and female age, basal FSH value, the amount of gonadotropin used during ovarian stimulation and properties of gametes.
What is known already: In ICSI applications, the causes of TFF include the mitosis errors, sperm aster formation defect, sperm decondensation defects, defects in PN formation, morphological abnormal oocytes and oocyte activation defects.
Study design, size, duration: In this retrospective study, semen parameters and sperm functions, oocyte morphology, basal hormone levels and treatment processes were compared in 32 cases with second time TFF after ICSI application and 91 fertile control cases treated between 2014 and 2018.
Participants/materials, setting, methods: A total of 123 patients, who underwent ovarian stimulation with antagonist protocol at Memorial IVF Center, Istanbul, Turkey, were evaluated. Exclusion criteria included polycystic ovaries, endometriosis, azoospermia and globozoospermia. The primary endpoint was basal hormone measurements and used amount of gonadotropins. Secondary endpoints were oocyte maturity, morphology and oocyte counts.
Main results and the role of chance: The male age (36.9±5.0 y vs 34.8±4.5 y, p=0.041), female age (33.5±5.1 y vs 30.8±3.9 y, p=0.004), basal FSH value (7.2±3.7 IU/L vs 5.7±2.0 IU/L, p=0.008) and the amount of gonadotropin used during ovarian stimulation (2725±1127 IU vs 2171±817 IU, p=0.004) were significantly higher in the TFF group than the fertile controls. Basal AMH level (1.8±1.7 ng/mL vs 3.8±2.8 ng/mL, p=0.002), total oocyte count (4.4±4.3 vs 9.6±4.4, p<0.001), M2 oocyte count (0.3±0.8 vs 2.5±2.7, p<0.001), quality oocyte count (2.7±3.1 vs 4.4±3.0, p=0.008) and normal ZP (2.6±2.8 vs 7.4±3.6, p<0.001) were lower in TFF cases compared to the fertile controls. There was no statistically significant difference between the two groups in terms of semen parameters and sperm function.
Limitations, reasons for caution: The main limiting factor of this study ins the small number of cases.
Wider implications of the findings: The oocyte-cytoplasm and zona-pellucida abnormalities, high FSH and low AMH values, and high-dose gonadotropin administration may be associated with TFF. Since the mean-female age was less than 35 and the oocyte count was lower in the TFF-group, the probability of TFF should be considered also in young patients with ovarian-insufficiency.
Trial registration number: 2018/BUEK-1.2.2018/34

P-193 Perishing IVF embryos: Evaluating different approaches in light of the bioethical status of the preimplantation embryo.

M. Simopoulou[1], K. Sfakianoudis[2], P. Giannelou[2], A. Rapani[1], E. Maziotis[1], P. Tsioulou[1], S. Grigoriadis[1], E. Simopoulos[3], D. Mantas[4], M. Koutsilieris[1], K. Pantos[2], J. Harper[5]
[1] *National and Kapodistrian University of Athens, Department of Physiology, Athens, Greece*
[2] *Genesis Athens Clinic, Reproductive Medicine Unit, Athens, Greece*
[3] *Democritus University of Thrace, Department of Medicine, Alexandroupoli, Greece*
[4] *Gynaecology & Fertility Hospital, Department of Gynaecology, Dubai, United Arab Emirates*
[5] *Institute for Women's Health, IVF and Reproductive Genetics Group, London, United Kingdom*

Study question: How do In Vitro Fertilization (IVF) laboratories worldwide perish supernumerary embryos?
Summary answer: Discrepancies in management of supernumerary embryos involve practice, timing, and allowing couples' involvement in the procedure. Practitioners recognize the need for a universal protocol implementation.
What is known already: Perishing surplus embryos in an IVF clinic constitutes a routine procedure for embryologists. These surplus embryos may be originating from fresh cycles, as poor-quality embryos fail to be qualified for embryo transfer or cryopreservation. Alternatively, they could be embryos diagnosed with genetic or chromosomal abnormalities following Preimplantation Genetic Testing, or cryopreserved embryos in storage that patients choose to perish. Current literature lacks data regarding the different practices employed in discarding embryos in IVF laboratories, as there is no universal protocol or guideline.
Study design, size, duration: A web-based questionnaire titled 'Anonymous questionnaire on embryo disposal practices' was designed employing the "google-forms" format in order to ensure anonymous participation of IVF professionals around the world. Demographic information regarding the name of the Country and, where applicable, the State the IVF clinic was based. During a 3 months data collection period 440 answers from 56 different countries were acquired.
Participants/materials, setting, methods: In an effort to reach a worldwide audience, the authors employed the contact platforms available in websites of respective associations and organizations, or used the provided contact email of clinics to reach IVF professionals. The questionnaires' link was posted online employing social media platforms while individual associations of embryologists were contacted worldwide. The answers were collected and analysed in order to unfold trends and patterns on embryo disposal practices around the globe.
Main results and the role of chance: The questionnaire was divided into three sections. The first section focused on how IVF practitioners perform embryo disposal of surplus embryos. In both fresh and frozen cycles, the majority of practitioners dispose of embryos by placing them directly in a biohazard bin for both fresh and frozen cycles (38.6% and 37.0% respectively). Moreover, 66.2% of practitioners perish the embryos separately, case by case, at different time points during the day. Over half of embryologists (53.7%) wait until Day 6 to perish the surplus embryos, while 65.9% do not implement a special allocated incubator space as a designated waiting area prior to the disposal procedure. Interestingly, 65.1% reported that this is a witnessed procedure. The second section of the survey assessed the various approaches employed in order to satisfy patient requests or requirements in regards to embryo disposal. The majority of embryologists (93.6%) do not employ different protocols for different groups of patients, but 18.6% reported that they have been asked to perform a ceremony for these embryos. The third section assessed the embryologists' perspective with 57.7% of participants stating that embryology practice would benefit from a universal protocol.
Limitations, reasons for caution: Employing google forms platform, reflecting an individual opinion was enabled and current practice was linked to the stated Country. The language barrier may have served as an obstacle reaching Countries where English is not spoken. Despite the anonymity, social reasons may have led some respondents not to mention certain practices.
Wider implications of the findings: The variety on the practices may be attributed to both moral and bioethical perceptions surrounding the preimplantation embryo's bioethical stance. This study provides insights into embryo disposal practices and raises questions on the standardization and regulation of clinical practices while highlighting the need for concurring on a universal protocol.
Trial registration number: Not applicable

P-194 Rab10 regulates actin-dependent cortical granule migration for fertilization in mouse oocytes

H.H. Wang [1], S.C. Sun [1]
[1] *Nanjing Agricultural University, College of Animal Science and Technology, Nanjing, China*

Study question: As cortical granule (CG) migration and exocytosis are important for meiotic maturation and fertilization, we investigated possible factors and mechanism regulating these processes.
Summary answer: We found a vesicle traffic protein Rab10 could affect myosin Va powered CG migration through RhoA-ROCK pathway-mediated actin assembly.
What is known already: During fertilization, cortical-area-distributed CG exocytosis takes place and CG contents are released into the perivitelline space, which could modify the zona pellucida (ZP) and make ZP stiff for blocking polyspermy. CGs are recognized deriving from Golgi complex and then are migrated to the cortical area waiting for fertilization. During this process, microfilaments play important roles both in vertebrates and invertebrates. Besides, CGs also could bind to Rab11a vesicles powered by myosin Vb and then are transported to the destination. RhoA-ROCK pathway are verified to regulate actin dynamics and Rab10 are reported to regulate endosome transport.
Study design, size, duration: RNAi was used to perform the knockdown of Rab10. Rab10 T23N and Rab10 Q68L site-mutant plasmids were used to overexpress inactive or active form of Rab10. At least 50 oocytes were used to

detect actin assembly and CG migration after microinjection of Rab10 siRNA and in-vitro transcribed cRNA. All experiments were performed at least three times.

Participants/materials, setting, methods: We used immunofluorescent staining and western blotting to examine the effects of Rab10 on oocyte meiotic maturation and fertilization.

Main results and the role of chance: siRNA-mediated attenuation of Rab10 expression led to a significant ($P<0.05$) decline of mouse oocyte maturation (the first polar body extrusion rate). Rab10 disruption did not affect spindle organization ($P>0.01$), but significantly decreased cytoplasmic microfilament actin ($P<0.01$). Compared to overexpression of active Rab10 (Rab10-GTP), Rab10 knockdown and overexpression of inactive state Rab10 (Rab10-GDP) could delay the CG migration to cortical area ($P<0.05$). Further, overexpression of inactive Rab10 could downregulate the expression of factors in RhoA-ROCK pathway, which are proved to be important for actin assembly. At last, we detected more Rab10-knock down oocytes presented polyspermy than control group and Rab10-GTP overexpression group ($P<0.05$). Taken together, these observations hint at a key role of Rab10 in the regulating of actin-dependent CG migration and fertilization.

Limitations, reasons for caution: Only in vitro investigation was conducted in our research and Rab10 knock out was lethal at embryo development stage in mouse.

Wider implications of the findings: Our findings indicated a vesicle traffic protein Rab10 participating in regulating oocyte maturation and blocking polyspermy. This information could contribute to a better understanding of fertilization mechanism.

Trial registration number: not applicable

P-195 Challenges in oocyte vitrification and fertility preservation: female age and oocyte quality

B. Wirleitner[1], P. Vanderzwalmen[2], A. Stecher[1], B. Batsuren[1], D. Schwerda[1], M. Schuff[1], M. Zintz[1], M. Murtinger[1]

[1]*Nextclinic IVF-Centers Prof. Zech, Bregenz GmbH, Bregenz, Austria*

[2]*CHIREC IVF center, Braine 'alleud, Brussels, Belgium*

Study question: Is there an age limit for patients to undergo oocyte freezing for fertility preservation and how many oocytes should be retrieved?

Summary answer: A birth rate of 28.6% in patients ≥39 years with Ø 5.1 oocytes warmed encourages the future application of oocyte vitrification in fertility preservation.

What is known already: Nowadays oocyte vitrification is widely used for fertility preservation, however clinical outcome published remains scarce, especially for IVF-patients accumulating oocytes (low responders) and cancer patients. Several publications report a dramatically increased amount of oocytes needed to achieve a pregnancy with increasing female age. However, the oocyte yield we can clinically expect is often far below these numbers. Further, IVF-patients often show multifactorial subfertility. Facing the poor knowledge on clinical outcome, this study aimed to analyze the impact of age, oocyte quality and infertility on IVF-success after aseptic oocyte vitrification to estimate clinical relevance of oocyte freezing at advanced female age.

Study design, size, duration: This retrospective study encompassed data of 6 years (2011-2016). A total of 43 aseptic oocyte vitrification / warming cycles were included. Patients were grouped according to female age: ≤38 and ≥39 years. Primary outcome parameters were survival rate (SR) after warming, fertilization rate (FR) and blastocyst development. Second endpoint included pregnancy rate (PR) and birth rate (BR).

Participants/materials, setting, methods: Oocyte vitrification was indicated by medical reasons (e.g. fertility preservation in ultra-low responder patients, before cancer treatment, or oocyte accumulation due to severe male factor infertility). Aseptic vitrification of oocytes was performed around 2 hours after oocyte pick-up with a standardized protocol (VitriSafe and FertiPro solutions). Warming was done in sucrose solutions according to the manufacturer's protocol.

Main results and the role of chance: Patients underwent a mean of 1.3 stimulation cycles for oocyte retrieval. Thereby, a total of 376 mature MII oocytes were aseptically vitrified and subsequently warmed for embryo transfer. When comparing the age groups, a slightly diminished SR was found in patients ≥39 years compared to the younger group (77.9% vs. 83.8%). No differences in FR (70.1% vs. 73.7%) or blastocyst rate were observed between both groups (42.2% vs. 39.6%). Differences were found in PR (35.7% vs. 56.5%) and BR (28.6% vs. 43.5%) for patients ≥39 or ≤38 years, respectively. Reduced incubation time before vitrification and subequently increased time after warming before ICSI increased the yield of top-quality blastocysts (58.1% vs. 37.7%).

Limitations, reasons for caution: Results might not be fully applicable to other vitrification protocols or sulutions. Larger studies should confirm the results obtained in this retrospective study.

Wider implications of the findings: Aseptic vitrification avoids cross-contamination with pathogens and chemicals during vitrification, cryo-storage, and warming, rendering this technique especially valuable in fertility preservation involving prolonged storage-times. Our results encourage to perform oocyte vitrification in patients with reduced ovarian reserve or advanced maternal age. Refined lab-techniques might improve future outcome of oocyte vitrification.

Trial registration number: not applicable

P-196 Are blastocyst development rates and quality related to chromosomal aneuploidy?

D. Besi[1], A. Rattos[1], R. Salim[1], M. Jansa Perez[1]

[1]*Hammersmith Hospital, Wolfson Fertility Centre, London, United Kingdom*

Study question: Are blastocyst development rates and quality related to chromosomal aneuploidy?

Summary answer: Our data shows that blastocyst quality and developmental rate correlate well with the ploidy status of the examined embryo.

What is known already: The goal of IVF is to maximize clinical pregnancy rates without increasing multiple pregnancy rates. Preimplatation Genetic Screening (PGS) allows the selection of chromosomally normal blastocysts with possibly better implantation potential. However, PGS is an invasive procedure with some limitations. For this reason, it would be interesting to assess whether non-invasive embryo selection techniques, such as those based on morphology and developmental rate, could reliably reflect the ploidy of the embryo for transfer. This knowledge could help us to avoid unnecessary biopsies in future. Controversial data have been reported so far and no clear conclusion has been made yet.

Study design, size, duration: PGS data, from IVF and ICSI cycles performed at Hammersmith Hospital, between January 2013 and December 2018 were collected. Retrospective analysis of 256 blastocysts [170 on Day 5 (D5) and 86 on Day 6 (D6)] was performed. The ploidy status of blastocysts of different quality on D5 and D6 was compared.

Participants/materials, setting, methods: Laser assisted trophectoderm biopsy was performed on D5 or D6 depending on the timing of blastocyst formation. Blastocysts were analysed either with comparative genomic hybridization or next generation sequencing. Blastocyst grading was performed using the Gardner's system. Biopsied blastocysts were divided into three categories based on their morphology [good quality-GG (AA,AB,BA,BB), average quality-AQ (AC,CA,BC,CB), poor quality-PQ (CC)]. Mosaic embryos were excluded. Chi-squared test was used for statistical analysis and significance was considered if $p<0.05$.

Main results and the role of chance: Our data shows significant difference in ploidy rates when D5 blastocysts were compared to D6 blastocysts, with the D5 blastocysts showing significantly higher euploidy rate [40% D5 euploid rate (n=68/170) vs 18.6% D6 euploid rate (n=16/86), $p=0.00026<0.05$]. Additionally, the euploidy rate was significantly higher for good quality blastocysts compared to lower quality ones [GQ euploidy rate 50% (n=60/120) vs AQ euploidy rate 18.47% (n=17/92) and PQ euploidy rate 15.9% (n=7/44), $p=0.00001<0.05$]. Then, embryos of similar quality were compared on D5 and D6. There were no significant differences in ploidy rates when good quality blastocysts where compared on D5 and D6 [euploidy rates: GQ on D5 and D6, 50.49% (n=51/101) vs 47.36% (n=9/19), $p=1>0.05$] or when average quality blastocysts were compared on D5 and D6 [euploidy rates: AQ embryos on D5 and D6, 21% (n=12/57) vs 14.28% (n=5/35), p=0.5815]. However, when poor quality blastocysts where compared on D5 and D6, poor quality blastocysts showed significantly lower euploid rate on D6 [euploidy rates: PQ blastocysts on D5 and D6, 41.66% (n=5/12) vs 6% (n=2/32), $p=0.011<0.05$].

Limitations, reasons for caution: A larger samples size would be required to confirm our findings. Also, confounders such as patient age, which could

possibly affect outcomes, were not considered within our analysis. The biopsy technique itself could be another limitation as the trophectoderm sample analysed may not be representative of the entire embryo.
Wider implications of the findings: Morphology and developmental rate are associated with ploidy status**.** Nevertheless, our data shows that poor prognosis blastocysts could also be euploid. This information could be beneficial when no good quality blastocysts are available. Also, PGS could improve the efficiency of traditional selection by avoiding using good quality but aneuploid embryos.
Trial registration number: not applicable

P-197 Embryo transfer under sedation: Five years of experience at Imperial College London

B. Manukian[1], D. Balfoussia[1], L. Stradiotto[1], K. Purugganan[1], M. Jansa-Perez[1], R. Salim[1]
[1]Imperial College London, Wolfson Fertility Centre- Hammersmith Hospital, London, United Kingdom

Study question: What were the indications and outcomes for women who underwent an Embryo transfer under sedation (ETUS) in our Centre over the last 5 years?
Summary answer: Our data shows that ETUS is a viable option for women with a range of medical and non-medical indications with reassuring pregnancy outcomes.
What is known already: ETUS is a recognised option for women in specific circumstances. However, most of the literature is focused on sedation or anesthesia in Transvaginal oocyte retrieval (TVOR), but there are few reports about ETUS. A Brazilian group reported 2 cases of ETUS in patients with vaginismus and they described some reasons why sedation was requested by patients such as pain and extreme anxiety as well as other medical causes as cervical stenosis or trouble inserting the catheter (Do Carmo B, 2018;22(1):35-41). Our study represents the first report in the literature about a group of patient who underwent ETUS.
Study design, size, duration: A retrospective descriptive study of consecutive patients who underwent ETUS at Wolfson Fertility Centre (WFC), Hammersmith Hospital London, between January 2014 and December 2018 (60 months). The variables analysed included: age, IVF/ICSI or Frozen embryo replacement cycle (FERC) protocol, reason of sedation, clinical pregnancy rate, live birth rate, type of delivery.
Participants/materials, setting, methods: We analysed 3,766 embryo transfer cycles which were carried out at WFC between January 2014 and December 2018. 100 patients were identified in that period. The causes were divided in three groups: Medical, non-medical and non-identified
Main results and the role of chance: The average age of the patients was 34.5 years old (range 24 – 43 yo). 64 patients underwent fresh embryo transfer (64%) and 36 patients had FERC (36%). Causes were divided in three groups: (A) medical causes (50 patients) and (B) non-medical causes (44 patients) and in 6 patients a cause was not identified (C). In group A, 37 patients had history of previous difficult ET or a difficult mock ET, 5 patients had trachelectomy, 5 patients presented cervical stenosis, one patient had history of female genital mutilation, one patient who had a spasm in the TVOR and one patient who had a severe vulvar Crohn's disease. In group B, we included 31 patients with vaginismus, 12 patients who requested sedation due to anxiety and one patient who was virgo intacta.

Overall, Clinical pregnancy rate in ETUS was 41%, which is comparable to the patients who had ET without sedation (37,9%). 28 patients had live birth (12 in Group A, 11 in Group B, 4 in Group C) and two are still ongoing. 19 births were by caesarean section (67.8%), 6 patients had forceps (21.4%) and 3 vaginal deliveries (10.7%)
Limitations, reasons for caution: Due to the difference in group sizes between ETUS and standard ET, it was not possible to perform a statistical analysis in this study, however results seems to be comparable to ET without sedation. Live birth rates are not available as some pregnancies are still ongoing.
Wider implications of the findings: To the best of our knowledge, this is the first analysis about Embryo transfer under sedation in the literature and confirms that it is a viable option for women with a wide range of indications, not only for medical, but also for non-medical reasons, such as vaginismus and anxiety.
Trial registration number: no trial registration

P-198 Embryo cleavage rate is enhanced by extending oocyte- cumulus cell contact: a randomized sibling oocyte study

S. Hebisha[1], H. Sharaf[1], A. Abdel Aziz[1]
[1]Faculty of Medicine-Alexandria University, OBGYN, Alexandria, Egypt

Study question: Does increasing oocyte- cumulus oophrous contact before denudation improve reproductive outcome?
Summary answer: Cleavage rate significantly increases after preincubation of oocyte for 2 hours before denudation and injection,but no effect was found on pregnancy and implantation rates
What is known already: Optimal embryonic developmental competence depends on proper oocyte maturation. Nuclear maturation is usually achieved in vivo and can be assessed by the time of ovum pick up, however, cytoplasmic maturation cannot be readily assessed and might be incomplete. Cumulus cells, surrounding the oocyte might play a role in the oocyte cytoplasmic maturation. Several studies that compared denudation timing were retrospective, did not evaluate the interval within first 2 hours of OPU, neither evaluated all laboratory and clinical outcomes.
Study design, size, duration: Randomized sibling oocyte study including 160 ICSI cycles carried out between January 2017 and June 2018 in a private fertility center; the integrated fertility center of Alexandria.
Participants/materials, setting, methods: A total of 2621 oocytes were randomized into two groups according to denudation timing, after 1 hour or 2 hours of OPU. MII oocytes injection performed immediately after denudation in each group. Each patient had 1-2 fresh embryo transfer (ET) from the best available embryos at day 5, from either group 1 or group 2,those required mixed ET were excluded. For all patients, OPU performed 35-36h post hCG administration after treatment with long agonist protocol.
Main results and the role of chance: The mean woman's age was 29.5 years (SD 5.10). No significant difference in maturation rate between group I (81.7%) and group II (78.7%, P= 0.055). The total fertilization rate between the two groups was comparable 72.6% & 73.4% for group I and group II respectively (P= 0.675), while the cleaved embryos/ diploid zygotes in group I (94.7%) were significantly lower than those in group II (99.1%, P<0.001) also cleaved embryos/MII was 68.7% in group I and 72.7% in group II, (P=0.045). Both groups had no significant difference in quality of embryos at day 2, day 3 and day 5. The available blastocysts at day 5 were comparable (59.2% vs. 57.6% for group I and II respectively, P=0.536). The proportion transferred grade I blastocysts from group I (61.9%) were similar to group II (66.4%) (P>0.05). The clinically pregnant females and implantation rates were not significantly different between both groups. Clinical pregnancies were 50% and 51.5% for group I and group II respectively, p= 0.854) and implantation rates 35.7% & 35.9% in group I and group II respectively (P= 0.977).
Limitations, reasons for caution: Only good prognosis patients were enrolled, so these results may not be generalized to all infertile couples. In addition, we cannot provide any guidance for patients undergoing either day 3 embryo transfers or treated with antagonist protocol.
Wider implications of the findings: Our findings underline the importance of oocyte- cumulus cells contact for cytoplasmic maturity. Although the impact of higher cleavage rate after 2 hours of preincubation does not affect clinical pregnancy rate in the fresh cycles, it increases the probability to achieve a live birth after utilization of all cryopreserved embryos.
Trial registration number: Alexandria University, Faculty Of Medicine, Research committee

P-199 An additional post-thaw culturing of cryopreserved full blastocysts (Gardner's 3) can improve clinical pregnancy rates

Y. Taga[1], S. Ohgi[1], S. Hatakeyama[1], R. Taniguchi[1], A. Yanaihara[1]
[1]Yanaihara Women's Clinic, Division of Reproductive Medicine, kanagawa, Japan

Study question: Can an additional post-thaw culturing of blastocysts affect the ART outcome of a single, cryopreserved, full-blastocyst (Gardner's classification 3) transfer (BT)?
Summary answer: An additional 24-hour culturing that follows the thawing of cryopreserved blastocysts, either early or full, improves the clinical pregnancy rate.
What is known already: According to Gardner's classification, embryo blastocyst development stages advance in the following order: early, full, expanded, and hatching. Blastocysts are usually cryopreserved at the full, expanded or hatching stage. Pregnancy rates using full blastocysts (Gardner's 3), however, are lower than the rates of expanded (Gardner's 4) or hatching (Gardner's 5) blastocysts.

Indeed, the reported pregnancy rate for the transferral of early or full blastocysts ranges from 25 to 35%, while the range for expanded or hatching blastocysts averages between 45 and 55%.
Study design, size, duration: This study was approved by the Local Ethics Committee. From January 2016 to December 2018, this study recruited 560 single BT cycles. In this study, the cryopreservation stage of the blastocysts included only full (Gardner's 3) and expanded versions (Gardner's 4). Hatching blastocysts (Gardner's 5) were not included. Endometrial preparation involved a hormone replacement cycle. Blastocysts were transferred 118 to 122 hours following progesterone initiation.
Participants/materials, setting, methods: The patients, who received single BTs with cryopreserved full blastocysts, were divided into two groups: The first group involved 409 BT cycles that used thawed full blastocysts on the same day (same-day group); the second group involved 151 BT cycles that used expanded or hatching blastocysts after full blastocysts had been thawed and cultured for 24 hours (additional-culturing group).
Main results and the role of chance: The average ages of the women in the same-day and additional-culturing groups were 37.5 ± 3.9 and 37.4 ± 4.2 years (NS) with previous BT attempts that averaged 1.6 ± 1.2 and 1.8 ± 1.5 (NS), respectively.

The clinical pregnancy rate for the additional-culturing group was 45.0% (68/151), which was significantly higher than that for the same-day group (35.4% [145/409], p=0.03). In the additional-culturing group, 21 women miscarried for a miscarriage rate of 30.9%. By contrast, 31 women miscarried in the same-day group for a miscarriage rate of 21.3%. There were no other significant differences between the two groups.

The pregnancy rate in our clinic using previously frozen, expanded (Gardner's 4), or hatching (Gardner's 5) blastocysts averaged 51.7% (849/1641) during the same period. Compared with this figure, the rate for the same-day group was significantly lower (p<0.01), but the rate for the additional-culturing group was comparable (p=0.36). With regard to full blastocysts, however, the clinical pregnancy rate for BT cycles with an additional regimen of post-thaw culturing was significantly higher than for that without additional culturing.
Limitations, reasons for caution: This study was an observational retrospective study. All transferred blastocysts were evaluated by morphological analysis rather than by chromosomal testing, because the Japanese Society of Obstetrics and Gynecology has imposed restrictions on the use of preimplantation genetic testing.
Wider implications of the findings: An optimal window of opportunity for the implantation of expanded or hatching blastocysts may be formed by decidualization of the endometrium approximately 120 hours following progesterone initiation in hormone replacement cycles. BTs using previously frozen full blastocysts will likely miss this window for implantation.
Trial registration number: None

P-200 Hyaluronan-enriched embryo transfer medium for frozen-thawed embryo transfer: a double-blind randomised controlled trial

S.S.F. Yung[1], S.F. Lai[2], M.T. Lam[2], M.W. Lui[1], J.K.Y. Ko[1], H.W.R. Li[1], E.Y.L. Lau[3], W.S.B. Yeung[1], E.H.Y. Ng[1]
[1]The University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong
[2]Kwong Wah Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong
[3]Queen Mary Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Does the use of hyaluronan-enriched embryo transfer medium (HETM) improve the live birth rate of frozen-thawed embryo transfer (FET) compared to standard medium?
Summary answer: The use of HETM compared to control does not improve the live birth rate of FET.
What is known already: Some studies suggest that the use of HETM when compared to transfer medium containing low or no hyaluronan improved clinical pregnancy and live birth rates of in-vitro fertilization (IVF). However, data on FET are limited.
Study design, size, duration: We performed a double-blind randomised controlled trial involving 550 women undergoing FET in two centres from April 2016 to April 2018. The sample size was chosen to detect a difference of 12% in the live birth rate with a power of 80% and type I error of 0.05. Women with donor oocyte/embryo treatment or pre-implantation genetic testing were excluded.
Participants/materials, setting, methods: Women under the age of 43 at the time of IVF undergoing FET were randomised into two groups in a 1:1 ratio: HETM group and control group. The HETM group used HETM (hyaluronan concentration 0.5 mg/ml) while the control group used a conventional medium (hyaluronan concentration 0.125 mg/ml). Up to two embryos/ blastocysts were replaced. Each woman took part once only. The primary outcome was the live birth rate per randomised woman.
Main results and the role of chance: Basic characteristics including age of women, BMI, and number of embryos replaced were comparable in the two groups. Thirteen women (8 in HETM group, 5 in control group) did not have FET because the embryos did not survive upon thawing. One woman in the HETM group had FET cancelled due to fever. One in the HETM group withdrew after randomisation and received conventional medium. All 550 women were included in the intention-to-treat analysis, with a mean of 1.4 embryos/blastocysts transferred in both groups. The live birth rate per randomised woman was 25.5% (70/275) in the HETM group versus 25.5% (70/275) in the control group (p = 1.00). The clinical pregnancy rate was 34.2% (94/275) in both groups (p = 1.00). The multiple pregnancy rate was 13.8% (13/94) in the HETM group versus 19.1% (18/94) in the control group (p = 0.33). One ectopic pregnancy occurred in each group. Other secondary outcomes including on-going pregnancy rate, miscarriage rate and incidence of obstetric complications were similar between the two groups. Subgroup analyses for different embryo stage (cleavage stage embryos versus blastocysts) and different types of endometrial preparation showed no statistically significant difference in the live birth rate between the two groups.
Limitations, reasons for caution: The study assessed the role of HETM in an unselected population of infertile women. While this made the results generalizable to the general infertile population, the results did not address specific population e.g. women with recurrent implantation failure.
Wider implications of the findings: In this study, the use of HETM did not improve the live birth rate following FET.
Trial registration number: ClincialTrials.gov: NCT02725827

P-201 External validation of a commercially available morphokinetic algorithm

R. Gibbons[1], W. Hoo[1], I. Sarris[1], A. Mania[1], L. Muriel Rios[1]
[1]King's Fertility, Assisted Conception Unit, London, United Kingdom

Study question: The aim of this retrospective study was to validate the KIDscore5 algorithm using an external dataset and assess its comparative value to standard morphological grading.
Summary answer: The KIDscore5 algorithm is predictive of implantation and live birth when retrospectively applied to an external dataset, which justifies its use prospectively.
What is known already: The widespread use of time-lapse incubators has proven safe and effective and has led to the development of morphokinetic algorithms. External validation of published algorithms has produced variable results, with several authors concluding that morphokinetic algorithms have

limited applications without replication of the original culture conditions. The KIDscore5 algorithm is a commercially available adjunct to the Embryoscope. It was developed using a large cohort of embryos, from multiple centres and is designed to be generally applicable. To the best of our knowledge, this is the first external validation of this morphokinetic algorithm to guide embryo selection.

Study design, size, duration: This is a retrospective analysis of all treatment cycles performed in a single centre, June 2015-June 2016. Patients who underwent a fresh blastocyst transfer, whose embryos were of known implantation outcome (KID embryos), were included. When the fate of the embryo could not be confirmed patients were excluded. Data were obtained from 529 cycles for 524 patients. Clinical pregnancy was confirmed by presence of a fetal heartbeat. Live births/miscarriages were confirmed by patient reporting.

Participants/materials, setting, methods: Following ovarian stimulation, oocyte retrieval and in-vitro fertilisation (IVF) or intracytoplasmic sperm injection (ICSI) treatment, all fertilised oocytes were cultured, observed and annotated in the Embryoscope until embryo transfer. All patients in the study had at least two good quality embryos on Day 3 and therefore had a blastocyst transfer. Embryo selection was based on morphological score. Retrospective additional annotation and application of the KIDscore5 algorithm was carried out for all 651 KID blastocysts.

Main results and the role of chance: 651 KID blastocysts were transferred on Day 5, for 524 patients who completed 529 fresh treatment cycles. IVF or ICSI was used to create 296 (45.5%) and 355 (54.5%) embryos, respectively. 407 (76.9%) SETs and 122 (23.1%) DETs were performed. Overall implantation rates (IR) and live birth rates (LBR) were 36.4% and 31.0%, respectively. Of the 651 KID embryos, 601 (92.3%) had all necessary annotations available for the KIDscore5 algorithm to be applied.

Logistic regression modelling was performed, with either the presence of a fetal heartbeat (FH) or a live birth (LB) as the outcome and KIDscore as the predictor. Logistic regression models were fitted between presence of FH or LB and KIDscore or morphology score. Statistically significant relationships were observed between both FH and LB and KIDscore ($p<0.001$), and both FH and LB and morphology score ($p<0.001$). There was no evidence of a difference in selecting successful embryos between KIDscore and morphology score in terms of IR ($p=0.3394$) or LBR ($p=0.5729$).

Overall, when predicting implantation or LB, there was no evidence that morphology score added anything over KIDscore, or vice-versa. However, it does appear that for fair/poor morphology embryos KIDscore may provide useful information when choosing between similar embryos.

Limitations, reasons for caution: This is a single centre, retrospective analysis and therefore results may not be universally applicable. Application of the algorithm is only available to Embryoscope users, for a fee, as the algorithm is not published and can only be applied using the Embryoscope Viewer platform.

Wider implications of the findings: This is the first study that externally validates the KIDscore5 algorithm. These results support using the algorithm prospectively. The algorithm's clinical usefulness may be limited when choosing between higher quality embryos but may be more effective for choosing between lower quality embryos; which requires further investigation.

Trial registration number: Not applicable

P-202 To transfer or not to transfer: this is the question

M. Parriego[1], L. Coll[1], G. Palacios[1], M. Boada[1], B. Coroleu[1], A. Veiga[1]

[1] *Dexeus University Hospital, Department of Gynaecology- Obstetrics and Reproduction, Barcelona, Spain*

Study question: How do patients manage the situation of having only a mosaic embryo for transfer?

Summary answer: Genetic counselling is fundamental to make an informed decision. However, the way to proceed when only a mosaic embryo is available varies widely among patients.

What is known already: The existence of mosaic embryos has been known for many decades. However, only recently new technologies have allowed such feature to be detected in Preimplantation Genetic Testing for Aneuploidies cycles. It has been reported that mosaic embryos can result in healthy live births with no post-natal affectations so far, but the potential risks of such embryos cannot be dismissed. Therefore, the clinical management of a situation when the only option for the patient is a mosaic embryo is challenging. Most studies have been focused on clinical outcomes but very few have presented actual data on how patients confront this situation.

Study design, size, duration: Retrospective observational study performed on 383 Preimplantation Genetic Testing for Aneuploidies cycles (PGT-A) from October 2017 to December 2018. The incidence of cycles in which the only option for transfer was a mosaic embryo was assessed. Such cycles were carefully analysed in terms of patients' decision making on the possibility of transferring mosaic embryos.

Participants/materials, setting, methods: Cytogenetic constitution results of 1602 embryos were obtained by NGS Veri-Seq PGS method (Illumina). Mosaicism was reported when the percentage of abnormal cells for an affected chromosome ranged from 30-70%. Consultation with an internal genetic counsellor was offered to all patients with mosaic embryos to discuss the potential expected outcomes and associated risks related to the transfer of mosaic embryos. All available reproductive options were considered.

Main results and the role of chance: Twenty-four percent of the cycles (95/383) had at least one embryo diagnosed as mosaic. However, in just 4.4% of the cycles (17/383) the only transferable option was a mosaic embryo. Moreover, from the cycles with available euploid embryos, 2.1% (6/288) have transferred all such embryos without success and had to face the decision of transferring or not a mosaic embryo.

In total, 23 patients have had to decide whether to transfer or not their mosaic embryos during the time the study was conducted.

Almost all patients followed the recommendation of receiving genetic counselling (91.3%). Only 2 patients refused the genetic counsellor advice as they were determined to repeat a PGT-A cycle before considering the transfer of mosaic embryos.

The patients' decisions were the following: 26.1% (6/23) of the patients decided to transfer their mosaic embryo, 39.1% (9/23) decided to keep them cryostored while performing a new PGT-A cycle and 34.8% (8/23) opted to discard the embryos.

Up to date, 5 out of 6 mosaic embryos have been transferred. Two of them resulted in an ongoing clinical pregnancy (2/5, 40%).

Limitations, reasons for caution: A limited series of cases is presented. More data are needed for conclusive results. No correlations with factors potentially affecting the decision could be established due to the sample size.

Wider implications of the findings: The safety of replacing mosaic embryos is still a matter of debate. A remarkable number of patients opt for conservative decision making. Uncertainty derived from mosaicism is difficult to manage, especially in the era when extensive and accurate genetic testing is available.

Trial registration number: not applicable

P-203 The impact of media/oil volumes and dish type on medium osmolality throughout embryo culture

T. Beckitt[1], D. Barcelo[1], T. Roy[1], S. McArthur[2]

[1] *Genea Biomedx, Research & Development, Sydney, Australia*

[2] *Genea, Science, Sydney, Australia*

Study question: Does the dish type and media/oil volume used during embryo culture impact upon evaporation?

Summary answer: Use of a suitable media/oil volume alongside an optimal dish design results in greatly reduced evaporation and subsequent osmolality changes, reducing likelihood of embryo damage.

What is known already: The importance of avoiding potential stressors on gametes and embryos while *in vitro* has been well documented. Osmolality is a crucial media parameter and thus, it is imperative to ensure it is adequately controlled to avoid compromising embryo development. The risk of significant osmolality increase is exacerbated in monophasic culture systems due to the time embryos spend in culture without medium replenishment. Mineral oil has been used as an overlay for culture medium for decades, the core function of which is to minimise medium evaporation and resultant osmolality changes.

Study design, size, duration: Experiments were conducted to monitor the level of evaporation of medium and consequently the change on osmolality in the Geri® dish using various configurations of medium and mineral oil for the intended period of culture in the Geri® incubator, used without humidification for the purposes of this study. Each dish configuration was tested a minimum

of three times. Geri Medium and Sage Oil for Tissue Culture were used throughout.

Participants/materials, setting, methods: Gravimetric measurements were performed using a Sartorius MSU324S analytical balance. To ensure results were in accordance with those obtained when using an osmometer, method validation was conducted using an Advanced 3250 Osmometer. Weights were measured before and after the intended culture period, including standard equilibration time, of 5.7 days (136 hours). Various medium and oil configurations were used in 60mm Falcon and Geri dishes, both commonly used in ART laboratories.

Main results and the role of chance: Larger volumes of medium and oil resulted in decreased evaporation, consequently minimising medium osmolality changes over the 136-hour simulated culture period. Specifically, the use of 40 µL drops of medium with a 2 mL oil overlay in a Geri® dish led to considerable evaporation, equivalent to an average osmolality change of 58.6 mOsm/kg. An increase in the medium drop size presented some mitigation, with 60 µL drops and 2 mL oil resulting in average osmolality change of 40.1 mOsm/kg. The minimal average osmolality change (7.9 mOsm/kg) was observed when using 80 µL medium drops with 4 mL oil overlay.

Furthermore, selection of a suitably designed dish for embryo culture proved to be imperative. The average osmolality change observed using a 60mm Falcon dish (comprising nine, 20 µL medium drops and 4 mL oil) was 70 mOsm/kg. With 11 mL oil overlay, the maximum possible without spillage, average osmolality change was 25.8 mOsm/kg, still presenting a potential risk to developing embryos. To that end, results highlighted that not only are medium and oil volume critical for minimising evaporation, but that selection of an optimised dish for embryo culture is equally important in the process of preventing osmotic shock.

Limitations, reasons for caution: Our results may be confounded by a small sample size; a larger scale study would be beneficial to improve confidence in the average osmolality change values obtained.

Wider implications of the findings: We concluded that dish type and media/oil volumes are crucial to avoid osmolality changes during the embryo culture period. Therefore, the decision on those parameters should be considered in-depth to ensure optimal conditions for developing embryos and, potentially improve clinical outcomes.

Trial registration number: Not applicable

P-204 Can follicular Emmprin and Bmp 4 levels predict ICSI outcome?

O. Takmaz[1], D. Yozgatli[2], S. Ozaltin[3], E. Ozbasli[1], Y. Kocyigit[4], S. Bulgurcuoglu Kuran[5], H. Bulut[6], M. Gungor[1], F. Buyru[4], E. Bastu[1]

[2]Istanbul University- Cerrahpasa School of Medicine, Internship, Istanbul, Turkey

[3]Acibadem Maslak Hospital, Obstetrics and Gynecology, Istanbul, Turkey

[4]Acibadem Fulya Hospital, Obstetrics and Gynecology, istnabul, Turkey

[5]Istanbul University- Istanbul School of Medicine, Infertility Center, Istanbul, Turkey

[6]Bezmialem University, Biochemistry, istanbul, Turkey

Study question: To evaluate the relationship of clinical pregnancy rates with Bone Morphogenic Proteins 2-4-7, Growth Differentiation Factor 9 and Emmprin levels in follicular fluid of intra cytoplasmic sperm injection patients.

Summary answer: Clinical pregnancy rates after ICSI may be associated with follicular fluid levels of Emmprin and BMP4.

What is known already: Bone Morphogenic Proteins (BMPs) and Growth Differentiation factor-9 (GDF9) which are members of transforming growth factor beta (TGF-beta) super family, have critical roles in oocyte and follicular maturation. Mutations affecting the function of these proteins lead to dysregulated signaling, thus interfering with the success of human conception [6. Emmprin (extracellular matrix metalloproteinase inducer), also called Basigin (CD147), is a transmembrane glycoprotein belonging to the immunoglobulin superfamily. Lack of Emmprin has been shown to be related with infertility in both male and female mice. Emmprin plays roles in oocyte maturation, fertilization, implantation and early embryonic development.

Study design, size, duration: Follicular fluid of seventy-seven patients who underwent ICSI procedure was collected during the oocyte retrieval procedure. And follicular fluid levels of BMP 2, BMP 4, BMP 7, GDF 9 and Emmprin (Basigin) were measured and compared for clinical pregnancy rates.

Participants/materials, setting, methods: The study analyzed the follicular fluid samples of 79 patients who underwent ICSI procedure for tubal factor or unexplained infertility. The first retrieved leading follicle's fluid was collected and used for analysis. Human BMP 2, BMP 4, BMP 7, EMMPRIN/CD147 and GDF 9 enyzme-linked immunosorbent assay (ELISA) kit (Hangzhou Eastbiopharm Co. Ltd, China) was used for the quantitative measurement. BMP 2-4-7 levels were expressed as ng/ml, Emmprin and GDF 9 levels were expressed as ng/L.

Main results and the role of chance: A total of 79 follicular fluid samples were examined. Of these, 23 (29.1%) were the ones obtained from women who achieved clinical pregnancy and the remaining 56 (79.9%) were the ones obtained from women who did not.

The median *BMP 4* level was significantly higher in women who achieved clinical pregnancy than in those who did not ($p=0.03$), whereas the median *Emmpirin* level was significantly lower in women who achieved clinical pregnancy compared with those who did not ($p<0.001$). The levels of other proteins studied were similar between the groups.

When *transformed levels of BMP 4 and Emmprin* were included together in logistic regression, AUC was found to be 0.70 (95% confidence interval: 0.55, 0.84, $p= 0.03$). A threshold of 0.14 had a sensitivity of 67% and specifity of 67%.**Limitations, reasons for caution:** Evaluating BMP2/BMP7, GDF9/BMP15 heterodimers can be more reasonable instead of evaluating homodimers because of the heterodimers' are more active and more potent in follicular development.

Wider implications of the findings: Follicular fluid assessment can be a research area for prediction of the ICSI outcomes. Follicular fluid proteins which have critical roles in oocyte and follicular maturation like as BMP 4 and Emmprin may be further assessed for choosing the most convenient retrieved oocyte for fertilization.

P-205 Comparison between paraffin heavy oil and light oil covering on early human embryo culture: a time-lapse imaging

H.J. Kim[1], J.E. Lim[1], E.J. Song[1], S.J. Yoon[1], K.M. Yang[1], S.H. Yoon[2], J.H. Lim[2]

[1]Suji Maria Fertility Clinic, Research center, Youngin-si- Gyeonggi-do, Korea- South

[2]Maria Fertility Hospital, Research center, seoul, Korea- South

Study question: Are there differences on early embryo morphokinetic parameters and abnormal cleavage events after culture under paraffin heavy oil and light oil?

Summary answer: We find significant difference in morphokinetic parameters after 4-cell stage, but no significant differences in abnormal cleavage events between the two groups.

What is known already: Mineral and paraffin oils are commonly used to overlay IVF media in order to maintain their stability throughout the embryonic culture. Indeed, without any oil overlay, the medium osmolality would quickly become too high and deleterious for embryo development. Despite the importance of an oil overlay, very few publications address this aspect and to our best knowledge, the Sifer study is the only one describing.Interested in human embryo development under several types of commercial oil. This study is the first to apply Time-lapse imaging (TLI) to embryo utilization rates after culture under paraffin heavy oil and light oil.

Study design, size, duration: Retrospective analysis of fertilized embryos (n=2885, 421 cycles) were cultured in time-lapse incubator from August 2017 to November 2018.

Participants/materials, setting, methods: This study was performed in 421 cycles (n = 2885) that had undergone ICSI treatment in an unselected population. They were culture in cleavage and blastocyst medium (MRC#D13 and 46; Maria Medical Foundation, South Korea) overlaid either by heavy oil (KITAZATO) or light (Ovoil™, Vitrolife). All embryos were cultured after ICSI insemination and assessed in a time-lapse incubator (EmbryoScope, Vitrolife) and annotated for the pattern time of cleavage.

Main results and the role of chance: We analyzed 10 parameters and abnormal cleavage events after culture under paraffin heavy oil and light oil. No significant differences were found from tPB2 to t3 between the two groups. However, Heavy oil-derived embryos developed significantly faster than those produced at t4 (38.9 vs 40.7, $P < 0.001$), t5 (47.8 vs 49.2, $P < 0.001$), t6 (50.6 vs 53.2, $P < 0.001$), t7(53.3 vs 57.2, $P < 0.001$), and t8 (55.3 vs 60.1, $P < 0.001$). Moreover, the cell cycle of cc2 (8.3 vs 9.0) and synchrony of the cell cycle of s2 (2.5 vs 3.5) were also significantly different (respectively; $P < 0.001$). We compared abnormal cleavage events in embryonic development. There were no differences between the two groups in the rate of multinucleated 2-cells (37.4% vs. 39.6%, $P = 0.292$), uneven 2-cells (18.6% vs. 19.7%, $P = 0.375$), or direct cleavage from 1 to 3-cells (26.1% vs. 25.1%, $P = 0.575$).
Limitations, reasons for caution: The study was monocentric and retrospective study. Data set size is small numbers. It should be extended to larger populations and additional morphokinetic parameters.
Wider implications of the findings: This study is the first observation thoroughly describing the development of embryos derived from culture under paraffin heavy oil and light oil using morphokinetic parameters and abnormal cleavage events collected until day 3.
Trial registration number: Not applicable.

P-206 Bisphenol S content in human follicular fluid and its effect on IVF outcomes

M. Jeseta[1], J. Moravec[2], J. Žáková[1], J. Nevoral[2], E. Lousová[1], I. Crha[1], P. Ventruba[1]
[1]*Faculty of Medicine- Masaryk University Brno and University Hospital Brno, Gynecology and Obstetrics, Brno, Czech Republic*
[2]*Faculty of Medicine in Pilsen- Charles University in Prague- Czech Republic, Biomedical Center, Pilsen, Czech Republic*

Study question: Does presence of Bisphenol S in follicular fluid negatively affect early embryonic development and implantation rate of human embryos?
Summary answer: Our results document that high concentrations of Bisphenol S in follicular fluid are associated with higher rates of embryos that stopped their development.
What is known already: Human fertility is influenced by a range of chemicals permanently present in our environment. One of these chemical is Bisphenol S (BPS), which is commonly used. BPS is an endocrine disruptor that can influence variety of physiological processes. It has been documented that BPS can disrupt spindle formation in oocytes and thus negatively influence IVF and embryonic development in porcine oocytes. BPS is currently commonly used in manufacture of plastics and it is often chosen to replace Bisphenol A, which has been prohibited in some countries. A direct effect of BPS on meiotic maturation of human oocytes is still unclear.
Study design, size, duration: In this study we evaluated relation between concentration of BPS in follicular fluid, IVF outcome and early embryonic development in human. A total of 38 patients aged 26 to 42 years were included in this prospective study from spring to autumn 2018. Their follicular fluid was collected during transvaginal follicle puncture. BPS content was determined by the LC-MS method (liquid chromatography-mass spectrometry).
Participants/materials, setting, methods: Based on detection of BPS in follicular fluid, the set of patients was divided into two groups – with high content of BPS (>5ng/ml) and with low content of BPS (<5ng/ml). Number of oocytes collected, efficiency of IVF, number of embryos suitable for transfer or cryoconservation, number of abnormal embryos, quality of embryonic development, biochemical and clinical gravidity were evaluated in each of the groups. Statistical evaluation was performed using one-way ANOVA and chi-square test.
Main results and the role of chance: The examination detected presence of BPS in 35 samples of follicular fluid (92.1 % of all samples analysed). In 19 samples, the concentration was higher than 5 ng/ml (50.0 % of samples analysed). Subsequently, individual parameters of IVF were assessed. There were no significant differences found between the groups of patients with high and low concentration of BPS in number of oocytes collected (low BPS 8.3 vs. high BPS 7.4), efficiency of fertilization (low BPS 80 % vs. 72 % high BPS) and number of embryos usable after in vitro cultivation (low BPS 4.4 vs. 4.2 high BPS). In the patients with high concentration of BPS, a significantly higher share of abnormal embryos after in vitro cultivation was found (low BPS 1.3 vs. high BPS 2.3). Similarly in the in rates of biochemical (low BPS 36.8 % vs. high BPS 21 %) and clinical (low BPS 31.5 % vs. high BPS 15.8 %) gravidities were not statistically significant differences.
Limitations, reasons for caution: A limitation is the number of samples included and analysed in this study which slightly reduced the power of statistical analysis.
Wider implications of the findings: In this study, BPS was detected in more than 90 % of analysed follicular fluid samples. Our results indicate a potential negative effect of BPS presence for development of human embryos.
Trial registration number: Supported by MH CZ – DRO (FNBr, 65269705) and project AZV NV18-01-00544.

P-207 Cumulative Live Birth Rates (CLBR) in patients following Freeze-all policy are higher compared to patients who undergo fresh embryotransfer (ET) followed by frozen-thawed embryotransfers

E. Timotheou[1], T. Chartomatsidou[1], P. Tatsi[1], E. Katsoula[2], C. Vlachou[2], S. Stamataki[2], I. Asouchidou[3], O. Zafeiratis[4], R. Najdecki[4], E. Papanikolaou[4]
[1]*Assisting Nature- Centre of Human Reproduction and Genetics, Embryology Lab, Thessaloniki, Greece*
[2]*Assisting Nature- Centre of Human Reproduction and Genetics, Coordination Department, Thessaloniki, Greece*
[3]*Aristotle University of Thessaloniki, Medical Department, Thessaloniki, Greece*
[4]*Assisting Nature- Centre of Human Reproduction and Genetics, Medical Department, Thessaloniki, Greece*

Study question: Is there any difference in the CLBR in patients following Freeze-all policy compared to patients who undergo first fresh and then subsequent frozen-thawed ETs?
Summary answer: The CLBR is higher in patients who follow Freeze-all strategy compared to those who undergo fresh and then frozen-thawed ETs of the available embryos.
What is known already: Elective freezing of all embryos, followed by frozen-thawed ET cycles emerged to prevent risk of Ovarian Hyperstimulation Syndrome and to allow endometrium recovery after Controlled Ovarian Stimulation (COS). The efficacy of embryo vitrification allowed Freeze-all policy to gain popularity. Previous studies have reported better In vitro Fertilization (IVF) outcomes after adopting the Freeze-all policy, instead of fresh ET, mostly in normal and high responders. Nevertheless, efficacy in terms of CLBR has not been studied yet.
Study design, size, duration: This prospective observational study includes two groups of patients. Group A concerned couples which followed Freeze-all Policy, with no fresh ET and up to 3 frozen-thawed ETs. Group B includes couples which completed one fresh ET and two subsequent frozen-thawed ETs. All patients followed blastocyst ET, with 1 or 2 embryos each time. The women's age was less than 40 and they all had at least 4 embryos available for ET.
Participants/materials, setting, methods: The study was performed from January 2016 until December of 2017 in Assisting Nature, Centre of Human Reproduction and Genetics, Thessaloniki, Greece. Group A included 87 couples with a mean female age of 32.8 years, while group B included 76 women with an average age of 33. All women followed COS with an antagonist protocol. No Preimplantation Genetic Testing (PGT), Testicular Sperm Extraction (TESE) cycles or poor responders (oocytes <4) were included in the study.
Main results and the role of chance: The CLBR was estimated for each group of patients for every ET (fresh ET, first frozen, cumulative of the first frozen ET/ second/ third frozen ET). The total CLBR was estimated for the two groups, regarding the total number of ETs in each case. X^2 test was used to compare live birth rates between the two groups. In group A the Live Birth Rate after the first frozen ET was estimated 57.5%, while the same rate after the fresh ET in group B was 39.5%. The total CLBR for all the completed ETs was 81.6% in group A and 76.3% in group B. The CLBR was significantly higher in group A compared to group B after the first ET (frozen versus fresh, $p<0.05$). Cumulatively, the live birth rates were again higher for the Freeze-all group ($p>0.05$). These results are consistent with previous published data which are in favor of ETs in a frozen cycle, subsequent to the stimulation cycle, as the endometrium receptivity and the hormone profile of the woman offer a better environment for a successful implantation. This indicates that women

considered normal or high responders have better chances of achieving live birth, if they follow Freeze-all policy.
Limitations, reasons for caution: No sperm quality was taken into consideration and no natural cycles were used for endometrium preparation for the frozen-thawed cycles. A higher number of cases is required in order to confirm the obtained results.
Wider implications of the findings: Adopting Freeze-all strategy after blastocyst culture can lead to a delivery in shorter period, comparing to a fresh ET. Moreover, the policy of Freeze-all can contribute to improve delivery outcome after IVF in terms of Cumulative Live Birth Rate, in a clinically significant way.
Trial registration number: N/A

P-208 Obstetric and perinatal outcomes: How far can in vitro culture influence it?

F. Gagsteiger[1], S. Musanovic[2], D. Zhu[2], N. Reeka[3], K. Eibner[3], J. Koglin[3], C. Trautmann[3], K. Bundschu[3], N. Sandi-Monroy[2]
[1]*IVF Zentrum Ulm, Reproduktionsmedizin, Ulm, Germany*
[2]*KWZ Ulm, IVF Labor, Ulm, Germany*
[3]*KWZ Ulm, Medical Department, Ulm, Germany*

Study question: Are obstetric and perinatal outcomes affected by embryo culture systems? Are singletons and twins similarly affected?
Summary answer: For singletons, *in vitro* cultured embryos presented similar obstetric and perinatal outcomes. For twins, group cultured embryos had better obstetric and perinatal outcomes.
What is known already: Newborns after assisted reproductive technologies (ART) usually have poorer perinatal outcomes if compared with newborns after spontaneous conception. Low birthweight (LBW), preterm birth (PTB), and proportion of large for gestational age (LGA) have been correlated to *in vitro* culture. Birthweight and inter-twin disparity have also been shown to be affected by culture medium in singletons and twins, suggesting a negative effect of *in vitro* culture. Previous analyses of perinatal outcomes in our center have revealed that single embryo culture in a time-lapse system (TLS) resulted in less PTB than single embryo culture in a standard incubation system (SI).
Study design, size, duration: A retrospective cohort of patients attending a fertility clinic in Germany between August 2014 and October 2018 were included in the study. Singletons and twins born after fresh ICSI cycles and cultured individually in a TLS (n=160 and n=94) were compared to singletons and twins after grouped embryo culture in a SI (n=128 and n=40). Patients with a vanishing twin were excluded from the study.
Participants/materials, setting, methods: Fresh ICSI cycles with embryo transfer were cultured either in the EmbryoScope© (n=864) or in a standard incubator (n=715). Fertilization, implantation, clinical pregnancy and live birth/ongoing pregnancy rates were compared among the groups. Obstetric and perinatal outcomes were compared among singleton and twin newborns in the groups. Z-scores were calculated based on customized birthweight data in a cohort of Dutch newborns. Statistical analyses were performed by Fisher´s exact test or Mann Whitney test.
Main results and the role of chance: There was no difference among female age and stimulation in the groups, although patients in the TLS had more oocytes (9.396±5.012 versus 9.055±5.993, p=0.0159) and consequently more zygotes in culture (3.469±1.747 versus 3.257±1.801, p=0.0152), embryos transferred (1.561±0.5012 versus 1.478±0.5055, p=0.001) and surplus blastocysts frozen (0.4549±0.8839 versus 0.3538±0.7701, p=0.0191) than the SI group. Nevertheless, the fertilization rate was significantly lower in the TLS group (62.72% versus 66.14%, p=0.0099). On the other hand, implantation (29.42% versus 25.45%, p=0.031) and clinical pregnancy rate (39.24% versus 33.85%, p=0.0278) were higher in the TLS group but no difference could be found for live birth/ongoing pregnancy rate (92.22% versus 92.69%, p=0.8712). We could not observe any significant differences in obstetric and perinatal outcomes for singletons among the groups. To avoid the birthweight paradox, we also compared the groups for the Z-scores and could not find any significant differences among the groups. Surprisingly, for twins, SI resulted in higher GA (37.08 weeks versus 35.99 weeks, p=0.0035), less PTB (20% versus 47.87%, p=0.0035), higher birthweight (2511±620.4g versus 2284±634.9g, p=0.0023), higher height (47.5±3.976cm versus 46.2±3.7cm, p=0.013) and less LBW (37.50% versus 59.57%, p=0.0236) than the TLS group. Data are presented as mean ± standard deviation or numbers (percentage).
Limitations, reasons for caution: This is a non-randomized retrospective analysis of a small cohort of patients. Furthermore, not all residual confounding factors could be considered, such as social background, smoking habits, length and cause of infertility.
Wider implications of the findings: Improving current incubation systems may be a valuable step towards more physiological and embryo-friendly *in vitro* culture. Fewer disturbances of embryos may favour not only embryo development *in vitro*, but also foetus growth and neonatal outcomes. However, positive effects of group culture should be considered to improve our current systems.
Trial registration number: Not applied.

P-209 Positive correlation trend between implantation potential of fresh Day 5 transfers, and a morphokinetic based blastocyst scoring system– a retrospective analysis of 318 treatments.

K. Simonsen[1], C. Christiansen[2], B. Lomholt[2], M. Hansen[2]
[1]*Maigaard Fertility Clinic, Maigaard Fertility Clinic, Fredericia, Denmark*
[2]*Maigaard Fertility Clinic, Maigaard Fertility Clinic, Aarhus, Denmark*

Study question: Is there a correlation between implantation potential of fresh blastocyst transfer and a universal blastocyst morphokinetic ranking model (KIDScore D5 v2).
Summary answer: Retrospective analysis of 318 known implantation treatment cycles shows that there is a correlation trend between morphokinetic score and implantation potential.
What is known already: The use of time-lapse technology to improve embryo selection is increasing. A challenge of using selection and deselection models is that they may not perform equally as well when applied in a different laboratory setting. Furthermore, some of the reported models do not incorporate development events past cleavage stage and therefore may not be as applicable to Day 5 embryo evaluation. A new universal model for predicting potential of implantation has been developed using multicenter known implantation data of fresh Day 5 transfers (KIDScore D5 v2, Vitrolife A/S).
Study design, size, duration: Retrospective Time-lapse analysis of 318 treatments with 351 blastocyst transfers from September 2015 until December 2018 having Known Implantation outcome. All embryos were cultured in the EmbryoScope or EmbryoScope+ time-lapse systems. Embryo development was annotated in the EmbryoViewer software. Model scores were calculated and compared with actual implantation ratio.
Participants/materials, setting, methods: Females of age range from (24-46) with a median age of 37. KIDScore values (continuous scores range from 1-9.9) were grouped into roughly five equal data size sets for analysis, and implantation ratios for each category were calculated. Statistical analysis was performed with R v3.4.4. Differences between groups were tested using Wilcoxon rank sum test.
Main results and the role of chance: KID ratios for the grouped KIDScore value categories were as follows: (score range, implantation rate,n) (1.0-6.5,21.9%,64) (6.6-7.2,34.2%,73), (7.3-7.7, 40%, 65), (7.8-8.2,42%,73), (8.2-9.9, 64.5%, 76). There was a clear trend between KIDScore D5 values and implantation rate. The implantation rate of scores less than of 8.2 and those higher than 8.2 were statistically significant different ($p<0.001$).
Limitations, reasons for caution: Our clinic performs all cycles in a time-lapse settings and therefore makes use of time-lapse information to select embryo. This may present some bias in the embryos selected for transfer. Larger datasets are required to confirm these findings and to determine score differences which represent statistically significant differing implantation potential.
Wider implications of the findings: The use of a morphokinetic Day 5 scoring model may assist in prioritization embryo transfer when multiple equally transferable embryos are available for transfer in a fresh cycle.
Trial registration number: Not applicable

P-210 A time-lapse comparison between genetically balanced and unbalanced human embryos

S. Nikolova[1], D. Parvanov[2], R. Ganeva[2], T. Chaushev[2], S. Hadjidekova[3], R. Staneva[3], M. Pancheva[3], M. Serafimova[3], I. Ivanova[1], K. Nikolova[1], I. Rangelov[1], G. Stamenov[4]

[1]*MHAT Nadezhda, Embryology, Sofia, Bulgaria*
[2]*MHAT Nadezhda, Research, Sofia, Bulgaria*
[3]*MHAT Nadezhda, Genetics, Sofia, Bulgaria*
[4]*MHAT Nadezhda, Obstetrics and gynaecology, Sofia, Bulgaria*

Study question: Are there differences between time-lapse variables of unbalanced human embryos and chromosomally normal embryos?
Summary answer: The time of pronuclei appearance (tPNa) and cleavage time to eight-cell stage (t8) are significantly delayed in unbalanced embryos compared with the normal embryos.
What is known already: Many morphokinetic parameters obtained from human embryos cultured in time-lapse imaging systems (TL) have been evaluated as potential biomarkers of embryo quality and successful implantation. They include static and interval time-lapse variables from the early cleavage stage to morula and blastocyst stages. However, it is still not fully clear whether balanced and unbalanced blastocysts differ in certain morphokinetic parameters.
Study design, size, duration: 214 blastocysts generated from ICSI between February 2016 and March 2017, derived from 98 patients were included in this cohort retrospective study. All embryos were cultured in single culture medium (Life Global) and a time-lapse system (EmbryoScope, Vitrolife, Sweden). After day 5 biopsy and preimplantation genetic screening (PGS) testing embryos were classified as balanced (chromosomally normal) and unbalanced.
Participants/materials, setting, methods: Fifteen morphokinetic parameters were analysed and compared between balanced (normal) and unbalanced embryos: time of pronuclei appearance (tPNa), time of pronuclei fading (tPNf), cleavage times (t2, t3, t4, t5, t6, t7, t8, t9), morulae formation time (tM), starting blastulation (tSB), full blastocyst stage (tB), expansion and hatching timing). Statistical analysis was performed by IBM SPSS Software v.21.
Main results and the role of chance: A total of 123 embryos (67.58%) were proven to be unbalanced and 91 blastocysts (32.41%) were chromosomally normal. There were no significant differences in women age, 3 Day FSH, BMI and embryo quality between the compared groups ($p>0.05$, Student t-test). However, there was a significant difference between normal and unbalanced blastocyst groups in two time-lapse variables – tPNa (6.45 vs. 6.85 hrs, respectively, P=0.037) and t8 (55.56 and 59.25 hrs, respectively, P=0.002).
Limitations, reasons for caution: The retrospective nature of this study is a limitation. Larger study with an increased number of embryos is needed to confirm our findings.
Wider implications of the findings: Specific time-lapse variables such as tPNa and t8 could be considered as potential predictors of chromosomal abnormalities. Morphokinetic embryo characteristics should be analysed and considered before a decision for taken a biopsy and PGS.
Trial registration number: Not applicable.

P-211 the effect of a transient premature luteinizing hormone surge without elevated serum progesterone on in vitro fertilization outcomes in a gonadotropin-releasing hormone antagonist flexible protocol

D. Zhang [1], J. Zhen [1]

[1]*Peking Union Medical College Hospital, Obstetrics & Gynecology, Beijing, China*

Study question: What are the IVF outcomes of patients experiencing transient premature LH surge (PLHS) but without an elevated progesterone in a GnRH antagonist flexible protocol.
Summary answer: Even a transient PLHS without elevated serum progesterone will lead to a detrimental effect on the IVF/ICSI pregnancy outcomes in fresh embryo transfer cycles.
What is known already: Many researchers have concluded that IVF outcomes may be inversely related to serum progesterone levels >1.5ng/mL by affecting endometrial receptivity and damaging embryo quality.Previous studies have paid attention to the association between a poor pregnancy rate and PLHS, but they either did not exclude the accompanying elevated progesterone or only focused on the PLHS on the hCG day after GnRH-ant administration.

In addition, the live birth rate has not been reported. Whether a transient PLHS without progesterone>1.5ng/mL during ovarian stimulation has a negative effect on the IVF/ICSI outcome has not been fully explored.
Study design, size, duration: This was a retrospective cohort study including all women who underwent IVF/ICSI fresh cycles with a GnRH antagonist flexible protocol at Peking Medical College Hospital (PUMCH) between January 2016 to December 2017. Patients whose progesterone ≥ 1.5 ng/mL during ovarian stimulation were excluded. A total of 405 women who had undergone IVF/ICSI-fresh ET cycles were reported during this timeframe.
Participants/materials, setting, methods: A PLHS was defined as LH higher than threefold of it's basic level on day 2 of the same menstrual cycle with the absolute value > 5 IU/mL.119 patients (29.4%) reached the criteria for the diagnosis of PLHS with progesterone <1.5ng/mL, while the other 286 women (70.6%) were assigned to the control group.Logistic regression models were fitted to the clinical pregnancy rates and the live birth rates to reduce the relevant confounders.
Main results and the role of chance: The baseline characters and ovarian response were comparable between both groups, and they had harvested similar number of oocytes, an accordant oocyte maturation rate, and an equal rate of high quality embryo formation after 3 days of culture. However, the remaining embryos from the PLHS group, except for those freshly transferred, were less likely to be cultured into blastocysts compared to the control group (31.9% (176/551) vs 38.2% (454/1187), P = 0.011). Compared between PLHS and control group, the implantation rates were12.9% (30/233) vs 25.0% (141/536), P = 0.000; clinical pregnancy rates were 21.0% (25/119) vs 41.6% (119/286), P = 0.000 ; live birth rates were17.6% (21/119) vs 29.7% (85/286), P =0.012. After adjusting for age, BMI, bFSH, and infertility factors, the adverse effects were still as pronounced for the clinical pregnancy rate (OR = 0.39, 95% CI = 0.24-0.66) and live birth rates (OR = 0.54, 95% CI = 0.32-0.93.According to the POSEIDON Criteria, we found more women belonging to the Group II (age≥35; ovum retrieved<9) and less from the Group III (age<35; ovum retrieved≥9) experienced the PLHS, compared to the controls (Group II 20.2%(24/119) vs 11.9%(34/286), P=0.030; Group III 11.8%(14/119) vs 20.3%(58/286), P=0.041).
Limitations, reasons for caution: we only looked into fresh cycles in this study. PLHS possibly deteriorates the potential for embryo growth and implantation, and so are the cumulative live birth rates. Our hypothesis should be further explored in frozen–thawed cycles before it is extrapolated to multiple subsequent live births within the same IVF/ICSI cycle.
Wider implications of the findings: There is a strong inverse relationship between the transient PLHS and the pregnancy outcomes, although the surge was suppressed immediately with the antagonist and no elevated progesterone was generated. An earlier antagonist administration may be a possible preventive measure, especially for those women with advanced age but highly responsive ovaries.
Trial registration number: not applicable.

P-212 Maternal Body Mass Index impacts on morphokinetic parameters of embryo development: a time-lapse study.

A. Bartolacci[1], J. Buratini[2], C. Moutier[1], M.C. Guglielmo[1], P.V. Novara[1], F. Brambillasca[1], M. Mignini Renzini[1], M. Dal Canto[1]

[1]*Biogenesi- Reproductive Medicine Centre, Istituti Clinici Zucchi, monza, Italy*
[2]*Department of Physiology- Institute of Biosciences, Sao Paulo State University, Sao Paulo, Brazil*

Study question: Does maternal body mass index (BMI) affect embryo morphokinetic parameters assessed by time-lapse technology?
Summary answer: Maternal overweight and obesity affect morphokinetic parameters during embryo culture and are associated with slower embryo development.
What is known already: Maternal obesity impairs natural and assisted reproduction regardless the occurrence of ovulatory disorders, being also associated with spontaneous abortions, preeclampsia, preterm delivery and gestational diabetes. The relative importance of the impact of high BMI on oocyte/embryo quality in the mechanisms undermining fertility is unknown. Static morphological analysis has not been capable to detect any impact of obesity on embryo quality. Since embryo developmental competence is not solely reflected by morphology, but also associated with develop-

mental speed, a dynamic evaluation of morphokinetic parameters appears necessary for a more reliable assessment of the impact of BMI on embryo competence.
